MR. SIEBOLD stated that he had been, and was still his intention to deal with this subject in a more complete manner at an early meeting next session.

The various published methods for the analysis of dyewood extracts were commented unfavourably upon, their being regarded as very unsatisfactory and affording no trustworthy indication of their value to the dyer and printer. Chemical knowledge of these preparations is still in a very imperfect state; and as long as this is the case the essayist prefers to rely for this purpose on carefully conducted dyeing experiments rather than on chemical analyses. In the majority of cases wool dyeing is much to be preferred to cotton dyeing for these tests, inasmuch as the former renders a complete exhaustion of the dye-bath possible, while the latter does not, and even where the extract under examination is intended for cotton dyeing he is still decidedly of opinion that the testing should be done by means of wool dyeing, which is in every way better calculated to show the actual strength of the preparation to be tested. Experimental cotton dyeing is in most cases less a criterion of the actual strength and money value of an extract, than of the more or less developed or oxidised condition in which the colouring matter exists in it, and gives the experimenter a better idea of the speed of dyeing than of the real extent of the dyeing power of the preparation. In many cases its indications are entirely deceptive. A number of instances in support of this view was mentioned by the essayist. He laid great stress on the necessity of conducting these dyeing trials with a degree of care and accuracy equal to that required in chemical analysis, and showed that it is impossible to distinguish with certainty between one extract and one but slightly inferior to it, unless the greatest care is given to the weighing of the extracts, the measuring of the solvents, and to the perfect equality of temperature, and other conditions during the dyeing process. The mordanting, too, should be conducted with the same degree of exactness. Mr. Siebold explained a variety of circumstances likely to lead to erroneous results, and the best conditions for ensuring success in these tests. All the details respecting these will be published in the more exhaustive paper promised by him on this subject.

#### DISCUSSION.

The CHAIRMAN, in proposing a vote of thanks, said: It seems to me that communications similar to those given by Mr. Hunt and Mr. Siebold are particularly valuable to the Society in showing how necessary it is—not less necessary in the workshop, the dye house, and the colour shop than in the laboratory—in all cases to adopt a system of scientific accuracy in order to bring our industries forward.

Mr. W. THOMSON, in seconding the vote of thanks, said: I understood Mr. Siebold to say that he added 3 per cent. of chromate of potash. It has always puzzled me to know how it is that if you use double the quantity of water you get the same results?

Mr. SIEBOLD: It is practically immaterial whether the quantity of water used in mordanting pieces of wool with bichromate of potash is exactly the same in each case or not. What is important is the ratio of the bichromate to the weight of the wool. If I were to mordant a piece weighing 10 grms. in a litre of water containing 0.3 grm. of bichromate, the result would not materially differ from that obtained by mordanting three such pieces together in the same quantity (1 litre) of water containing three times that proportion (0.9 grm.) of potassium bichromate. The main point in testing a dyewood extract by wool dyeing, is the presence in the cloth of a sufficient amount of mordant to fix the entire quantity of colouring matter used in the experiment, or, in other words, to completely exhaust the dyebath. In the case of logwood extract, this end is completely attained by boiling such a piece of well-mordanted wool, in the case

of logwood or fustic extract, for 1½ hours in a litre of solution containing not more than 0.6 grm. of the extract to be examined.

May 3. 1. "Wood Naphtha" by Mr. C. A. Fawcitt; 2.

"Notes on Destructive Distillation," by Professor Mills.

APPENDIX.—Mr. COLEMAN desires to state that upon coming to complete his paper on an "Improved Air Thermometer," preliminary notice of which was communicated to the Society on the 6th of January, 1885, he finds he ought to have stated that the lengths of degrees being doubled when the absolute temperature of the air in the bulb is diminished one half, is only true when the expelled air is measured at the reduced temperature, for when it is measured at the initial temperature the degree will be quadrupled in length, as the density of the air at the reduced temperature will be double of what it was at the commencement.

#### II.—FUEL, GAS, AND LIGHT.

The Illuminating Power of Hydrocarbons. F. Ethane and Propane. Percy F. Frankland, Ph.D., B.Sc. Abstr. Proc. Chem. Soc. 1884-5 [4], 31.

IN continuing his researches on illuminating gas, the author has determined the illuminating powers of ethane

and propane. The gases were prepared by the action of the zinc-copper couple on ethyl and isopropyl iodides respectively, and then subjected to purification by passing them through bromine. The illuminating power of ethane, when consumed from a "referee's burner," at the rate of 5 cubic feet per hour, was found to be 34.8 candles, and that of propane 53.3 candles. The illuminating power of ethane is thus almost exactly half that of ethylene (68.5 candles), whilst that of propane is 1.5 times as great as that of ethane. From these results it appears that in the paraffin series of hydrocarbons, excluding the first member, methane, the illuminating power is directly proportional to the number of carbon atoms in the molecule.—W. S.

*Combustion in Dried Gases.* By H. Brereton Baker, B.A. Abstr. Proc. Chem. Soc. 1884-5 [5], 37.

LED BY Dr. Dixon's experiments, the author has investigated the question whether moisture is necessary for the combustion of carbon and phosphorus in oxygen. The phosphorus used (commercial amorphous phosphorus) had been washed with water and dried at 100° in a current of carbon dioxide previously passed through two wash-bottles of sulphuric acid; it was then heated in a Sprengel vacuum, at 150-160°. The carbon (finely powdered charcoal) had been heated to bright redness in a current of dried chlorine for three hours; the tube containing it was then transferred to an air-bath and heated at 200° while a current of dried air was passed through it. Portions (0.5-1 gram.) were sealed up in bent hard glass tubes along with phosphoric oxide, the tube being filled with oxygen prior to sealing; to free the glass from adhering moisture, the ends of the tubes containing the carbon or phosphorus were heated in an air-bath at 130-150°, the other ends being kept cool.

	Wet.	Dried 1 Week.	Wet.	Dried 2 Weeks.	Wet.	Dried 4 Weeks.	Wet.	Dried 8 Weeks.	Wet.	Dried 12 Weeks.	Wet.	Dried 16 Weeks.
CO <sub>2</sub> .....	50.1	15.4	51.0	19.0	45.3	14.1	23.3	12.5	58.8	15.8	52.4	17.8
CO .....	22.2	20.6	31.2	11.8	32.5	27.8	60.0	27.5	23.2	24.2	25.2	16.5
O <sub>2</sub> .....	—	41.3	—	46.1	—	28.2	—	39.0	—	33.3	—	45.0
N <sub>2</sub> .....	27.6	22.6	17.7	20.1	22.1	29.8	16.6	21.0	17.9	26.6	22.3	20.6

After about eight days, the tube containing phosphorus and dried oxygen, and another similar tube with phosphorus in oxygen saturated with water, were supported at the same height above the flame of an Argand burner: the phosphorus in the wet gas soon took fire, but that in the dried gas slowly distilled and formed a red and yellow deposit on the cooler part of the tube. A similar pair of tubes containing carbon was placed over the large flame of a Bunsen burner: the moist carbon burnt with bright scintillating flashes, but no apparent combustion took place in the tube containing dried gas, though it was heated to bright redness for several minutes. A series of such experiments with carbon were then made, in which the drying extended over various periods, the gaseous contents of the tubes being analysed after the tubes were heated. The results obtained clearly show that the burning of carbon is much retarded by drying the oxygen to the extent which is possible with the arrangement adopted by the author. Other forms of the experiment were described, which led to similar results. The author successfully made an experiment before the Chemical Society with two tubes, the one containing dried, the other undried, oxygen and carbon.—W. S.

*The Explosion of Coal-dust.* A. Gurlt. Berg-u. Hüttenmannische Zeitung, 1885, No. 3, p. 21.

THE author describes experiments which show that coal-dust can give rise, like marsh gas, to dangerous explosions.—A. G. G.

*Improvements in Apparatus for Purifying Coal-gas.* W. T. Walker. Eng. Pat. 2279, January 28, 1884.

THIS specification describes a modification in the construction of Walker's scrubber. The lower portion of the scrubber is filled with thin boards set on edge, each layer crossing the next; the upper portion is filled with coke. The topmost portion of the scrubber is made of an enlarged diameter, and an annular seal cup is formed inside the enlarged part to act as a seal in which the inverted edge of a perforated dashplate rotates above the coke. The perforated dashplate being of greater diameter than the main body of the scrubber, the water is distributed over the entire area of the scrubber. Above the dashplate are the water-distributing arms, which will be rotated in the direction opposite to that of the dashplate. The outlet for the gases from the scrubber is placed above the dashplate to compel them to pass through the wet perforations in the dashplate. The lowermost portion of the scrubber is arranged as a washer to remove the tar, of which, however, no description is given.—C. C.

*Improvements in Apparatus for use in the Manufacture of Gas.* B. Midgley and Wm. Nunnwick. Eng. Pat. 2485, January 31, 1884.

DESCRIBES an apparatus designed for the purification of coal-gas from tar and ammonia. In a cylinder placed horizontally is arranged another cylinder. Both cylinders are closed at each end by plates, which are common to both of them. The space within the inner cylinder forms a scrubber and washer, and the space between the inner and outer cylinder a condenser. Within the inner cylinder is a wrought-iron shaft, one end of which is supported in a socket, the other end passes through a stuffing box to receive the driving gear. Fixed alternately to this shaft and to the inner circumference of the inner cylinder, are

circular iron plates having perforations. The perforations of the fixed plates are near their centres, the perforations of the revolving plates are around the outer edge. At each side of the revolving plates are secured circular brushes, filling up the space between the fixed plates and the revolving plates, so as to prevent any gas passing otherwise than through the brushes. Tar and liquor run from end to end of the cylinder, either continuously or through separate compartments. The inlet and outlet of the gas are in the end plates. The space between the inner and outer cylinder forms a condenser, and water is supplied to it in regulated quantities. The gas passing through the perforations in the plates, and through the wetted brushes, is freed from ammonia and other impurities.—C. C.

*Method of and Means or Apparatus for Generating Gas from Hydrocarbons.* A. J. Boulton. Eng. Pat. 5794, April 1, 1884.

THIS specification describes an arrangement for vaporising hydrocarbon oils for the purpose of using the vapour as fuel in the manufacture of iron, but it is too replete with minor details to allow of abstraction. The gist of it is apparently that the hydrocarbon oil is injected by means of superheated steam into the annular space formed by two pots of different diameters, placed one inside the other. The outer pot is heated by fire. The mixture of steam and hydrocarbon vapour passes from thence into a mixing chamber, and from it to the space where combustion takes place.—C. C.

*Improvements in the Construction of Gas Retorts.* G. K. Harrison, Stourbridge. Eng. Pat. 5833, January 2, 1885.

The retorts are made circumferentially in four segments, a number of which, breaking joint, are connected together to form the length of the retort. In oval or round retorts the top and bottom segments are interchangeable, as are also the side segments. The segments have rabbeted edges, and are made to correspond with one another. Of the four segments forming the mouth of the retort, the top and bottom pieces are not only rabbeted at their edges, but also have indents formed therein, while the two side pieces are provided with projections fitting into the said indents, so that when the mouthpiece is bolted on the tightening of the screws draws all close together, and prevents the too common occurrence of the retort cracking at or about the neck.—A. R. D.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

*On the Presence of an Isocyanide (Carbylimine) in the "Light Stuff" from Commercial Benzene.* E. Noeltling. Bulletin de la Soc. Ind. de Mulhouse, October, 1884, p. 461.

The experiments resulting in the detection of the above compound were undertaken at the request of Dr. Werner, who had performed the autopsy of a workman, who died suddenly whilst engaged in his duties at an india-rubber works at Thann, where the "light stuff" from naphtha was employed in the manufacture. When ninety per cent. and fifty per cent. benzene are rectified in aniline works, a certain quantity of a more volatile liquid than benzene distils over first, and this is technically termed "light stuff." This product has been studied at different times. Helling found, besides a certain amount of benzene, carbon bisulphide, crotonylene, anylene, and hexylene. Witt further detected ethyl alcohol; and, finally, Vincent and Delachanal obtained, in addition to these, considerable quantities of acetonitrile and methyl cyanide. The author, who had on various occasions some of this light product in his possession, has often observed the strong odour of isocyanides. The probability of one or more of this class of bodies being present seemed to gain force from the fact that on the addition of an acid the odour in question disappeared, and was replaced by that of carbon bisulphide, alcohol, hydrocarbon, and acetonitrile. By evaporating the hydrochloric acid solution, sal-ammoniac and a small quantity of the hydrochloride of a primary amine was obtained. The proportion of isonitriles contained in the "light stuff" is very small, but the odour is very penetrating and characteristic, and its poisonous properties exceedingly energetic. From the boiling point of the "light stuff" it can only contain methyl or ethyl isocyanide, the former boiling at 59.6°, the latter at 78.1°. The "light stuff" from benzene has no practical use. The benzene is extracted as far as possible by distillation. Sometimes it is employed for dissolving caoutchouc; but for this purpose solvent naphtha, which distils at 120-150° (a mixture of a little toluene, xylene, cumene, and hydrocarbons of the fatty series, and the oils of turpentine), is generally preferred.—J. B. C.

*Synthesis of Thiophen.* Victor Meyer. Ber. 18, 217.

A SHORT note of the results of experiments made with a view to demonstrate the constitution of thiophen by synthetical reactions. Thiophen was formed, but in too small quantities to afford support to any proposed structural formula. By passing ethylene or petroleum spirit vapours over heated pyrites, or ethyl sulphide alone through a red-hot tube, or by heating crotonic or butyric acid with sulphide of phosphorus, thiophen was in each case obtained, whilst, according to expectation, no thiophen was obtained by the action of phosphorus sulphide on isobutyric acid.—G. H. B.

*Synthesis of Thiophen and Pyrroline Derivatives.* C. Paal. Ber. 18, 367.

THE author has previously shown that acetophenone-acetone by the action of dehydrating agents gives a furfuran derivative, and supposes that the diketone

group  $\text{—CO—CH=CH—CO—}$  in the reaction changes into the unstable form  $\text{—C=C=C—C—}$  and from this

the constituents of water are eliminated. From the analogy existing between furfuran, thiophen, and pyrroline, both in their method of preparation and properties, it seemed possible that by the action of H.S. a thiophene-, of ammonia, a corresponding pyrroline-derivative, might be prepared. This supposition has been confirmed.

Phenylmethylthiophen is formed by the action of  $\text{P}_2\text{S}_5$  on acetophenoneacetone at a temperature of 120-130°. The crystalline body obtained has the formula  $\text{C}_{11}\text{H}_{10}\text{S}$ , and gives the characteristic blue colour with isatin and sulphuric acid. By heating acetophenoneacetone with alcoholic ammonia to 150° a corresponding pyrroline-derivative is obtained, having the formula  $\text{C}_{10}\text{H}_{11}\text{N}$ , and which is therefore phenyl-methylpyrroline.—J. B. C.

*On a Simple Method of Preparation of Thiolen and Thioxen.* K. E. Schulze. Ber. 17, 2852.

THE process described by V. Meyer for the preparation of thiophen is inconvenient owing to the large quantities of liquid which must be operated on, and to the loss by the destructive distillation of the ammonium salt of the sulphonic acid. The author attempted to obtain thiotoluen and thioxen directly by the distillation of the impure sulphonic acids with aqueous vapour. In the first experiment with the xylene acid steam was passed rapidly into the acid heated to 100°, but the yield was small, and large quantities of sulphur dioxide were evolved. A much better result was obtained by mixing the acid with one fifth of its weight of boiling water, and passing a slow current of steam into the solution. The yield of oil thus rose from two to nine per cent. The product boiled, for the most part, between 135° and 138°, and the distillate contained 44.4 per cent. of thioxen. The acid contained xylene mechanically mixed with it, and this would account for twenty per cent. of the fractionated oil. The results with the toluene acid were not so satisfactory, the decomposition being greater. A better yield was again obtained by the addition of water to the impure acid. Only about four per cent. of oil was obtained, and it did not boil nearly so constantly as the crude thioxen. The product after rectification boiled between 111° and 113°, and contained 22.3 per cent. of thiotoluen. A portion boiling at about 80° contained thiophen, and the author hopes to obtain this substance by the same method.—S. Y.

*Thiophen from Mucic Acid.* C. Paal and J. Tafel. Ber. 18, 456.

PAAL has shown (Ber. 18, 367) that acetophenone-acetone ( $\text{C}_6\text{H}_5\text{CO.CH}_2\text{CH}_2\text{CO.CH}_3$ ), according as it is treated with  $\text{P}_2\text{O}_5$  or  $\text{P}_2\text{S}_5$ , yields a furfuran derivative (phenyl-methyl-furfuran), or a thiophen derivative (phenyl-methyl-thiophen). As now mucic acid also gives a furfuran derivative by splitting off water (pyronucic acid or furfuran-carboxylic acid), it seemed probable that under the influence of H.S. it would give thiophen carboxylic acid, and this proved to be the case.

*Thiophen-carboxylic Acid.*—A mixture of mucic acid and barium sulphide was heated to 200-210° in sealed tubes, the product boiled with water and filtered; the filtrate was acidified and extracted with ether. After purification the thiophenic acid formed long fine needles melting at 126-127°. Yield, 10 to 12 per cent. of the theoretical.

**Reactions.**—It gives the blue colouration with isatin and sulphuric acid. With  $\text{Fe}_2\text{Cl}_6$  it produces a citron-yellow precipitate.

**Salts.**— $(\text{C}_6\text{H}_5\text{SO}_2)_2\text{Ca}$ ,  $3\text{H}_2\text{O}$ —easily soluble needles.  $(\text{C}_6\text{H}_5\text{SO}_2)_2\text{Ag}$ —difficultly soluble crystals.

The formation of thiophen-carboxylic acid from mucic acid probably takes place in the following stages:—

(1) Mucic acid and BaS give barium mucate and  $\text{H}_2\text{S}$ .  
(2)

(3) The thiophen-dicarboxylic acid then splits off  $\text{CO}_2$ , forming thiophenemonocarboxylic acid.

**Thiophen.**—By distilling the thiophenic acid with lime a distillate was obtained, which, on purification, gave pure thiophen, boiling at  $83-84^\circ\text{C}$ . (731mm.). The yield was 40 per cent. of the theoretical. The thiophen thus obtained was in every respect identical with the coal-tar thiophen.—A. G. G.

**Preparation of Thiophen.** K. E. Schulze. Ber. 18, 497.

THE author proposes the following simple method for the preparation of thiophen. Strong sulphuric acid, which has been shaken for three or four hours with 20 times its weight of benzene (of constant boiling point), is at once diluted with two or three times its volume of water and distilled with steam. The thiophen separated from the distillate (about three per cent. by volume of the acid used) is nearly pure, since the sulphonic acids of the benzene hydrocarbons are not decomposed in such a dilute solution; 96 per cent. of the product distilled between  $84^\circ$  and  $85^\circ\text{C}$ . The specific gravity at  $15^\circ\text{C}$ . was 1.1.—A. G. G.

**Thiophen.** V. Meyer and O. Stadeler. Ber. 17, 2778.

It is a well-known fact that commercial dinitrobenzene dissolved in alcohol gives a light magenta colouration on the addition of a drop of potash solution. The following experiments have fully explained the cause. The preparation of the nitro derivatives of thiophen made it appear probable that the corresponding amido compound analogous to aniline could be obtained. Every attempt in this direction with any of the ordinary reducing agents failed. A violent reaction occurs, the substance being completely decomposed with evolution of sulphuretted hydrogen. The nitro derivatives of thiophen, however, resemble the amines of the benzene series in their property of forming colouring matters, a fact which at first sight might appear remarkable. When, however, it is considered how much more marked are the colour-forming properties of thiophen and its homologues, compared with hydrocarbons of the benzene series, it is not surprising that the nitro derivatives should have a similar tendency. Mononitrothiophen turns red on exposure to light; boiled with aqueous alkali it dissolves, forming a deep brown solution. The colouration produced by reduction of the sulphonic acid is particularly striking. Mononitrothiophen dissolves in fuming sulphuric acid, and forms a well-defined sulphonic acid, the potassium and ammonium salts of which readily crystallise. On reduction of the nitro-sulphonic acid with ammonium sulphide a magenta-coloured solution first forms, the colour gradually vanishing on further reduction. The reaction is more striking when bibulous paper moistened with the sulphonic acid is exposed to the vapours of ammonium sulphide. The paper is coloured deep red. The reaction with dinitro-thiophen is still more intense. This substance is dissolved in alcohol, and on the addition of one drop (not more) of aqueous potash a deep red solution is produced, which in thin layers has a violet tint. An excess of alkali or acid destroys the colour; but it is restored by carefully neutralising, the colour

being due to the formation of the potassium salt. By precipitation with ether a violet-red resin is left, which dissolves in alcohol without change of colour. The corresponding silver salt is a reddish brown explosive powder. The above reaction of dinitro-thiophen with potash explains then the phenomenon observed by adding alkali to dinitro-benzene. A comparison of the colours prepared from both sources leaves little doubt as to its true nature, which is further confirmed by the fact that dinitro-benzene prepared from benzene free from thiophen gives no colouration whatever. Commercial mononitro-benzene gives the same reaction as the dinitro compound, that free from thiophen remains colourless. This distinction can therefore serve as a test for thiophen in the benzene, from which the nitro compounds have been prepared.—J. B. C.

**Perchlorophenol from Perchlorobenzene.** A. Weber and N. Wollf. Ber. 18, 335.

PERCHLOROBEZENE ( $\text{C}_6\text{Cl}_6$ ) heated to a high temperature with caustic soda yields perchlorophenol. Commercial glycerine is heated to  $250^\circ$  in a flask, caustic soda, and then perchlorobenzene, gradually added. The mixture is kept at a temperature of  $250-280^\circ$  for half-an-hour, and repeatedly shaken. On cooling, water is added, and the aqueous solution filtered and saturated with HCl. The precipitate which forms is recrystallised from benzene. Perchlorophenol has the formula  $\text{C}_6\text{Cl}_5\text{OH}$ , melts at  $187-188^\circ$ , and is identical with that obtained by chlorinating phenol.—J. B. C.

**The Reverse Action of Friedel and Craft's Synthetic Method for Preparing the Hydrocarbons.** O. Jacobson. Ber. 15, 338.

By the action of aluminium chloride and methyl chloride on pure mesitylene, in addition to isodurene, a quantity of durene was formed. It appeared therefore that either mesitylene gave metaxylene, then pseudocumene and durene, or that penta- and hexamethylbenzene were first produced, and then durene, by elimination of the methyl groups. In either case the formation of durene must be due to the reverse action of Friedel and Craft's synthetic method. Experiments confirmed this supposition. The hydrocarbons were heated with  $\text{AlCl}_3$ , in some cases alone, and in others in a current of HCl.

Hexamethylbenzene was heated with half its weight of  $\text{AlCl}_3$  to  $200^\circ$ , the chief products being pentamethylbenzene, durene, and isodurene and small quantities of benzene, toluene, xylene, and trimethylbenzene.

The elimination of the methyl groups is more complete if the above experiment be conducted in a current of HCl.

Pentamethylbenzene and Durene gave similar results to those of the hexamethyl derivative, durene and isodurene being formed, also a certain quantity of hexamethylbenzene.

Pseudocumene treated in the same way gave benzene, toluene, xylene, durene, isodurene, and traces of pentamethylbenzene.

Mesitylene heated to  $150-160^\circ$  with  $\text{AlCl}_3$  in a current of HCl, produced traces of the lower methyl benzenes, also pseudocumene, isodurene, and durene. The chief portion, however, consisted of unaltered mesitylene.

From metaxylene the higher methylated hydrocarbons were principally obtained. The results of the experiments may be stated shortly as follows:—

By the action of dry HCl on methyl benzenes in presence of  $\text{AlCl}_3$  the methyl group may be eliminated, and the hydrocarbons reduced to their lowest homologues. In every reaction the methyl chloride formed acts upon the hydrocarbons, producing the higher homologues. These higher methylated hydrocarbons can then again undergo decomposition, so that by this reaction a process of synthesis and decomposition is going forward until a state of equilibrium is attained. Usually the elimination of the methyl group by HCl is facilitated by a high temperature, its substitution by a lower temperature.—J. B. C.

*The Carbonisation of Wood.* Hugo Blank. Dingl. Polyt. Journ. 255 [10], 435.

WILH. SÖLTZ, of Sehmnitz, has recorded his observations during a visit to the works where wood is carbonised in Trzynietz (Austrian Silesia), which are all the more interesting because the arrangements show many differences from those existing in English works, and especially in the means adopted for working up all by-products.

The plant arrangement shown in Figs. 1 to 6 is designed for an annual consumption of 18,000 cubic meters of wood. This wood is carbonised in 22 cylinders or retorts R, set up in a line and enclosed in brickwork. These retorts are of wrought iron, and measure  $2\frac{1}{2}$  meters in length, and 1 meter in diameter. Each retort has a cast-iron door, and a wrought-iron false bottom, supported by a bar with an ear or loop at its extremity, so that by attaching the chain of a locomotive windlass *a* (Fig. 5)

small flues *i* under the fire-place, but so as eventually to enter amongst the fuel, and thus aid in heating the ovens.

The retorts only last, it is stated, from 9 to 18 months, whereas in England the wrought iron cylinders are good for 6 years, and cast-iron ones for 15 years.

For the charring of 250kilos. of wood, 100kilos. of coal were necessary, the temperature is maintained at from 350° to 400°, and the carbonisation period covers from 8 to 12 hours.

As soon as the glowing charcoal has fallen into the sheet-iron box, the latter is closed with an iron lid, the luting made good with mortar, and the box, together with the tram-wagon, is let stand 24 hours in the cooling-chamber. The condensed products of distillation pass from the trough *c* (Fig. 3) into the vat *m*, and from this trough the overflow pipe *n* into the vat *p*, standing deeper still. In both these vats, the greater part of the tar will have already settled down; in order

to it, the false bottom can be drawn out, and thus the charcoal can be emptied. It falls into sheet-iron boxes placed on tram-wagons. The false bottom is furnished with holes 2 to 3 cm. wide, so that the gaseous distillation-products can more easily be drawn off. The retorts are surrounded by brickwork, and the fire circulates around them, afterwards passing down the flue *b* (Fig. 5) into the main flue *c*, and then to the chimney. Fig. 6 shows how that each pair of retorts is combined with one and the same condenser K, in which the gases pass through a pipe *l* made fast in the hindmost door of the retort.

The distillation products flow through the small side-tubes *d* into the common trough or gutter *e*, whilst the noncondensed gases pass through *f* into a common gas-holder *g*, and from this through 2 or 3 pipes into the main-pipe *h*, from which the gases pass through the

that this may take place more completely, the supernatant liquid is drawn off by means of a steam pump into a cistern set on a higher level, from which it is run off, just as before, into a second, and finally into a third vat (Fig. 4), which, however, contains in the middle of it a double false bottom perforated with narrow holes, and filled with good coles.

For obtaining acetic acid, acetone, allyl- and methylalcohols, the watery liquid, completely freed from tar, is brought into a copper still A (Fig. 2), holding from 20 to 30 hectolitres, and heated there with a steam coil through which steam at from 3 to 4 atmospheres' pressure enters at *a* and escapes at *b*. The copper pipe from the still-head passes into an air-tight copper receiver B, where it branches off into two parts, furnished with small holes. From this vessel or boiler a copper pipe passes, branching off at right angles at *c*; the one branch passes into the

open copper-boiler C, upon the bottom of which it ends in a U-shaped tube perforated with small holes; the second branch passes into the copper tubular condenser D. The vessels B and C are filled with milk of lime to fix the acetic acid. As soon as the liquid in A evaporates, the escaping acetic acid is retained by the milk of lime in B, and calcium acetate is formed; the

After evaporating off the first 10 per cent. of the contents of A, all the volatile products named are driven off completely; it is then necessary, when all the milk of lime in B is already combined with acetic acid, and still acetic acid vapours are perceptible, to absorb these vapours completely in the vessel C, effected by closing the cock *c* and opening *d*. The solution of calcium acetate formed in B and C is now concentrated in iron evaporating vessels over open fires, or in lead-lined wooden evaporating pans, arranged in step fashion, one above the other, and heated with steam coils, till pellicles of salt form on the surface. In order to free the salt thus separated from adhering tarry matters, it is cautiously and gently ignited. If completely pure calcium acetate is to be obtained, then the calcined crude salt is purified by solution and crystallisation. If acetic acid is to be prepared, the calcium acetate is decomposed with hydrochloric acid (100 parts of the salt require 90 to 95 parts of hydrochloric acid of 1.16 sp. gr.), and the mixture distilled in copper vessels; the condenser is best made of tin. For the preparation of chemically pure acetic acid, sodium acetate is taken.

The separation of the acetone, allyl- and methyl-alcohol from the water, and from each other, is effected by means of fractional distillation, which in Trzynietz was performed in an arrangement like a Savalle's column-apparatus (Fig. 1). The liquid to be distilled is placed in the boiler or still A, heated with steam, and connected above with a column separated into several compartments by a number of copper-sieves; the ascending vapours pass through the sieves, and separate the water, which, condensing, falls on the sieves and forms a layer of a certain height. Whilst the vapours must pass through this layer of water, they become constantly drier, until they pass through the pipe *a* into the tubular condenser (dephlegmator) B. The liquid condensed here, and still containing water, is returned to A, whilst the still gaseous alcoholic constituents condense later on in the dephlegmator C, and according to the different periods of their boiling-points, first acetone, then methyl-alcohol, and, lastly, allyl-alcohol, flow out.

This Trzynietz Works is an example of the advantage of charring in retorts, and of the profit to be realised under circumstances in which the by-products can be recovered and utilised. With the ever-increasing scarcity of cheap wood-charcoal, this process in the region of great forests and rich iron-ore deposits would be of great influence in increasing profits, or making competition possible in many works. It remains yet to be ascertained by practical experiments, how far the wood charcoal obtained in retorts as described can replace that obtained in the mellers or mounds; as a contribution to such experience, experiments with Trzynietz charcoal in the Erzherzog Abrecht Works in the Bindt (Zips) have borne favourable testimony in the direction of such advantageous replacement.

—W. S.

*The Action of Chloropierin and Chloroform on Toluene in presence of Chloride of Aluminum.* K. Ellis and O. Wittich. Ber. 18, 347.

THE method is the same as that adopted for the preparation of triphenylmethane, the mixture of chloropierin and toluene being, however, diluted with an equal volume of  $\text{CS}_2$ . The product was distilled with zinc dust, and an oil obtained distilling at  $270\text{--}290^\circ \text{C}$ , and also a portion distilling above  $360^\circ$ . The former was found to be ditolylmethane, the latter tritolylmethane. In all probability the tritolylmethane consists of several isomers, as it could not be crystallised. By repeating Schwarz's experiments (Ber. 14, 1526)—i.e., substituting chloroform for chloropierin—the authors obtained small quantities of di- and tritolylmethane and a substance identical with that described by Schwarz as tetra-tolylmethane, but which bears a strong analogy in its chemical properties to an anthracene derivative. The results of the analysis would also agree with a compound of the formula of dimethylantracene. The

other products of distillation on closing the cock *d* and opening the cock *c* pass into the condenser D, from whence they are run off at *f*, completely condensed; the result is, besides water, acetone, allyl- and methyl-alcohols.

reaction which occurs can be represented by the following equation:—

The following proportions of the different substances employed are found to give the best yield of dimethylanthracene: 3 parts of toluene, 3 parts of  $\text{CS}_2$ , 1 part of  $\text{CHCl}_3$ , and 2 parts of  $\text{AlCl}_3$ . The dimethylanthracene obtained in this way melts at  $215\text{--}216^\circ$ , and is therefore not identical with either of the two already known.

—J. B. C.

**Fluorene.** Dr. W. R. Hodgkinson. *Abstr. Proc. Chem. Soc.* 1884-85 [5], 36.

IN two previous notes to the Chemical Society, the author has remarked upon, and given examples of, the facility with which fluorene and its derivatives condense to a double molecule, owing to the presence of the  $\text{CH}_2$  group. This action takes place when fluorene is heated to a high temperature alone or in contact with even very gentle oxidising agents. In a previous note two isomeric difluorenes were described, which were obtained from the red body produced when fluorene is passed over red-hot manganese dioxide. At that time the red body was distilled under reduced pressure, as the red colour could not be removed by crystallisation, and the distillate was then crystallised from acetic acid. It has since been found that the hydrocarbon,  $\text{C}_{22}\text{H}_{18}$  (melting at  $246^\circ$ ), termed *para-difluorenyl*, suffers considerable, if not complete, decomposition even when distilled under reduced pressure. However, by distilling the crude product only so far as to separate the main bulk of unaltered fluorene, and treating the highly-coloured residue with cooled ether—which dissolves the red colouring matter and any unchanged fluorene—a very slightly coloured residue of the  $\text{C}_{22}\text{H}_{18}$  hydrocarbons is obtained. The crude product forms about 10 per cent. of the original fluorene, and contains at least three isomers of the formula  $\text{C}_{22}\text{H}_{18}$ . The one present in greatest quantity, and the only one as yet examined, is that melting at  $246^\circ$ . This body forms long prisms, very slightly soluble in cold ether or chloroform, and only moderately in hot acetic acid. On slightly heating it above its melting point, it decomposes, forming another hydrocarbon of lower melting point, and a large amount of carbonaceous matter. It is not easily brominated; a cold solution in  $\text{CHCl}_3$  may be treated with bromine without much action taking place, and, when heated, a tetrabromo-compound, extremely insoluble in all solvents, is formed, which melts, with decomposition, at about  $302^\circ$ . On boiling it with fuming nitric acid, a di-nitro-compound is formed. It is not very easily oxidised; the acetic solution requires to be boiled with a large excess of  $\text{CrO}_3$ . The product crystallises from acetic acid in very fine rhombs, melting at  $255^\circ$ , and sublimes unchanged. It has the composition  $\text{C}_{22}\text{H}_{14}\text{O}_2$ , and is probably an oxide not a quinone. Alkalies, bromine, and nitric acid scarcely affect it. The di-haloid derivatives of fluorene, as mentioned in the author's previous note, contrary to statements by Van Dorp and others, are readily acted upon by alkalis, halogen being removed and difluorene compounds formed; with fused or concentrated potash the action is violent, and pure products are not easily obtained. The action of alcoholic potash is more manageable, but the best result is obtained by the action of sodium ethoxide. On dissolving  $\text{C}_{22}\text{H}_{18}\text{Br}_2$  in alcohol, and adding sodium, a green solution is formed; on dilution with water and boiling this deposits a brilliant red crystalline powder, which is exceedingly insoluble. Analysis shows it to have the composition  $\text{C}_{22}\text{H}_{18}\text{Br}_2\text{O}$ . This body crystallises from boiling cumene or acetic anhydride in red microscopic prisms, melting above  $360^\circ$ ; the chloro-derivative is analogous. It appeared possible that this body might be produced by the simultaneous action of bromine and potash on fluorene; it was found, however, that the main product is monobromofluorene, identical with that already described, melting at  $103\text{--}104^\circ$ ; this is an excellent way of making the mono-haloid deriva-

tives of fluorene, as in the ordinary way much di-haloid derivative is always formed. Sodium ethoxide acts on monobromofluorene; the product is of a yellow colour and free from bromine. A mononitrofluorene is obtained by very careful addition of the calculated amount of nitric acid to a cooled solution of fluorene in acetic acid; it forms small prisms, very soluble in hot alcohol, and melts at  $151^\circ$ . The amido-compound from it is rather unstable. On heating nitrofluorene above its melting point it decomposes, one product being a  $\text{C}_{22}\text{H}_{16}$  hydrocarbon that is not identical with any of those directly obtained from fluorene.—W. S.

**Improvements in and connected with the Treatment of Gas-liquor for use in the Purification of Coal-gas.** F. C. Hills, London. Eng. Pat. 5874, April 3, 1884.

IN a previous specification (Eng. Pat. 934, March 14, 1874) the inventor proposed to heat the gas-liquor to be purified in a still, and pass the gases driven off into a scrubber, whilst in the present communication the gas-liquor is heated as it descends in the scrubber, the heat being applied at the lower part of the scrubber. By this means the temperature of the descending stream of gas-liquor is gradually raised, and most of the sulphuretted hydrogen and carbonic anhydride, and some ammonia, are expelled, the latter being absorbed by the cool gas-liquor in the upper part of the scrubber, whilst the sulphuretted hydrogen and carbonic anhydride pass from the scrubber at the upper part as described in the previous patent.—D. B.

**Improvements in the Distillation of Coal in the Manufacture of Coal-gas, for the purpose of Facilitating the Subsequent Purification of the said Gas.** R. Irvine, of Royston, Granton, near Edinburgh, Scotland. Eng. Pat. 5932, April 4, 1884.

THE inventor proposes to distil the coal in the presence of ammonia or its carbonate, by passing their vapour either alone or with steam into the retorts in which the coal is being carbonised. The sulphur combines with the ammonia, forming compounds of ammonia and sulphur, which may be readily arrested in the subsequent purification of the gas without the necessity for using lime or oxide of iron.—D. B.

**On the Dry Distillation of Wood.** M. Senff. Ber. 18, 60-64.

THE author, who has had a long practical experience in the dry distillation of wood, made an extensive series of determinations concerning this special branch of chemical industry. Although the experiments were carried out in the laboratory, all conditions of the working on the large scale were carefully observed, so that the results may serve as a guide for practical work. The distillation was performed in a cylindrical retort of cast-iron, 60cm. long by 20cm. diameter, set horizontally in a small furnace. It could be hermetically closed by means of a lid and bolts. The cooling worm was very long and kept well supplied with cold water in order to effect a complete condensation, even when the distillation was carried out at the quickest rate. Air-dry wood was employed in all experiments, and great care was taken in collecting the material to be operated upon. The wood was charred without removing its bark, just as it is done on the large scale. The pieces were 20cm. long by 2-3cm. thick. If the operation of distilling was to be carried on slowly, the retort was not heated, but after charging and closing, and a uniform small fire was kept up for six hours. In a quick operation the empty retort was heated to bright redness, quickly charged with the material, closed, and a strong heat applied for three hours. The retort held from 4-6kg. wood according to quality. After finishing the distillation, the retort was kept closed till it was completely cold, and the residual charcoal was weighed immediately after opening. Its absorption of moisture was also ascertained after an exposure of several weeks to the atmosphere of a room. The term "total distillate" in the table below, means crude wood-vinegar

and tar. Both were separated by means of a separating funnel. The uncondensed gas was estimated by difference—i.e., wood minus (total distillate plus charcoal) equals uncondensed gas. A determination of the quantity of methyl alcohol in the distillate is difficult and untrustworthy in working on a small scale and was therefore omitted. Besides it is known from practical experience that the yield of methyl alcohol is in direct proportion with the amount of wood-vinegar. The following table shows the results, in which *a* and *b* mean slow and quick distillation respectively:—

coal is distilled with steam, in the presence of ammonia or ammonium carbonate, the ammonia being recovered in the usual manner, and used again for a further operation. By this treatment the yield of paraffin is said to be increased.—D. B.

*Improvements in the Distillation of Mineral Oils and in the Apparatus employed therefor.* W. Young and G. T. Beilby, Scotland. Eng. Pat. 6094, April 8, 1884. THE object of this invention is the reduction of the cost of labour and fuel in the process of refining, and the

\* Not completely charred.

Practical conclusions from the experiments: 1. The yield by weight of wood, vinegar, tar, charcoal and uncondensed gas, do not greatly vary with different kinds of woods. 2. The percentage of real acid in the wood-vinegar—i.e., the yield of anhydrous acetic acid—differs very much. In this respect trees, bearing foliage, are better than pines; wood, from the trunk, yields more acid than wood from branches; wood in good state is preferable to such in rotten state. 3. A quick distillation yields an increased quantity of uncondensed gas, but at the cost of the amount of total distillate and charcoal. 4. A quick distillation yields a distillate poorer in acid; and 5. The resulting charcoal is much more hygroscopic than that produced by a slow process of distilling.—S. H.

*Improvements in the Distillation of Shale Coal or the like for obtaining Solid Paraffin therefrom.* Robert Irvine, of Royston, Granton, near Edinburgh, Scotland. Eng. Pat. 5933, April 4, 1884.

THE object of this invention is to prevent the decomposition of the paraffin by sulphur or its compounds during the process of distillation. For this purpose the shale or

more efficient fractionating of the various grades of oils, of which the crude oils are composed. The guiding principles on which the process and arrangements are founded are:—(1) continuous distillation, (2) the utilisation of the heat from the fuel employed to effect the distillation in such a manner that the high temperature, where the combustion is effective, is made to distil the oils having a high boiling point, and that as the products of combustion lose heat they are made successively to distil the more volatile oils, so that by the time they reach the chimney the heat has been fully utilised, (3) the separation of the oil vapours arising from the oils of different densities as they flow from the colder to the hotter end of the still, and (4) the conjoint heating and partial distillation of the oils on their way to the still, and the condensation of the oil vapours coming from the still in such a manner that the cold oil flowing to the still will first act as the condensing agent for the more volatile vapours from the still, and that as the oils become gradually heated by so acting as the condensing medium of the more volatile vapours, it will be made to act successively as the condensing medium of the heavier vapours, and by being thus heated and applied, will act

as a means of further fractionating the oils, and at the same time conserve the heat from the condensation of the oil vapours.—D. B.

*Improvements in the Distillation of Mineral Oils, their Residues and Tars, and in the Apparatus employed therefor.* W. Young and G. T. Beilby, Scotland. Eng. Pat. 8409, April 8, 1884.

The apparatus for carrying out this invention consists of an iron vessel, containing a series of iron trays placed over each other. The oils are made to flow down from tray to tray of the arrangement, whilst a current of super-heated steam which is forced upwards effects the distillation of the descending oils. The coke remaining on the trays is either removed by mechanical scrapers or by hand through openings. Instead of trays the apparatus may be filled with broken coke, fire brick, hollow iron balls or similar substances presenting a large surface and having considerable spaces between.—D. B.

*Improvements in the Bleaching or Purifying of Dark Coloured Mineral and other Distillable Oils.* W. P. Thompson. Eng. Pat. 6786, April 25, 1884.

THIS patent is a reissue of part of the invention protected by provisional application (Eng. Pat. 5969, December 31, 1883), the remaining part of the provisional specification being covered by patent No. 5208. It consists essentially in distilling the oil through a layer of thoroughly desiccated hot porous material, preferably animal charcoal with or without superheated steam, and with or without atmospheric pressure. The vapour then passes to the condensing apparatus, which consists of a single worm in a cooling liquor, or it can be composed of a rather hot worm, then a collecting receptacle, then another worm kept a little cooler than the last, then another collecting receptacle and so on. Thus the oils of higher boiling point are still further fractionated from the lower, being deposited in the first receptacle. From the last of the receptacles (and in most cases one worm and one receptacle will suffice) a pipe is led to an air pump so as to keep up a vacuum, and enable the oil to be distilled at a lower temperature, and also to come over of a lighter colour.—D. B.

#### IV.—COLOURING MATTERS AND DYES.

*Apparatus for the Manufacture of Colours containing Sulphur.* Dingl. Polyt. Journ. 254 [8], 345.

M. MAJERT, of Heidelberg, has found (Ger. Pat. 27,277, October 25, 1883) that in the preparation of colouring matters from aromatic paradiamines by Lanth's process—treatment with sulphuretted hydrogen and ferric salts

very dilute solutions, so that a sufficiently large excess of sulphuretted hydrogen is retained in the liquor. The best yield of colouring matter is obtained by employing for 1 part phenyleneparadiamine 200 parts of the solvent saturated with sulphuretted hydrogen at 15°, this being three times the amount of sulphuretted hydrogen required by theory. The yield of colouring matter increases with the amount of acid contained in the solution, but it is out of proportion with the cost involved by the employment of such large quantities of liquor which have to be dealt with when a certain amount of acid is exceeded. To obviate these drawbacks, and allow of the use of a more concentrated liquor, a lead-lined boiler A, holding 2 cubic metres and standing a pressure of 25 atmospheres, is employed. It is furnished with a copper agitator *r*, vacuum and pressure gauges, manihole *m*, and a safety valve, opening at 20 atmospheres pressure. Fifty kilos. paraphenylenediamine dissolved in 1200 kilos. sulphuric acid at 25° B. are introduced into the boiler A; the safety valve is then lifted and 40 kilos. of compressed sulphuretted hydrogen are allowed to pass through the pipe *d* into A. The valve is closed again as soon as all the air in the boiler A has been displaced. The temperature of the liquor in A falls considerably, whereas the pressure rises to five atmospheres. The agitator is then set in motion, and a 20 per cent. solution of ferric sulphate is by means of compressed air transferred from the vessel C through the pipe *c* into A, until a vacuum of 200 millimetres is reached. It is advisable to cool the boiler A while the reaction is proceeding. When it is finished, a green solution, containing ferrous sulphate and sulphur in solid form, is obtained, which is discharged through *g* into a tank containing about 2 cubic metres of water. The solution, which now assumes a violet colour, is filtered, and the colouring matter precipitated by means of zinc chloride and common salt. It dyes violet shades. Paramidoethyl-aniline, under the same conditions, forms a blue; para-amido-*lim*-thylaniline, para-amido-diethyl-aniline, and para-amido-methylethylaniline, greenish-blue colouring matters.—F. M.

*Action of Alcohol on Diazo-Compounds.* Ira Remsen. Ber. 18, 65.

A. W. HOFMANN, Hallen, and of Wroblewsky (Ber. 17, 1917, 1887, and 2703), and other investigators, have found that a diazo-compound, when decomposed by boiling with alcohol, does not *always* yield the corresponding hydro-carbon as previously supposed, but that *sometimes* the ethyl-ether of the corresponding phenol is produced. The author points out that Brown (Amer. Chem. Journ. 4, 374) has also made the same observation, obtaining ethoxymetatoluic acid by boiling the diazo-compound of

in a cold dilute, acid solution—hye-products of a red colour, and containing a larger amount of sulphur, are formed, and that the greater part of the sulphuretted hydrogen is oxidised to water and sulphur without taking part in the reaction. In order to obtain a good yield of colouring matter it is necessary to work with

amidometatoluic acid with alcohol. Palmer has just found that by the decomposition of the diazo derivative of amido-orthotoluene sulphonic acid by alcohol, both orthotoluene sulphonic and ethoxorthotoluene sulphonic acids are formed, their relative proportions depending apparently on the pressure under which the

decomposition was carried out. The author is now investigating the influence of pressure on this decomposition of diazo-compounds by alcohols.—S. II.

*Conversion of Phenols into Amines.* K. Buch. Ber. 17, 2634.

BENZENE-PHENOL and *p*-toluidine, or *p*-cresol and aniline, on heating with zinc chloride from 260° to 300°, yield phenyl-*p*-tolylamine

Also by heating benzene-phenol and *p*-toluidine with calcium chloride to 300°, phenyl-*p*-tolylamine is formed, although in very small quantity. A better yield of the mixed secondary amine was obtained by the action of antimony trichloride on a mixture of aniline and *p*-cresol. Along with this diphenylamine was formed, and metallic antimony obtained. The mixed secondary amine evidently escapes the double decomposition of the aniline with *p*-cresol, whilst the diphenylamine escapes that of the aniline with its hydrochloride. By heating *p*-toluidine and benzene-phenol with phosphorus pentoxide, no phenyl-*p*-tolylamine was obtained, but only diphenylamine. By the action of ammoniacal zinc chloride, or continued heating to 300° and above that temperature, *p*-cresol was converted into *p*-toluidine, concurrently some di-*p*-tolylamine was obtained. The oxide crystallised in silky plates or needles, was somewhat sparingly soluble in alcohol, melted at 165°, and is a volatile substance. Di-*p*-tolylamine was also formed by heating *p*-cresol with zinc chloride, or with the zinc chloride-aniline compound. Aniline and phenol yield, on heating with excess of calcium chloride at 300°, diphenylamine, but only in small quantity. Diphenylamine is formed along with metallic antimony and resinous matters, by the action of antimony trichloride or aniline alone, but in much larger quantity, when for aniline, a mixture of aniline and phenol with its hydrochloride is substituted. In this case, the reaction of the aniline associates itself with that with phenol.—W. S.

*Orthonitraniline-sulphonic Acid and Orthonitraniline.* R. Nietzki and T. Benekiser. Ber. 18, 294.

THE authors prepare this acid by nitrating the acetyl derivative of sulphanilic acid. For this purpose the sodium salt of acetyl-sulphanilic acid is dissolved in conc.  $\text{H}_2\text{SO}_4$ , and the calculated amount of  $\text{HNO}_3$ , previously mixed with  $\text{H}_2\text{SO}_4$  added. The mixture is run on twice, saturated with lime, and the lime salt at once decomposed with sulphuric acid, by which method the acetyl group is at the same time eliminated. On heating the potassium salt to 170–180° with conc.  $\text{HCl}$  in a closed tube the sulpho group is replaced by hydrogen, and orthonitraniline (m.p. 71.5°) obtained. Starting from acetanilide and treating this with fuming  $\text{H}_2\text{SO}_4$  the authors have prepared sulphanilic acid. On the addition of nitric acid as before, nitraniline-sulphonic acid and nitraniline may be obtained in nearly theoretical quantities. A further study of the acetyl derivatives of naphthylamine sulphonic acid is intended.—J. B. C.

*Azonaphthalene.* R. Nietzki and O. Goll. Ber. 18, 297.

IN order to determine whether the substance, called by Laurent "naphase," is actually an azonaphthalene as supposed, the authors have succeeded in preparing from amido-azonaphthalene a compound having the formula  $\text{C}_{20}\text{H}_{14}\text{N}_2$ , differing in its properties from naphase of Laurent, but possessing colouring powers analogous to azobenzene. The action of ethylnitrite on amido-azonaphthalene, according to Griess's method, does not eliminate the amido group; but by treating amido-azonaphthalene sulphate with sulphuric acid and sodium nitrite at a temperature of 10–15°, diazo-azonaphthalene sulphate crystallises out on standing. This yields  $\alpha$ -azonaphthalene when boiled with alcohol, nitrogen and aldehyde being at the same time evolved. By adding water gradually to the alcoholic solution,  $\alpha$ -azonaphthalene separates out as a brown flocculent precipitate, which may be purified by recrystallisation from alcohol.

Azonaphthalene obtained thus melts at 190°, and dissolves in the ordinary solvents with characteristic colours.—J. B. C.

*Colouring Matters from Phenols.* H. Brunner and W. Robert. Ber. 18, 373.

IN the preparation of nitrosoresorcin and nitrosoresin by the action of amylnitrite on the sodium salts of the respective phenols, and precipitation with sulphuric acid, the authors observed that from the washings a new substance separated out on standing. This was dissolved in ammonia, and by the addition of hydrochloric acid a reddish-brown precipitate formed, part of which dissolved in ether. The portion soluble in ether dissolves in alkalis with a violet colour and brown fluorescence, and has the formula  $\text{C}_{10}\text{H}_7\text{NO}_2$ . According to the authors these compounds are produced by the union of one molecule of the nitrosophenol with two molecules of the phenol, the oxygen of the nitroso group uniting with two hydrogens of the hydroxyl groups to form water as follows:—

The portion insoluble in ether is likewise a colouring matter dissolving in alkalis, and concentrated  $\text{H}_2\text{SO}_4$  with a violet or blue colour. This compound has not been fully investigated, and will form the subject of further research.—J. B. C.

*Methylene Blue and Related Colouring Matters.* August Bernthsen. Ber. 17, 2554.

THE author has proposed the following constitutional formulae for Lauth's violet and methylene blue (*Berl. Ber.* 17, 611; 16, 1025 and 2596):—

IN support of this view the author draws attention to the analogous formation of these colouring matters, and those of the rosaniline group from the leuco-bases, and to their monovalent character. If the above formulae are correct, it might be inferred that by the introduction of two amido groups into methyl-thio-diphenylamine—

a diamido-compound—

would be formed, and not a colouring matter analogous to Lauth's violet, and this is in fact the case. By the action of fuming nitric acid the methyl-thio diphenylamine is converted into a dinitro-methyl-diphenylamine sulphoxide—

which differs from the homologous dinitro-diphenylamine sulphoxide,  $\text{NH}(\text{C}_2\text{H}_5)(\text{NO}_2)_2\text{SO}$ , in being insoluble in dilute alkalis. The nitro-compound is reduced by stannous chloride and hydrochloric acid, and the resulting amido-compound is insoluble in hydrochloric acid, but dissolves readily in water. The hydrochloride crystallises in colourless prisms. Ammonia liberates the base from the aqueous solution of its salt. It is readily oxidised. Ferric chloride colours the solution of the hydrochloride blue-green, and by addition of zinc chloride and common salt an extremely unstable crystalline compound is precipitated. This compound differs greatly from Lauth's

violet, which is very stable. Lauth's violet may be prepared not only by conversion of thio-diphenylamine into the amido compound, but also by introduction of sulphur into para-amido-diphenylamine, by simply heating the two substances together, thus:—

It has also been prepared qualitatively by heating para-nitroaniline with sulphur.—S. Y.

*Methylene Blue and Related Colouring Matters.* August Bernthsen. Ber. Berl. 17, 2857.

THE author has shown (Berl. Ber. 17, 611) that by the action of fuming nitric acid on thio-diphenylamine  $\alpha$ - and  $\beta$ -dinitro-diphenylamine sulphoxides are formed, and that these substances, by reduction and subsequent oxidation, yield Lauth's violet and an isomeric colouring matter. The author has prepared a new colouring matter by introducing only one nitro group into thio-diphenylamine. When a weaker nitric acid is employed, besides the two dinitro bodies, a mononitro compound

is formed. The leuco compounds were obtained by the action of stannous chloride and hydrochloric acid, and after the removal of the tin, by means of zinc, a compound separated out, which gave a deep violet red colour with ferric chloride, while the isomeric diamido-compounds remained in solution. The base was set free by an alkali, and was found to have the composition

It forms glittering white needles, which are soluble in alcohol and ether, and though readily oxidised, it is more stable than Lauth's white (diamido-thiodiphenylamine). The hydrochloride, which crystallises in small white or grey scales, was analysed. On addition of ferric chloride to its acid solution, a violet-red colouring matter is formed, which must have the constitution

and which may be called imido-thiodiphenylimide. It may be precipitated by addition of water to its alcoholic solution in rust-coloured crystals, which are readily decomposed. It is reduced by ammonium sulphide, forming a leuco-base. The hydrochloride is best obtained by passing hydrochloric acid gas into an ethereal solution of the base. It forms a well-crystallised double salt with zinc-chloride, the composition of which is

The salts of imido-thiodiphenylimide colour silk a violet-red with a brownish tint. They have little value as colouring matters. The same substance may be prepared by the introduction of sulphur into the para-amidodiphenylamine obtained from Orange IV.,

by the action of ammonium sulphide. When heated with sulphur, the following reaction takes place—

The identity of the two bodies and their leuco compounds was proved by a comparison of their properties. The above-mentioned method of formation of amidodiphenylamine shows that the amido and imido group stand in the para position with regard to each other.—S. Y.

*Methylene Blue and Related Colouring Matters.* August Bernthsen. Ber. 17, 2860.

COLOURING matters are produced by the introduction of amido groups into thiodiphenylamine, and subsequent removal of two hydrogen atoms. The author and A. Simon have succeeded in preparing similar colouring matters by introducing hydroxyl groups. It was not considered probable that hydroxyl groups could be introduced into thiodiphenylamine, and therefore hydroxydiphenylamine was heated with sulphur, so as to form the thio compound. Paraoxydiphenylamine

was prepared by Calu's method (Berl. Ber. 16, 2786; 17, 2431) from hydro-quinone, aniline, and zinc chloride, and the crystals were melted with sulphur, when the following reaction took place:

The fused mass containing hydroxythiodiphenylamine was powdered, extracted with hydrochloric acid, and the residue dissolved in alcohol and a little hydrochloric acid, and treated with ferric chloride, when a brown precipitate of oxythiodiphenylimide was produced. The substance was purified and analysed. It dissolves easily in aniline, and crystallises from its solution in this substance in dark microscopic needles. Its method of formation, together with the fact that it possesses neither acid nor basic properties, shows that its constitution is

It is analogous to the amido-compounds, and is a colouring matter.

Reducing agents convert oxythiodiphenylimide into the hydroxy compound, which has the properties of a phenol, and is taken up by alkalis from its ethereal solution. It is oxidised on exposure to air, and is reconverted into oxythiodiphenylimide. The alkaline solution resembles that of indigo, in its liability to oxidation, and in its colouring properties, but the scum which forms on the surface has a red-brown colour. The composition of the leuco compound  $\text{C}_{12}\text{H}_9\text{NSO}$  was confirmed by analysis.—S. Y.

*Note on Flavaniline.* O. Fischer and E. Täuber. Ber. 17, 2925.

EXPERIMENTS on the oxidation of flavanol, obtained from flavaniline, show that the latter substance belongs to a new class of quinoline colouring matters. By oxidation of flavanol a lepidine carboxylic acid is formed, and this on further oxidation yields a picoline tricarboxylic acid. The authors now find that the final oxidation product of flavanol is a pyridine tetracarboxylic acid, identical with that described by R. Michael (Ann. Chem. Pharm. 225, 142). Picolinetricarboxylic acid was prepared by treating nine molecules of potassium permanganate with one of flavanol. The oxidation of 30 grm. of flavanol was completed in about three days. Oxalic acid was found to be present in considerable quantity. The acid melts at 230-232°, decomposes rapidly at 236°, and begins to darken at 190°. A dilute aqueous solution of the acid gives a brown-red colouration with ferrous sulphate, a very dilute solution a gold-yellow colour. Calcium chloride gives a white precipitate, insoluble in hot water, with a concentrated solution of the ammonium salt. With a very dilute solution, however, no precipitate is formed. The acid thus resembles malonic acid. Barium chloride gives a similar precipitate; copper acetate and sulphate produce no precipitates. This picoline tricarboxylic acid is identical with that prepared by Michael from collidimonomonocarboxylic acid, for on oxidation they both yield the same pyridine tetracarboxylic acid. This acid was prepared directly from flavanol, by treating one molecule

dissolved in dilute caustic soda with eleven molecules of permanganate. The reaction was completed by heating the mixture on the water-bath for a day. The solution was filtered, neutralised with dilute nitric acid, treated with lead nitrate and the lead salt decomposed by sulphuretted hydrogen. Oxalic acid was removed by means of calcium chloride. The pure acid was prepared from the little soluble copper salt. After removal of water at 115° the composition of the acid was found to be  $C_6H_2NO_5$ . The acid dried at 100°, melts at 187°, the anhydrous acid at 227°, with decomposition. Michael gives the melting-point 188°. The aqueous solution of the acid gives a slight precipitate with calcium chloride, a heavy white precipitate with barium chloride, an intense cherry-red colour with ferrous sulphate, a dirty white precipitate with ferric chloride, and a green precipitate with copper salts, insoluble in hot acetic acid. The silver and barium salts were analysed. The latter contains one molecule of water, which it retains at 170°. These reactions show that the picoline tricarboxylic acid and the pyridine tetracarboxylic acid are identical with those prepared by Michael; and the constitution of the substances described must be represented by the formulæ:

—S. Y.

On  $\beta$ -Amido-alizarin. Heinrich Brunner and Ernest Chuard. Ber. 18, 445.

IF in the method of preparing alizarin blue another polyatomic alcohol (erythrite, mannite, glucose or saccharose), be substituted for the glycerine, an analogue of alizarin blue is not produced, but instead the nitro-alizarin is reduced to  $\beta$ -amido-alizarin. For instance, if a mixture of nitro-alizarin (1 part) and erythrite (5 parts) is heated to 100° C. with 10 parts of  $H_2SO_4$ , and the melt poured into water, a precipitate is produced, which, after recrystallising from alcohol, forms the glistening red prisms of  $\beta$ -amido-alizarin. It dissolved in caustic alkalis with a blue colour; and dyed red with alumina mordants, and greyish violet with iron mordants. The yield is small.  $\beta$ -amido-alizarin (mixed possibly with some alizarin blue) is also formed by the action of  $H_2SO_4$  on a mixture of nitro-alizarin and allyl alcohol.

—A. G. G.

On Compounds of Nitrosanaphthols and Nitrosanaphthol-sulphonic Acids, with Iron and Cobalt. O. Hoffmann. Ber. 18, 46.

SEVERAL nitrosanaphtholsulphonic acids—e.g., that obtained from Schaeffer's  $\beta$ -naphtholmonosulphonic acid, etc.—yield, with iron and cobalt salts, green or brown-red dye-stuffs, which are the subject of a patent taken out by Messrs. Gans and Co., Frankfurt-on-the-Maine. The metals in these compounds cannot be precipitated by alkalis or their carbonates. A determination of the iron in the green dye from nitroso- $\alpha$ -naphtholsulphonic acid, showed it to contain 7.9 per cent. Fe.  $\beta$ -nitroso- $\alpha$ -naphthol and  $\alpha$ -nitroso- $\beta$ -naphthol show a similar behaviour with iron and cobalt salts; but

their precipitates are not applicable for dyeing. Only ortho-nitroso-naphthols give precipitates with iron and cobalt; and it therefore seems probable that the ortho position of the nitroso and hydroxyl group is necessary for the reaction.—S. H.

On Pseudocumidine. S. Haller. Ber. 18, 89-94.

A. W. HOFMANN, and recently Liebermann and Kostanecki, have shown that commercial crystallised cumidine, prepared on the large scale from dimethyl-xylidine, is identical with Schaper's pseudocumidine, derived from pseudocumene. The author has again investigated this question from other points of view, and has arrived at the same conclusions as the former investigators. In order to obtain the hydrocarbon, diazo-cumidine sulphate was treated with alcohol; but the reaction, as Hofmann and Wroblewski have recently shown, does not proceed in the usual manner, but yields the ether of pseudocumol. However, by treating pseudocumylhydrazine

with copper sulphate—a new reaction, suggested by Baeyer—the hydrocarbon can be easily prepared. The hydrazine was produced by converting pseudocumidine into the diazo compound

reducing it with zinc-dust to

and treating the latter with dilute hydrochloric acid. For the purpose of converting pseudocumylhydrazine into the hydrocarbon pseudocumene, the former is boiled with water, while a copper sulphate solution is gradually added until the liquor has a permanent greenish-blue colour. The reaction probably proceeds thus:—

The free hydrocarbon showed all the characteristic properties of that detected by Beilstein and Kögler in coal-tar, or prepared synthetically from bromised xylois by Fittig, Jannasch, Ernst, and Laubinger. In order to determine the position of the amido-group in pseudocumidine, the cyanide of the hydrocarbon  $C_6H_3(CH_3)_2CN$  was prepared by treating a solution of diazopseudocumenechloride with copper sulphate and potassium iodide. After saponifying it with an alcoholic potash solution, the acid formed, durylic acid,  $C_6H_3(CH_3)_2COOH$  was liberated by adding sulphuric acid and distilling with steam. The durylic acid thus obtained is identical with that prepared by Jannasch, from pseudocumene; and whereas on the one hand there can be no further doubt that commercial cumidine is identical with Schaper's pseudocumidine, we obtain on the other hand a new argument for the presumption that the position of the substituents  $NH_2:CH_3:CH_3:CH_3$  is 1:2:4:5, as Schaper has shown for his amido-compound.—S. H.

Derivates of the Two Isomeric  $\alpha$ - and  $\beta$ -Naphthol-azobenzenes. L. Margary. Gazz. Chim. 14, 271.

Two isomeric monobromo derivatives are formed by the direct action of bromine on an acetic acid solution of  $\alpha$ -naphtholazobenzene. They are analogous to those obtained from  $\beta$ -naphtholazobenzene, and correspond to the two isomeric  $\alpha$ -naphthol-azobenzenes described by Typke. They melt at 185 and 195-196° respectively, and do not resemble the brom derivatives of  $\beta$ -naphthol-azobenzene in their solubilities. By reduction with tin and hydrochloric acid parabrom aniline and  $\alpha$ -naphthol were obtained.—S. R.

Improvements in the Manufacture of Colouring Matters. Gerard Wenzeslaus von Nawrocki, Berlin. From Paul Böttger, of Lodz, Russia. Eng. Pat. 4415, March 5, 1884.

This invention claims the series of colouring matters produced by combining tetrazodiphenyl with  $\alpha$ - and  $\beta$ -

naphthylamines and their sulphonic acids. The first compounds which have the formula

are insoluble in water, but soluble in alcohol, and are made soluble by conversion into their sulphonic acids, or the naphthylamines can be first sulphonated, and then combined with the tetrazo-salt in the usual way. The colours are of various shades of red, and are especially useful for cotton dyeing.—R. M.

*Improvements in the Preparation of Purple, Blue, and Green Colouring Matters suitable for Dyeing and Printing, from Halogen-Derivatives of Tetramethyldiamidobenzophenone and Analogous Ketone Bases.* John Henry Johnson, London. From Dr. H. Caro, Ludwigshafen, Germany. Eng. Pat. 5038, March 18, 1884.

THE colouring matters described are all triphenylmethane derivatives or allied bodies, and the haloalketone derivatives are prepared in the manner described in a previous specification (Eng. Pat. 4850, 1884). In order to bring about condensation between these ketone halogen derivatives and aromatic bases it is not necessary to isolate the haloalketone derivatives in the first instance, but the two operations can be carried on at once by mixing the ketone base, the deoxidising and halogenising agents and the aromatic base. The five following examples illustrate the application of the process to the production of purple colouring matters:—(1) Tetramethyldiamidobenzophenone (10 parts) is mixed with twice its weight of dimethylaniline, and heated to 100° C., and when cool mixed with six parts of  $\text{PCl}_5$ . The halogenising action first occurs, and then condensation takes place with the dimethylaniline producing "methyl purple," the salts of which are crystalline. (2) Oxylchloride of phosphorus is employed, and the order of mixture reversed, 25 parts of dimethylaniline being mixed with 10 parts of the oxylchloride, and then 10 parts of dry powdered tetramethyldiamidobenzophenone gradually added, the whole mixture being finally heated to 90–100° C. By employing carbon oxylchloride as the halogenising agent, a complete synthesis of "methyl purple" can be effected in a combined series of operations from tertiary alkalis derivatives of aniline and its homologues. Bluer shades of purple are obtained by using tetraethyl instead of the tetramethyl ketone. (3) The tetraethylamido ketone is in this process condensed with dibenzylaniline by means of phosphorus oxylchloride, the final product being "benzyl violet." (4) A phenylated "methyl purple" is produced by condensing the tetramethylated ketone with diphenylamine by means of phosphorus trichloride, toluol being used as a solvent. The salts of this colour, and of the corresponding compound from methylphenylamine, are soluble in hot water. (5) Purple colouring matters are also obtained by condensing the tetramethyl ketone with dimethylanisidine (ortho) or tetramethylmetaphenylenediamine. Blue colouring matters of the same series are obtained by condensing the haloalketone base with tertiary alkylised derivatives of  $\alpha$ -naphthylamine, such as dimethyl- $\alpha$ -naphthylamine, which gives a purplish blue, or phenyl- $\alpha$ -naphthylamine, which gives a bright, pure blue. In a similar manner green colouring matters are produced by the condensation of the haloalketone derivatives of the ketone base, with quinoline. Tetramethyldiamidobenzophenone gives a yellowish shade of "quinoline green" than the tetramethyl derivative.—R. M.

*Improvements in the Manufacture of Yellow Colouring Matters.* Fritz Machenhauer, Reddish, near Manchester. Eng. Pat. 5458, March 26, 1885.

THESE colouring matters are prepared from triphenylated derivatives of rosaniline; more especially the blue produced by the action of aniline upon aurine known as "azuline." Two methods are given for converting "azuline" into the desired yellow dyestuff:—(1) The

glacial acetic acid solution of the blue is acted upon by nitric or nitrous acid. (2) The sulphonic acid of "azuline" is acted upon by nitric or nitrous acid.—R. M.

*Improvements in the Preparation of Yellow Colouring Matters suitable for Dyeing and Printing from Tetramethyldiamidobenzophenone and Analogous Ketone Bases, or their Halogen Derivatives.* John Henry Johnson, Lincoln's Inn Fields, London. From Dr. H. Caro, Ludwigshafen, Germany. Eng. Pat. 5512, March 26, 1884.

THESE colouring matters, for which the inventor proposes the name of "auramines," are produced directly by the action of ammonia upon the CO group of tetramethyldiamidobenzophenone, or indirectly by the action of ammonia upon the halogen derivatives of the ketone bases. For the carrying out of the direct method, a salt of ammonia must be employed, and heat is necessary to bring about the reaction. Thus, 10 parts of dry, finely powdered tetramethyldiamidobenzophenone, 10 parts of sal ammoniac, and 10 parts of dry zinc chloride, are mixed and heated in an enamelled iron pan in an oil-bath to about 200° C (outside temperature) for 5–6 hours, till a sample of the melt dissolves completely in hot water. The hydrochloride of the colouring matter, after purification, is crystalline. The indirect method, which is the less advantageous, is carried out by chlorinating the tetramethyl ketone in nitrobenzene solution, by means of oxylchloride of phosphorus, and then acting upon the product with ammonia of 0.95 sp. gr. The auramines are all basic dyes, the free bases being colourless, and the salts yellow without any fluorescence in solution. These compounds are decomposed by boiling with strong acids, or with water, ammonia and the original ketone base being regenerated.—R. M.

*Improvements in the Preparation of Yellow, Orange, and Orange-Brown Colouring Matters, suitable for Dyeing and Printing from Tetramethyldiamidobenzophenone and Analogous Ketone Bases, or their Halogen Derivatives.* John Henry Johnson, London. From Dr. H. Caro, Ludwigshafen, Germany. Eng. Pat. 5741, March 31,

THE colouring matters referred to are substitution derivatives of the "auramines" referred to in the previous specification. Three processes are given for their preparation:—(1) The auramines produced by the methods described in the former patent are heated with primary amines in precisely the same manner as when rosaniline is phenylated by the action of aniline. In this way phenyl, tolyl, xylyl, naphthyl, etc., auramines are produced. (2) Primary amines or their secondary methyl, ethyl, etc., derivatives are made to react upon the haloalketone derivatives of the ketone bases. (3) This method, which is the most direct and economical, depends upon the action of aromatic amines upon the CO group of the tetra-alkylised ketone base. The invention is confined to aniline and its homologues, naphthylamine, chloraniline, meta and paraphenylene diamine, etc. These amines must be employed in the form of salts and heat is applied, the yield of colouring matter being greatest in the presence of zinc chloride. Phenyl-auramine, which may be regarded as a type of this class of colouring matters, is a bright orange-red powder, soluble in water, and decomposed by heating with acids into aniline and tetramethyldiamidobenzophenone. It produces orange shades upon wool or mordanted cotton. The corresponding colours from the diamines mentioned, and from the naphthylamines, give various shades of orange-brown.—R. M.

*Process for the Separation of the Azo-Colours which are prepared from Diazotized  $\beta$ -Naphthylamine-monosulphonic acids by Combination with  $\alpha$ -Naphthol-monosulphonic Acids.* Dahl and Co., of Barmen. Ger. Pat. 30,640, May 20, 1884.

WHEN a solution of an azo-dye is prepared by the action of the diazotized difficultly soluble  $\beta$ -naphthylamine-

monosulphonic acids on the  $\alpha$ -naphthol-monosulphonic acids, which correspond to the naphthionic and naphthalidamic acids, an  $\alpha$ -azo dye separates out either directly or on addition of a little salt. This  $\alpha$ -azo dye is derived from the  $\beta$ -naphthylamine monosulphonic acids marked I. and II., and already referred to in Ger. Pat. 29,084. In the filtrate the dye of the III. or new  $\beta$ -naphthylamine-monosulphonic acid, remains in solution, and can be separated by salting out.—W. S.

*An Improved Method of Preparing Alizarin and other Anthracene Colouring Substances.* William Edward Gedge, London. From Gustav Jagenburg, Sweden, and Dr. C. Leverkus and Sons, Leverkusen, Germany. Eng. Pat. 15,456, November 24, 1884.

THE object of the present invention "is to obviate the expensive and troublesome oil impregnation," the colouring matters being rubbed in the dry state with oils or fat so as to prepare them for printing.—R. M.

## V.—TEXTILES: COTTON, WOOL, SILK, Etc.

*Improvements in the Treatment of Vegetable and other Tissues or Fibres for the Purpose of Preserving or Waterproofing the same.* Arthur William Lovell Reddie. A Communication from Messieurs Dillies & Co. Eng. Pat. 5317, March 22, 1884.

THE process of preserving does not present any novel feature, as it simply consists in soaking the article in a solution of tannic acid derived from gall-nuts, sumach, etc. To render tissues waterproof as well as imperishable they are, after being first treated as above, placed in a bath of the following composition until thoroughly saturated:—

Linseed oil .....	500 Litres.
Birchbark distilled oil .....	20 to 25
Yellow litharge (litharge jaune) ..	1 to 2 Kilos.
White lead .....	1 to 2 "
Talc .....	1 to 2 "

In certain cases 1 to 4 kilos. sulphate of iron may be added. These constituents are well mixed and boiled until everything is completely dissolved. The bath is then allowed to cool down to 200° F., and 10 to 20 kilos. of animal or mineral wax added.—E. J. B.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

*Vat Appliance for Dyeing Fabrics in an Unstretched Condition.* Diagl. Polyt. Journ. 1884, 254, 207.

AN apparatus by means of which the cloth may be passed through the dye-bath in an unstretched state, so

(Ger. Pat. 27,560, Nov. 25, 1883). A mould-shaped conducting channel formed by the two half round perforated sheets *b* and *c* and two movable side walls *n* (the distance between which can be adjusted by means of the screw spindles *s* to suit the width of the cloth to be dyed) is suspended in the vat *K*. The cloth is in front of the rollers *d* attached to an endless web which continually remains in the apparatus, and after passing through the rollers *c* is folded by the attachment *l m*. It is then being conducted through the dye-bath in a folded condition. The whole apparatus rests on the rim of the dye-heck and is easily removable. The gearing is fixed to the latter, and is by means of a coupling connected with the driving shaft situated above the rollers *d*.—F. M.

*Preparation or Compound to be employed in the Finishing or Surfacing of Printing Rollers and Blocks, and other Articles.* A. Barrett, London. Eng. Pat. 4153, February 29, 1884.

THE emery wheels and lumps of pumice stone, which have hitherto been employed for this purpose, leave the surfaces with burrs, and less smooth and even than is desirable. The inventor employs pumice stone, broken into small pieces or powdered, and mixed with a sufficient quantity of plaster of Paris to agglomerate it into a solid mass, capable of being moulded into any required shape. The plaster of Paris may be replaced by other materials, provided that they are not harsh or gritty.—E. G. C.

*Machinery, etc., for Bleaching, Dyeing, Sizing, or Washing Hanks of Yarn.* Peter Thomas, Manchester. Eng. Pat. 6043, April 7, 1884.

THE vats in which the various operations are to be performed are arranged side by side in a row. Rails are laid on each side of the series of vats, on which a carriage runs, and may be stopped at any required vat. This carriage supports a framework by means of shafts at the top of the carriage, provided with pulleys and ropes. These ropes are at one end connected with the framework and counterpoised at the other end, so that the frame may be lowered into and raised out of such vat as the carriage may be over. Removable cross-bars, which two by two are arranged to take a number of hanks, are carried on each end respectively by two longitudinal bars, and these latter are suspended from two shafts, forming a part of the framework, by means of levers working on eccentrics and fixed on the shafts. The eccentric motion imparts a reciprocating motion to the longitudinal bars, thus causing the cross-bars to change their respective position continually from a higher to a lower level, and so the yarn is kept in constant agitation in the liquor. The various parts are suitably connected, so that the carriage may be run to any required vat, the framework lowered, and the eccentric

that the liquor can freely circulate around it, and which conducts the cloth through the vat in an even and uniform manner, leaving it at the same time exposed to view where it enters and leaves the former, has been patented by F. Braun, of Vogelsmühle, near Lennep

motion being brought into action the hanks on the cross-bars are agitated in the liquor contained in the vat. When the operation is over, the framework is raised and the carriage run to such other of the vats as is next required. (Drawings given).—W. E. K.

*Dyeing Garments, etc.* Joseph P. Delahanty, Pittston, Pennsylvania, U.S.A. Eng. Pat. 11,231, August, 13, 1884.

A LARGE revolving octagonal reel or cage, the faces and ends composed of open slab work, is supported on its axis over the dye-vat. On the interior surface a series of pins project from the periphery towards the axis of the wheel, and a door is provided for the insertion and removal of the goods. The lower half of the cage only is immersed in the liquor, and, on the rotation of the reel, the goods are caught by the pins and carried forward, and are dropped again into the liquor when that part of the reel reaches its highest point. For removal of the goods a screen is inserted extending from the axis to the periphery of the reel, and by a revolution of the cage the goods are brought up on this to the surface. (Drawing given.)—W. E. K.

## VII.—ACIDS, ALKALIS, AND SALTS.

*On Pyrosulphates.* H. Schulze. Ber. 17, 2705.

THE author has prepared salts of pyrosulphuric acid by the action of sulphuric anhydride on sulphates at ordinary temperatures, a method similar to that adopted by R. Weber. The author in the present paper confirms the results so far attained by R. Weber, and adds some new observations of his own. In the first place he found that sulphuric anhydride acts readily upon potassium sulphate at ordinary temperatures, a fact about which chemical literature contains conflicting views. R. Weber employed a closed tube and a high temperature. The author, on the other hand, found that the dry sulphate absorbs sulphuric anhydride with a considerable evolution of heat. The experiments were made with rectified sulphuric anhydride and 20 to 50 grm. of finely powdered sulphate. The sodium, ammonium silver and thallium salts absorb the anhydride with even greater energy than potassium sulphate. In order to completely convert the sulphate into pyrosulphate, a higher temperature was necessary, the method employed being to soak the sulphate with the anhydride and distil off the excess at 100° to 120°. It is doubtful if Weber's octosulphates can be obtained by this method, as at the relatively high temperature employed for eliminating the excess of  $\text{SO}_3$ , the disulphate was invariably formed. Pure potassium pyrosulphate was prepared in this way. In the preparation of the sodium salt the product contained only 85 per cent. of pyrosulphate. The ammonium, like the potassium salt, can be obtained pure by the above method. Pure disulphate of silver and thallium are formed by simply mixing the sulphates with  $\text{SO}_3$ . In addition to these barium, strontium, calcium, magnesium, zinc and lead absorb sulphuric anhydride and form pyrosulphates. The purity of the product, however, varies, zinc and lead especially being only capable of taking up a comparatively small quantity of the anhydride. It is quite possible that Weber's method may give the pure compounds. The salts of magnesium and the alkaline earths gave, on analysis, results corresponding to the pure disulphates. The method of Berzelius for preparing pyrosulphates, that is, by heating the hydrosulphates, was next tried, but gave unsatisfactory results. A better method is to heat sulphates with chlorosulphuric acid. Schiff had previously prepared the potassium salt by this reaction—

Experiments showed that an excess of chlorosulphuric acid is necessary, and this is afterwards distilled off. In this way the sodium ammonium and barium salts are readily prepared.—J. B. C.

*Action of Ferric Oxide on Sulphates at a High Temperature.* Scheurer-Kestner. Compt. Rend. 99, 876, 877.

WHEN two parts of gypsum are heated to a bright redness with one part of ferric oxide, sulphuric anhydride is given off and a mixture of lime and ferric oxide is left from which the lime can afterwards be removed by acetic acid. Probably the mixture first fuses and forms

ferric sulphate, which is decomposed when a higher temperature is reached. By mixing 175 parts of gypsum with 100 parts of fluorspar and ferric oxide, the decomposition takes place at a lower temperature (that of a Bunsen burner), and the sulphuric anhydride formed is prevented from being dissociated into sulphurous acid and oxygen. Lead and magnesium sulphates behave in a similar way to calcium sulphate.—S. R.

*Action of Lead Hydrate and Silver Oxide on Aqueous Solutions of Sodium Pentasulphide and Sodium Dithionite.* A. Geuther. Annalen, 226, 232-240.

AT ordinary temperatures lead hydrate reacts with the pentasulphide in the following way:—

Silver oxide reacts in an analogous way, but a secondary reaction, resulting in the formation of a definite quantity of sulphuric acid from the action of the silver oxide on the finely divided sulphur, also takes place. With sodium dithionite, the changes which take place are represented by the following series of equations:—

From these reactions the author considers that the name dithionite should be given to  $\text{Na}_2\text{S}_2\text{O}_3$ , as the name thiosulphate conveys the idea that the oxygen has been replaced by sulphur.—S. R.

*Preparation of Hydrochloric Acid free from Arsenic.* H. Beckurts. Arch. Pharm. 22, 684.

COMMERCIAL hydrochloric acid said to be free from arsenic contains generally distinct traces, and cannot therefore be used in judicial chemical cases. The acid, however, can be easily purified by distillation with ferrous chloride, all the arsenic coming over in the first portion of the distillate and more readily if the acid is concentrated. A solution of ferrous chloride is added to a 30 to 40 per cent. acid, the first 30 per cent. of the distillate contains arsenic and the remaining 60 per cent. is collected separately, and is quite pure. In this way a 20 to 30 per cent. acid is obtained. This method can be used technically for preparing hydrochloric acid free from arsenic. Further, arsenic can be detected when present in small quantities, by distilling with ferrous chloride and testing the first portion of the distillate.—J. B. C.

*Improvements in the Treatment of Sulphate of Ammonia, for obtaining the Ammonia in the Free State and utilising the Sulphuric Acid.* E. Carey, H. Gaskell, jun., and F. Hurter. Eng. Pat. 2118, Jan. 25, 1884.

THE object of this invention is accomplished by mixing intimately sulphate of ammonia and sulphate of soda, in equivalent quantities, and heating the mixture to the point of fusion. Super-heated steam is then introduced into the fused mass. At about 500° F. a decomposition begins, by which free ammonia and hydrogen sodium sulphate (bisulphate of soda) are produced. To hasten the reaction the temperature is gradually raised to from 700° to 800° F. The operation of heating is best carried on in a revolving cast-iron cylinder, heated outside by an open fire. The steam is admitted through a hollow agitator shaft, which rotates in the cylinder, the steam assisting the agitation at the same time. The ammonia set free by this treatment passes away from the cylinder, together with the steam, through an aperture in the cylinder, and is conveyed by pipes into condensers. The steam hastens the reaction by removing the ammonia from the charge as soon as liberated. If steam be admitted before the fusion of the mixed salts, too much sulphate is volatilised as such. The volatilised sulphate is absorbed in water and used over again. By the introduction of the steam into the fused mass, the formation of pyrosulphate is avoided. The pyrosulphate of soda decomposes ammonia producing nitrogen, consequently

causing loss of ammonia. The bisulphate of soda produced in this process is proposed to be used for the decomposition of common salt, and for the production of hydrochloric acid.—C. C.

*Improvements in and appertaining to the Manufacture of Sodium Bicarbonate.* L. Mond and G. Jarman. Eng. Pat. 2996, February 9, 1884.

DESCRIBES a method for converting the sludgy precipitate of bicarbonate of soda, obtained by the ammonia-soda process, into a more granular material, to facilitate the removal from it of ammonia and other impurities. For this purpose the crude salt is dissolved in warm water of about 60° C. and the solution allowed to cool, pure bicarbonate separates and all the ammonia remains in solution. The operation of cooling the solution of bicarbonate is varied, in the well-known manner, according to the size of grain desired to be obtained for the crystals. The mother-liquor is separated from the crystals by centrifugal machines. The solution of the crude bicarbonate of soda is best effected under pressure in an atmosphere of carbonic acid. A higher temperature may be employed in this case without decomposing the bicarbonate, but the solution requires to be cooled down to 65° C. before being run off. The mother-liquors may be used several times for washing and dissolving fresh crude salt.—C. C.

*Improvements in and Relating to the Manufacture of Salt from Brine.* G. S. Hazlehurst. Eng. Pat. 3015, February 9, 1884.

ACCORDING to this specification common salt is precipitated from brine by the addition thereto of chloride of calcium or of any other innocuous salt more soluble than common salt. If the solution of precipitant be hot and strong, salt of a fine grain is precipitated from the brine, if cold and of only slightly higher specific gravity than the brine, salt of a coarser grain is obtained. The salt is freed from the precipitant by washing. The liquid is reconcentrated and used over again for the same purpose.—C. C.

*Improvements in the Treatment of Sulphurous Oxide in the Manufacture of Sulphurous Acid (H<sub>2</sub>SO<sub>3</sub>), Sulphites or Bisulphites.* H. E. Scholefield. Eng. Pat. 3059, February 11, 1884.

CONSISTS in the application of an injecting apparatus for drawing off the sulphurous anhydride from sulphur burners or pyrites burners, and forcing it through coolers, and through scrubbers and washers (to remove arsenic and other impurities), into the absorbing apparatus. The injector may be worked by steam, air, or some other gas. The SO<sub>2</sub>, after being cooled and after the condensation of the steam accompanying it, passes into the absorbing vessels, in which it is taken up by water to which lime or other alkaline oxide, or hydrate, has been added. For the absorbing vessel a high column may be used and the basic material fed in at the top, and extracted at the bottom fully sulphited. If sulphites are wanted no water is used, but the gas is passed through shallow layers of the alkali or alkaline earth.—C. C.

*Improvements in the Manufacture of Bichromate of Soda.* W. J. Chrystal. Eng. Pat. 4028, February 27, 1884.

FOR the purpose of manufacturing bichromate of soda free from other salts of soda, the inventor evaporates the solution, which is obtained by adding to the solution of neutral chromate of soda the necessary quantity of sulphuric, muriatic, carbonic, nitric, acetic, or other acid, until the respective salts of sodium—viz., sulphate, nitrate, chloride, carbonate, etc.—are salted out and eliminated. The solution then contains only bichromate of soda, which crystallises out on cooling. The composition of the crystals is represented by the formula—

By evaporating the solution of bichromate beyond the point at which the other soda salts are eliminated,

crystals containing less water may be obtained. By evaporation to dryness and subsequent fusion, bichromate of great purity is obtained.—C. C.

*Improvements in the Manufacture of Bichromate of Soda.* C. S. Gorman. Eng. Pat. 4198, March 1, 1884.

250 PARTS by weight of chrome iron ore, 80 parts of chloride of sodium, 100 parts of sulphate of soda, and 250 parts of hydrated lime are placed in a furnace and subjected to the action of steam superheated to from 1000° to 1600° F. The hydrochloric and sulphurous acids evolved are conveyed to condensers. The finished charge in the furnace is treated in the usual manner. To the chromate of soda solution sulphuric acid is added to convert the same into bichromate of soda. The solution is then placed in coolers, chloride of sodium and sulphate of soda separate out on cooling. After this the solution is evaporated, the evaporation being completed by blowing air heated to from 400° to 700° F. into the liquid.—C. C.

*Improvements in the Manufacture of Bichromate of Soda.* C. S. Gorman. Eng. Pat. 4929, March 15, 1884.

IN this invention neutral chromate of soda is treated with hydrochloric acid gas. The neutral chromate of soda is converted thereby into bichromate, and the chloride of sodium formed at the same time is thrown down as insoluble and separated from the liquid, thus saving evaporation of the bichromate solution.—C. C.

*Improvements in the Manufacture of Cream of Tartar.* F. Wirth. Eng. Pat. 4362, March 4, 1884.

THE object of this invention is the production of cream of tartar direct from crude tartar or argol. The argol is dissolved in boiling water or mother-liquor, to which about 15 per cent. (of the weight of argol) of phosphoric acid is added. The solution is then decolourised with animal charcoal or the like, and cleared by the addition of pipeclay. To remove the small traces of iron, copper and other bodies remaining in the clear solution, a small amount prussiate of potash ( $\frac{1}{2}$  to 1%) is added, after which the solution is allowed to settle. The clear solution is then allowed to crystallise, and yields large, bright, colourless, almost chemically pure crystals. The mother-liquor is used for dissolving fresh quantities of argol, and the quantity of phosphoric acid which has disappeared from the same (by having formed precipitates of iron and alumina in the previous operation) has to be replenished.—C. C.

## VIII.—GLASS, POTTERY, AND EARTHENWARE.

*Machinery for and Method of Preparing Potters' and other Clays.* J. H. Key, Newton Abbot. Eng. Pat. 2538, February 1, 1884.

THE various kinds of clay to be operated upon are first dried in the usual manner and then placed in the desired proportions in the different removable divisions of a wooden shoot, leading to a wooden box, furnished with corresponding removable divisions, and with a hinged bottom divided into two or more parts. This box or truck receives the clays, and is then drawn up an incline, by means of a rope or chain winding upon a drum, to the top of a machine for breaking up the clays. This is provided with an ordinary hopper, in the middle of which is a revolving vertical shaft carrying knives. The bottom of the truck falling, the clays drop through an opening near the top of the incline into the hopper, where they are mixed together and the lumps broken up. The clay broken by the knives falls on to a horizontal screen, made of perforated steel bars, parallel and very close to each other, on which it is crushed small by rollers attached to the vertical shaft and covered with rubber or other elastic material. When crushed sufficiently small, the clay is swept from the surface of the screen into a sifter by series of movable brushes and scrapers, also attached to the shaft and capable of being set to any

angle. The sifter consists of an upper and second sieve of wire-gauze, placed in an inclined position and shaken by cranks connected with a horizontal shaft. The finer particles of clay pass through both sieves and fall into a trough beneath, from whence they are conveyed by a revolving worm to the pugmill. The coarser particles, together with the coarse impurities, are caught by the upper or first sieve, and fall into a water tank, where the impurities separate to the bottom, and from which the clay and water are pumped into a "water-sifter." The water-sifter also receives the smaller particles of clay and impurities caught by the second sieve. Two or more sieves of wire-gauze and graduated fineness, working in water, in an inclined position, constitute the water-sifter, by means of which the coarser particles of clay are reduced to a fine state of division, and the remaining impurities finally separated. The "slop" clay is now raised by a pump or elevator to the revolving worm, along which it passes for a short distance, partially mixing with the dry powdered clay, and from thence to the pugmill.—E. G. C.

*Improvements in the Manufacture of Imitation Stained Glass for Decorative Purposes.* W. Cunliffe, Hornsey. Eng. Pat. 3080, March 18, 1884.

THE objects of this invention are to overcome the various defects in previously devised methods of imitating stained glass, and to produce a "permanent and perfect substitute" at a very small cost. The required designs are executed in colours or monochrome, upon thin unglazed tracing paper or some other suitable medium, which is then saturated with a solution of bichromate of potash, chrome alum, or other chromate, with a gelatinous solution, as of glue or gelatine, and with a solution of shellac, mastic, or other gum, in turpentine or spirits of wine. The tissue is then thoroughly dried and placed between two adjacent sheets of glass, which are firmly held in position and subjected to a "gentle and gradual heat until the proper point of cementation is reached." When cold they firmly adhere together and are free from all air-bubbles and drops of liquid between the glass and tissue. The finest transparent colours in tubes, such as carmine, ultramarine, Prussian blue, raw and burnt sienna, Van Dyke brown, etc., are preferred; but the aniline colours and others may also be used effectively.—E. G. C.

*Method of and Apparatus for Drying China, Clay, and similar Materials.* J. Lovering and J. Bell, St. Austell. Eng. Pat. 6252, April 10, 1884.

ACCORDING to this invention, a chamber is constructed of any desired length, width, and depth, and perfectly air-tight except at its top, which top forms the drying pan, and is composed of porous tiles or specially formed bricks, which are laid upon iron bars placed transversely over the air-chamber. The tiles are from 12-24 in. long, about 4 in. thick, and they vary in breadth as may be desirable; they are cemented or otherwise secured together. If bricks be used, they are about 1 ft. long, 24 in. wide, and 6 in. deep; their sides are vertical for about 2 in. down, and are then bevelled off, so that when two bricks are placed side by side there shall be a wedge-shaped space between them open to the air-chamber. The bricks are placed end to end on the bars, the ends being cemented or otherwise secured together; but the sides must be made to fit together accurately, no cement or other material being placed between them. Into the air-chamber so formed heated air is forced by any convenient means. It finds its way through the porous tiles or the crevices between the bricks, and through the wet clay placed on the pan to be dried, thereby driving off the moisture, and effectually and speedily drying the clay. If desired, cold air may be forced into the chamber and there heated. By the use of the apparatus described clay will be dried much more quickly than by the usual method and without any risk of burning.—E. G. C.

*Improvements in the Manufacture of Potters' Ware.* J. & J. F. Muddock. Eng. Pat. 5400, March 26, 1884. This invention consists in the manufacture of earthenware, china, and porcelain from plastic clay by means of plaster of Paris moulds incased in metal rings or cases, by pressure.—E. G. C.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, CEMENTS.

*Kilns and Ovens for Economically Burning Limestone, Bricks, and Pipes, etc.* H. Hargreaves, W. Beckett, and W. Chilf, Chester. Eng. Pat. 2368, Jan. 30, 1884.

THE exhaust heat from ordinary lime-kilns is applied and utilised by passing it through flues into an oven or kiln, in which limestone, bricks, and pipes of a very superior quality can be burnt without fuel of any description. The ordinary open kilns are covered with fireclay slabs placed in iron frames on wheels running upon iron rails placed on each side of the open mouth of the kilns. "This process does away with any possibility of nuisance from smoke or fumes arising from the process of burning limestone, etc.," and the application of the covers, flues, and chimney to the old kilns was found by the inventor to result in a saving of 20 per cent. in fuel, the new oven not requiring any fuel.—E. G. C.

*Manufacture of Bricks, Paving Blocks, and the like from Blast Furnace Slag or Scoria.* G. Patchett, J. Dixon and R. Teasdale, Durham and York. Eng. Pat. 3339, February 2, 1884.

THE kilns in which the bricks, etc., are annealed are constructed with converging or sloping bottoms, and are arranged side by side in a circle or part of a circle, so that all the kilns of the series are situated under the rim of a wheel carrying the moulds or boxes for moulding the molten material. The moulds are provided with a flange or lip overlapping the space between every two consecutive moulds or boxes, in order that waste of slag or scoria may be avoided as far as possible.—E. G. C.

*Improvements in the Manufacture of Bricks from Wet Clay.* C. and W. Cooper, Great Crosby. Eng. Pat. 3737, February 22, 1884.

ACCORDING to this invention, a column of clay issuing from the mouth or die of a pugging mill is cut by suitably arranged wires into blocks for burning into bricks, the machinery by which this is effected being so constructed that the wires descend through the clay at the same time that the latter is forced horizontally through the range of wires. The clay is thus sawn through, as it were, instead of being cut or torn apart, and the surfaces produced are smooth and even.—E. G. C.

*Improvements in the Manufacture of Artificial Lithographic Stones.* F. Wirth, Frankfurt-on-the-Main. From Louis Rosenthal, Frankfurt-on-the-Main. Eng. Pat. 3508, February 23, 1884.

THE disadvantage attending the use of cement for the preparation of plaster, artificial stone, etc., has hitherto been the liability of the material to crack, in consequence of contraction produced by change of temperature. The admixture of sand with the cement has been found to answer for ordinary purposes, such as plastering walls or casting stone blocks, but not for polished surfaces or for imitation marble. This invention is claimed to offer the possibility of making artificial lithographic stones "equal in every respect to the natural ones, and in some respects superior, as they can be made to any required form." The process by which such a homogeneous cement-mass is to be produced is as follows: One half, or rather more, of the cement to be worked is made into a paste with water, and formed into thin plates, which are allowed to harden as quickly as possible, by the aid of heat if necessary. The hardness is increased by repeatedly moistening the plates with water and heating them until

they appear full of cracks in consequence of the sudden changes of temperature to which they have been subjected. These plates are then ground to a fine powder and thoroughly mixed with the remaining portion of fresh muscel cement. The mixture is transferred to a cast-iron mould of the desired shape, and therein exposed to a pressure of more than 20 atmospheres; the mould is divided into two compartments by a horizontal perforated plate covered with linen cloth. The quantity of water necessary to set the whole mass is now poured over it, and the air is exhausted beneath the perforated bottom by means of an air-pump or other convenient apparatus. In this way the water is sucked through the mass, all the air being removed and its place filled by the turbid fluid. Excess of water is eliminated, and the particles of the mass are caused to approach one another more closely by a second application of more than 20 atmospheres' pressure. Finally, a liquid containing in solution the alkaline and soluble constituents of cement, is prepared by agitating cement with 100 per cent. of water and pouring off the fluid containing the soluble portions. This liquid is forced through the solidified and hardened stone until "the most microscopic bubble holes are filled out by the soluble constituents contained in the water." The inventor states that repeated experiments have proved impressions taken from the artificial stone so prepared to be sharper than those taken from the natural Solenhofer stone. Such artificial lithographic stone requires no especial treatment with regard to applying colours or cast-ising, etc. The explanation of the effect of an admixture of already hardened cement with fresh muscel cement in preventing shrinkage, is not clear, but it would appear that, by the addition of the former to the latter, a compound is formed which possesses less shrinking qualities than the cement by itself. Finely ground carbonate of lime can be substituted for the already hardened cement.—E. G. C.

*Apparatus for Treating Clay to be used in the Manufacture of Bricks, Blocks, Tiles and Terra-Cotta.* T. H. Sharpe, Ruabon. Eng. Pat. 4249, March 3, 1884.

THE object of this invention is to beat, cut, pulverise and reduce clay, as dug from its bed or after preliminary treatment of any usual kind, to a finely divided and pulverulent condition suitable for being at once shaped into any desired article. This is effected by an apparatus constructed with a series of beater knives revolving past each other in opposite directions.—E. G. C.

*Improved Apparatus to be used in the Manufacture of Cement.* J. Watson, Greenhithe and Gateshead-on-Tyne. Eng. Pat. 4879, March 4, 1884.

THE object of this invention is to separate flint and other similar hard substances, liable to injure the grinding machinery, from the "slurry" as it passes to the grinding apparatus. This is effected by causing the slurry to flow at intervals through a trough provided with stops or gates, behind which hard or heavy particles are deposited. A trap or well may be constructed behind each stop or gate, furnished with a double slide arrangement, so that deposited matter may be received into the well, and allowed to escape from thence without interruption to the flow of the slurry. The deposition of flinty and other heavy particles can be facilitated by giving a vibratory movement to the trough or passage.—E. G. C.

*Improvements in the Manufacture of Cement.* F. Ransome, Lower Norwood. Eng. Pat. 6547, April 18, 1884.

IN a previous specification (No. 4664, 1878), the inventor recommended a method for the manufacture of cement by the calcination of slag sand with chalk or other calcareous matter. According to this invention the sand and chalk were to be ground, and then calcined together. The inventor now advises the admixture with the slag sand of lime in a caustic or hydrated condition; and for this purpose, spent lime which has been used in the purification of gas may be employed. Sulphur may be

removed from the gas lime by adding to the mixture of lime and slag sand a small quantity of coal or coke before calcination. A jet of steam is introduced into the furnace during the ignition. A revolving or rotating furnace is employed, and the mixture, admitted in a state of fine powder, is kept in motion in the furnace; it is thus discharged after calcination in the state of powder, and ready for use without further grinding.—E. G. C.

*An Improved Asbestos Compound especially applicable for Use as Boards or Sheathing for Roofings, Wearing Surfaces of Car Brakes, and for Building Purposes.* Complete Specification. David Hunter Brandon. From Daniel Austin Brown and Charles Francis Brigham. Eng. Pat. 7304, May 6, 1884.

To prepare the improved compound asbestos, preferably in a fibrous form, is incorporated with oxide of magnesium, and then mixed with chloride of magnesium or any chemical equivalent, and the mass moulded to any desired form. To render the compound lighter, and also to cheapen it, vegetable fibre may be added.—E. J. B.

## X.—METALLURGY, MINING, Etc.

*Purification of Zinc containing Arsenic.* Dingl. Polytech. Journ. 1884, 254, 400.

L'HOTE (*Revue Industrielle*) has tested a number of samples of sheet and block zinc, and found all of them to contain arsenic, the quantity varying in the case of sheet zinc from 10.5 to 36 milligrammes per kilo., and amounting only to traces in the case of block zinc. An efficacious and quick method of purification consists in adding to the melted zinc from 1 to 1.5 per cent. of anhydrous magnesium chloride, and stirring it well up with it. All the arsenic is given off in the form of trichloride, and by pouring the metal into water it is obtained in a granulated condition, and perfectly free from arsenic. Contrary to that obtained by purification through melting with potassium nitrate and subsequent distillation, it is readily soluble in sulphuric acid. The same method of purification may be applied to zinc containing antimony.—F. M.

*Carbon in Iron and Steel.* F. A. Abel. Proc. Inst. Mech. Eng. 4, 1885, 30-57; and Engineering, 35, 187, 188.

PRELIMINARY experiments were made to ascertain whether any characteristic differences could be established in structure or chemical condition between thin discs of steel cut from the same piece, but differing from each other in regard to the treatment to which they had afterwards been subjected. No light was thrown upon the mechanical structure of the different specimens by submitting them to the action of the solvent (a chromic acid solution), specially selected on account of its gradual action. Considerable differences were found to exist between the total amounts of carbon contained in different discs, from one and the same piece of steel, but in the hardened, tempered, and annealed states respectively. The proportion in the annealed steel was comparatively very low, and experiment showed that the reduction in the proportion of carbon, during annealing, was due to the prolonged exposure of the discs, 2.5 in. diameter, 0.01 in. thick, to heat in contact with, or in close proximity to, the wrought-iron plates between which they were confined. In a particular case the carbon was reduced from 1 per cent. to 0.1 by 24 hours, annealing between wrought-iron plates in a cast-iron box. The action of a chromic acid solution (cold saturated solution of potassium bichromate mixed with one-twentieth its volume of pure concentrated sulphuric acid) on the cold-rolled and annealed discs yielded, in different proportions, a black scaly or spangly substance, which was attracted by the magnet, and which was found to contain, in combination with the iron, an amount of carbon equal practically to the whole amount which had been found to exist in corresponding discs,

in the same cold-rolled and annealed condition. On the other hand, a disc of hardened steel, similarly treated, yielded only a small quantity of dark particles of similar appearance, in admixture with some lighter coloured sediment, and the carbon in this residue amounted only to about one-sixth of the total carbon in this steel. The proportion borne by the carbon to the iron in this particular residue, was found to be decidedly higher than in the spangly residues furnished by the annealed samples. Chromic acid solutions of different strengths were employed in the following experiments; an excess of the solution was always employed. In some cases the steel, about 7 grm., was supported on a perforated platinum tray in the upper portion of the liquid, but later perforated glass was substituted to avoid possible galvanic action. In the paper published, 1883 (*Engineering*, vol. 35), the author remarks:—On the whole these results appear to furnish some foundation for the belief that the material separated from cold-rolled steel by the action of a sufficiently dilute solution of chromic acid, contains an iron carbide approximating to the formula  $\text{Fe}_3\text{C}$ , or to a multiple of that formula. These results appear to confirm the view that the carbon in cold-rolled steel made by the cementation process exists, not as simply diffused mechanically through the mass of the steel, but in the form of an iron carbide—a definite product, capable of resisting the oxidising effect of an agent which exerts a rapid solvent action upon the iron through which this carbide is distributed. In the recent report (*Proc. Inst. Mech. Eng.*, above cited), it is stated that on examining a majority of the cold-rolled discs (series A, B, C and F) prepared from the same metal, it was found that variations, in some instances considerable, existed in the amount of total carbon in these. This circumstance much diminishes the value of the results furnished by these series of discs. It was suggested to anneal the discs when held between fire-clay blocks and packed in magnesia, instead of wrought-iron plates and soot, to avoid the decarbonising action shown to be caused by the plates; but no conclusive results were obtained by this method owing to the uncertainty as to the composition of the discs before annealing; further experiments in this direction are desirable. Reference is made to results obtained by F. C. G. Müller, who treated Bessemer steel in the cold with dilute sulphuric acid (one of acid to five of water). After 12 hours the black residue (found to be pyrophoric) was dried in coal-gas and found to contain from 6.01 to 7.38 per cent. of carbon, and Müller regards his “amorphous iron” as being probably  $\text{Fe}_3\text{C}$ . From the numbers given, 20 to 50 per cent. of the total carbon in the steel must have been converted into hydrocarbons. In the author's earlier experiments, with one kind of steel in one condition, when the steel was acted upon by a solution (potassium bichromate solution plus sulphuric acid) containing more than enough acid to dissolve its iron, together with combined oxygen, which was able to greatly diminish the formation of hydrogen, about 90 per cent. of the total carbon was left as insoluble carbide. The ratio of sulphuric acid to bichromate was kept constant, the proportion of bichromate in the solution being varied. Three experiments showed a good agreement both in amount and composition of the carbides left; the fourth showed that there was a limit to the stability of the carbides. In recent experiments the result of varying the ratio of the sulphuric acid to the bichromate was first tried; and then, for the remaining solutions, one uniform ratio (equal weights) between the sulphuric acid and bichromate was maintained. The steel operated on and its condition were also varied. The numbers obtained are put together in the accompanying table, and to a great extent explain themselves.

**Method of Experimenting.**—The weighed portion of steel (previously cleaned with emery, then with cold ether, and wiped) was dipped into the solution, stroked while moist with the finger, then placed on a glass sieve near the surface of the chromic solution contained in a capacious beaker. In the case of hardened steel much hydrogen was evolved. The solution was probably in all cases complete within 24 hours; the sieve was rinsed into the liquid, the latter stirred up, and allowed

to stand for another 24 hours. After decantation and slight washing, some fresh chromic solution was added and shaken occasionally for 24 hours at least. After decanting on to a filter and washing with water, alcohol and ether, the residue was dried over sulphuric in vacuo and weighed. A correction for the small amount sticking to the filter was made by estimating the iron in it. As the amount of sulphuric acid affects greatly the yield of carbide, it was desirable, in the later experiment, to avoid the presence of large quantities. The number given in the table under the head of “free sulphuric acid sufficient for dissolving grams iron,” was calculated from the following equations:—

The solutions are, however, able to dissolve more iron than this calculated amount. With the exception of one or two darker preparations, which proved to be partly decomposed, all the carbides obtained were grey-black heavy powders, not at all pyrophoric at ordinary temperatures. The unfused cemented (L) Danmemora steel contained: Total carbon, 0.941 per cent.; silicon, 0.006 per cent.; manganese, 0.009 per cent. After experiments 1-5, a second portion gave: Total carbon, 0.913 per cent. Digested with hydrochloric acid, a residue of carbon unconverted into hydrocarbon amounting to 0.018 per cent. was obtained. The products of experiments 2, 3, and 4 are obviously decomposed carbides. The number for “percentage of total carbon in the steel obtained as carbide” is too favourable; the actual carbide is better given by the percentage of iron in these insoluble products. Experiment 4 shows that diluting a solution containing an excessive quantity of sulphuric acid, causes less decomposition of the carbide, but does not give a much improved result in the total obtained. Experiment 6 shows that a large excess of the chromic solution compared with the steel taken can be used without detriment.

**Annealed and Hardened Steel.**—Eight pieces were cut off, four were annealed in fireclay blocks and magnesia, and four hardened between planed cast-iron plates. The annealed steel contained 1.015 per cent., the hardened 0.995 per cent. of total carbon. The agreement in the amount of carbide obtained in 7 (12.8 per cent.) with the 12.5 per cent. furnished by the much stronger (in chromic acid) solution of 9, is of importance in connection with the experiments with the tempered steel. The three small quantities of carbide from the hardened steel were strongly attracted by the magnet, but there was not enough for analysis. Experiments 13 and 14 were made with discs of series F already mentioned. The halves of three discs were taken for experiment, the other halves were used for estimation of total carbon. In the case of the annealed specimens this estimation was lost, and the mean of three discs previously examined (1.140) had to be taken. The hardened halves contained 1.093 per cent. carbon. The important numbers for carbon, water, and for carbon not converted into hydrocarbons, agree well with the numbers given by the other annealed steels.

**Tempered Steel.**—The halves of three discs were used for experiment 15, and the other three halves for carbon estimation; and similarly for 16. The straw contained 0.928 per cent., the blue 0.917 per cent. of total carbon. In the repeat experiments 17 and 18, less carbide was obtained than in 15 and 16, it is not easy to see why. A lower yield of carbide from blue than from straw-tempered steel was also not expected; the hotter blue discs may in some way have been chilled on removal from the tempering bath, considering the small weight and large surface of the discs. Experiments 19-24 were made with 24 discs of fused steel, each 0.01in. thick, and 2½ in. in diameter; they were cut from the same strip of steel. The halves of three discs were used for the estimation of total carbon, while the other halves were used for 22 and 23. “Straw, hot chamber 6 hours,” gave 1.148 per cent.; and “blue metal bath, 15 minutes,” gave 1.120 per cent. total carbon. The steel also contained 0.161 per cent. silicon, and 0.169 per cent. manganese.

Experiments 30 and 34 showed that the addition of water to the solutions did not affect the yield of carbide. The yield of carbide in experiment 22 was 2.52 per cent., which is inappreciable. The low number, 4.61 per cent., obtained in 24 may be set aside. Had these tempered steels behaved like annealed steel in leaving 90 per cent. of their total carbon as a carbide, containing 7 per cent. carbon, the yield of carbide would have been 14.5 per cent. The mean composition of the carbides obtained in the best experiments is given in the following statements, which include the mean of the three given in the report of January, 1883:—

	Water.	Carbon.	Iron.
Cold-rolled steel, mean of experiments 1 to 6 .....	0.93 %	6.92 %	92.77 %
Annealed steel, mean of experiments 7, 9 and 11 .....	1.32 %	7.01 %	91.89 %
Tempered steel, mean of experiments 25, 26, 27, and 28 .....	2.28 %	7.23 %	89.92 %
Cold-rolled steel, January, 1883, mean of preparations 1 to 3 .....	2.09 %	7.12 %	90.87 %

Probably the greater part of the water in the carbide is present as a constituent of a carbo-hydrate, which is a product of decomposition of the carbide, as this increase in the proportion of water is attended by an increase of carbon and a decrease of iron.

The specific gravity of some of the specimens of carbide, and of the steel from which they had been prepared, is as follows:—

#### CEMENTED (D) DANNEMORA STEEL.

Specific gravity at 60° F. (Water at 60° F.=1.000).

Steel cold-rolled, 7.75	Carbide from cold-rolled steel .....	6.9
Steel annealed, 7.76	Carbide from annealed steel (Ex. 9). 7.2	
Steel hardened, 7.61	(Ex. 11). 7.2	

In estimating the total carbon in the steels by means of copper chloride, it was noticed that the "carbon" was left by the chloride in the following conditions:—By one cold-rolled steel, in a powdery form; by two annealed steels, in powder; by one hardened steel, in plates and bulks; by another hardened steel, in large plates; by a straw-tempered steel, in bulky plates; by a blue-tempered steel, in bulky plates.

The author draws the following conclusions from his work:—(1.) In annealed steel the carbon exists entirely, or nearly so, in the form of a carbide of iron of uniform composition ( $\text{Fe}_3\text{C}$ , or a multiple thereof), uniformly diffused through the mass of metallic iron. (2.) The cold-rolled samples were very similar to the annealed steel in this respect. (3.) In hardened steel the sudden lowering of the temperature appears to have the effect of arresting the separation of the carbon, as a definite carbide, from the mass of iron in which it exists in combination, its condition in the metal being mainly the same as when the steel is in a fused state. (4.) In tempered steel the condition of the carbon is intermediate between that of hardened and of annealed steel. The maintenance of hardened steel in a moderately heated state causes a gradual separation (within the mass) of the carbide molecules, the extent of which is regulated by the degree of heating, so that the metal gradually approaches in character to the annealed condition; but, even in the best result obtained with blue-tempered steel, that approach, as indicated by the proportion of separated carbide, is not more than about half-way towards the condition of annealed steel. (5.) The carbide, separated by chemical treatment from blue and straw-tempered steel, has the same composition as that obtained from annealed steel.

#### Discussion.

W. H. DUGARD observed that Prof. Norris had found that very hard steel would dissolve in sulphuric acid without leaving any residue whatever, while annealed steel left a residue of carbon, exactly in the form of the original steel, and according to the different degrees of hardness so the amount of residue varied.

L. L. BELL on one occasion took a disc of malleable iron containing a mere trace of carbon, and had its surface planed and polished, and also a similar disc, in point of size, made of cast iron, which was also planed and polished. These two discs were screwed together and enveloped in molten cast iron, where they were kept

for different periods, from a week to four weeks. He found that, without there being a trace of fusion, the carbon from the cast iron had passed as it were into the disc of malleable iron.

A. PAGET remarked that seven of the thin steel discs had been bolted between a cast-iron plate on the one side and a wrought-iron one on the other, and the whole had been kept at a good red heat, short of fusion, for 24 to 36 hours. Judging by practical tests the one nearest the cast iron was the most steely, while the one nearest the wrought iron was least steely, and they followed a somewhat regular gradation from the first disc to the seventh.

Sir F. ABEL, replying, said that twenty-five years ago he obtained results similar to those described by Mr. Dugard as having been obtained recently by Prof. Norris.

#### On the Oxidation of Copper. Debray and Joannis. Compt. Rend. 99, 688.

COPPER becomes oxidized by heating it in air from 350° up to a temperature at which the dissociation of the oxide attains a tension of  $\frac{1}{2}$  atmosphere, when cupric oxide is formed without passing through the intermediate state of cuprous oxide. Cuprous oxide is oxidized at a moderate heat even more rapidly than metallic copper. At a very high temperature cupric is converted into cuprous oxide.—J. E. C.

#### On the Decomposition of Copper Oxide by Heat. E. J. Mautméné. Compt. Rend. 99, 757.

THE author points out that the results of the experiments of Debray and Joannis must be regarded as incorrect, and states that an intermediate oxide of copper exists between cuprous and cupric oxide, having the formula  $\text{Cu}_2\text{O}$ , soluble in acids with a brown colour, whereas  $\text{Cu}_2\text{O}$  gives a colourless, and  $\text{CuO}$  a blue or green solution; and further that  $\text{Cu}_2\text{O}$  colours glass a brilliant red,  $\text{CuO}$  producing no change, and  $\text{CuO}$  a green colour. From his "general theory" the author derives a series of complicated intermediate oxides of  $\text{CuO}$  and  $\text{Cu}_2\text{O}$ .—J. E. C.

#### An Improved Method of Manufacturing Metals and Metallic Alloys. John Lewthwaite, Halifax, England. Eng. Pat. 3240, February 13, 1884.

THIS is an addition to or completion of a former patent by the same inventor (No. 1553, March 27, 1883), and refers to the admixture of titaniferous or other metallic sands or refractory ores of suitable properties with molten metals for the purpose of producing improved or purified metals or alloys. The claim is for the production of a superior class of iron, steel, bronze or other metallic compound by the introduction into the clear molten metal or metals of titanic sand or ore or other ores containing certain mineral acids, such as titanic, manganic, silicic, etc., in a finely comminuted form, in which they are in the fittest state to produce an electrochemical combination.—B.

#### Improved Means for Preventing Galvanic Action in Iron and Steel Ships when Protected by Copper or other similar Sheathing; applicable also to other like Submerged or Partially-submerged Surfaces. B. L. Thomson, London. Eng. Pat. 4658, March 10, 1884.

THE iron or steel surface to be protected is coated with a vitreous layer (as of sodium silicate or other materials which will form glass when subjected to the action of heat), to which the sheathing plates are affixed by means of india-rubber solution or otherwise. "A layer of india-rubber or cork, felt, paper or canvas, or the like saturated with india-rubber solution is preferably interposed between the sheathing plates and the surface of the metal to be protected." When the sheathing plates are secured in position the vitreous coating surrounding their edges is heated by means of a blowpipe or otherwise, so that the vitreous material may cover the joints and thus

produce a perfect junction impervious to moisture. Galvanic action is by these means entirely prevented.

—E. G. C.

*Improvements in the Manufacture of Chromium Alloys.*  
Thomas Slater, Bayswater, London. Eng. Pat. 9460, March 21, 1884.

THE object of the inventor is to produce alloys of chromium in an economical manner so as to make them more readily available for use in the arts. He takes chromate of potash or other salt of chromium, or chromic acid, mixes them with an equal weight of charcoal in coarse grains, and heats them together in a covered crucible. When the mass has been softened by heat he pours thereon about two-and-a-half times its weight of molten copper, and further adds from one-half to two parts in weight of molten tin. After thoroughly heating and stirring together for some time the mixture is poured into water for the purpose of reducing or disintegrating the same. The resulting granulated mass is then remelted with a flux of the following composition—viz., one part of bichlorate of soda, two parts of nitrate of potash and two parts of carbonate of potash, when it is cast into moulds, plates, ingots, etc., for employment in the arts. It will then be found to have a rich golden yellow colour, but if a white alloy be required it can be produced by the addition to the chromium salts or oxides of metallic nickel mixed with tin and with copper in suitable proportions.—B.

*A Method of Producing Alloys of Iron or Manganese or Iron and Manganese with Tin.* Charles Billington and John Newton, Langport, Staffordshire. Eng. Pat. 5345, March 24, 1884.

THE inventors claim the introduction of iron or manganese, or of iron and manganese not previously alloyed, into a bath of molten tin kept at a suitable temperature, the iron or manganese being connected by wires to a dynamo machine or battery. When put in circuit it is claimed that the current of electricity throws off the iron or manganese or iron and manganese into the tin bath, and produces chemical action between the metals, which causes them to alloy with each other in any desired proportion that can be regulated with great nicety.—B.

*Improvements in the Manufacture of Metallic Alloys.*  
George Alexander Dick, Cannon Street, London. Eng. Pat. 6172, April 9, 1884.

THE object of the invention is to produce manganese copper in a readier and less expensive way than at present. For this purpose pure copper is melted in a crucible with ferro-manganese containing a large percentage of manganese, and in the presence of silicon. When pouring out into ordinary moulds, the manganese will be found to have combined with the copper, and the silicon with the iron, the latter forming a layer upon the manganese copper. The greater the amount of silicon present the more perfect is the separation, though even so small a quantity as 1 per cent. of silicon as compared with the manganese present suffices for the desired effect. In some cases the ferro-manganese contains in itself sufficient quantity of silicon to produce the necessary reaction upon the iron so as to set the manganese free to combine with the copper.—B.

*Improvements in the Treatment and Production of Iron, and in the Apparatus employed therefor.* Samuel Richard Smyth, Surrey. Eng. Pat. 5853, June 4, 1884.

THE inventor proposes to produce in a single heat, from indifferent materials and with a low pressure of blast, iron of the best quality, ready for the rolling mill or hammer, and dispensing with the usual processes of puddling, etc. For this purpose he first melts the ore in any convenient way, or he re-melts pig-iron and he taps a charge, preferably of about 10 tons' weight, into his

improved refining "Manipulator." This consists of a cylindrical body or shell hung in trunnions mounted on its axis, and supported on a cradle-track, which is carried on wheels. The shell is lined with any suitable material of a refractory nature, such as, for instance, a compound consisting of 96 parts of silica, about 2.3 parts of alumina containing some iron oxide, and about 2 parts of plumbago wetted moist and hand rammed. It is fitted with gear for rotating, and has an external chamber or box with movable cover, into which liquid compounds, air, gases, and other elements in a sub-divided state, are forced through holes in the refractory lining after entering through a central aperture in the shell and passing an internal chamber, which communicates with the external one. The charges, when finished, are withdrawn through a tapping hole. The liquid compounds spoken of above as forced into the metal are chlorine compounds, carbon and hydrogen compounds and oxyhydrogen compounds. These are first minutely sub-divided or "atomised" in an apparatus hereafter described, and are carried forward into the body of the metal in the manipulator by either atmospheric air or other gases, which may either serve as carriers only or may be used partly for chemical action in combination with the atomised liquids. The "Atomiser" for preparing the liquid compounds and conveying the air gases into the metal, consists of a horizontal vessel or reservoir, to which the blast is connected at one end and an outlet provided at the other. Upon the reservoir are fitted three or more cylindrical upright tanks, each connected with it through a pipe and valve. Another pipe is tapped to the top of each tank, and reaches on the inside nearly to the bottom. These latter pipes convey the liquid to atomising injectors and to a mixing box, whence the mixture passes through a connecting pipe and valve into the external chamber of the manipulator previously referred to. There are also gauges, valves, floats, and supply pipes to regulate the quantity of the various liquids admitted to the tanks. Absorbents of carbonic oxide or of iron oxide from the charge of metal may be added to the charge in the manipulator as required, and it may also be stirred with wood poles for absorbing the oxygen, similar to what is practised in the manufacture of copper. When the treatment of one charge is completed the manipulator may be removed on its truck, and another previously filled with molten metal substituted for it, thus making the operation continuous. A sheet of drawings representing the manipulator and the atomising apparatus accompanies the specification.—B.

*Improvements in the Extraction of Cobalt, Nickel, and Manganese from their Ores, and of Nickel from its Ores, when such Ores are found in a similar condition to those of New Caledonia.* Henri Herrenschmidt, Bouli, near Sydney, N.S.W. Eng. Pat. 12,044, September 5, 1884.

THE patentee deals with the extraction of metal from two kinds of ore found in New Caledonia—viz., the mangiferous ores of cobalt and nickel, and the plain ores of nickel. Where both kinds of ores are to be treated at the same place, the mangiferous ore is first manipulated by placing it in a solution of proto-chloride of iron, and heating to boiling, when the cobalt, nickel, and manganese will dissolve. From the solution the cobalt and nickel are precipitated by the addition of a sufficient quantity of sulphide of manganese or hydrated oxide of manganese. The supernatant liquor being a solution of pure chloride of manganese, is either crystallised for marketable purposes, or evaporated at a moderate heat, whereby hydrochloric acid is driven off, and oxide of manganese obtained as residue. The plain ores of nickel are now treated with the hydrochloric acid by heating the latter, and using it as a bath for these ores until the complete dissolution of the nickel, which is then precipitated from the solution as before. Or the hydrochloric acid obtained as above may be used for the production of proto-chloride of iron for the treatment of the mangiferous ores, and thus the process carried on in a continuous round of operations involving very little loss.—B.

*Improvements in the Process of working Auriferous and Argentiferous Arsenides and Sulphides of Iron, Copper, or other similar Substances by Litharge or Lead.* Edward Probert, San Francisco, California. Eng. Pat. 15,057, November 15, 1884.

THE invention relates to an improved method of stirring the molten materials in the process of working auriferous and argentiferous arsenides and sulphides of iron, copper, or other similar compounds in which litharge or lead is introduced for the purpose of extracting the precious metals. The improvement consists in a novel mode of stirring the materials by means of elastic vapour generated by the action of the molten mass upon substances placed within the melting pot, and without the aid of mechanical stirring. The inventor takes iron pots of conical shape and lines them inside with a refractory material worked in the plastic state. He then places upon the bottom a further lining of suitable thickness, composed of mineral carbonates, mixed with a sufficient quantity of the original lining material to give it consistency. After being slightly dried for the removal of the excess of water the pots are ready for use. When the molten material from the furnace is tapped into the pot, and simultaneously therewith or immediately after the charge of litharge or lead, the evolution of steam and carbon dioxide causes a considerable and very regular ebullition and agitation of the materials, with the effect of inducing an intimate mixture of the ingredients. The duration of the action can be regulated to suit the quantity and the heat of the molten mass, as well as its composition, by altering the thickness and the composition of the calcareous bottom. Other means than that described may be used for holding the calcareous materials to the bottom of the pot within the molten mass.—B.

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

*A New or Improved Process for the Separation of Glycerine from Fatty Substances.* C. Rumble and F. Sear. Eng. Pat. 4264, March 1, 1884.

ZINC or magnesium salts of fatty acids are first prepared by boiling together in an open vat with free steam, dilute alkaline solution, fatty substances, and zinc or magnesium sulphate. The fatty substance to be deprived of its glycerine is then heated with one-third its weight of water, and from 5 to 8% of the zinc or magnesium salt of fatty acids, to a steam pressure of 120 to 130 lbs. per square inch, and a temperature of 365° F. The glycerine is separated from the "sweet water" in the usual way, and the zinc or magnesium soap may be decomposed by a mineral acid, the salts so produced being employed over again.—W. L. C.

*An Improved Method or Process of, and Apparatus for Recovering Paraffin, Stearin, or similar Wax-like Substances from Petroleum or other Oil.* Communicated by Rollin H. Smith, Pennsylvania, to H. H. Lake. Eng. Pat. 13,579, December 15, 1884.

THE usual mode of separating the solid constituents of oils from the liquid ones, is by filtration or by pressure, heavy hydraulic presses being usually employed. The patentee proposes to effect the same object by spraying the oil upon a travelling blanket, which afterwards passes between pressing rollers; the oil is squeezed out, and the solid portions, which are left on the belt, are removed from it by a scraper, and carried away by a travelling belt. The process is rapid and continuous, but requires very close attention to the temperatures of the room, and of the oil. The spraying apparatus is a pipe furnished with a number of "bib-cocks."—W. L. C.

*Improvements in Lubricating Compounds.* Communicated by D. D. Wass, of New York, to A. M. Clark, London. Eng. Pat. 5901, December 30, 1884.

THE patentee mixes 1 lb. paraffin with 1 lb. mineral oil and  $\frac{1}{16}$  lb. of alcohol.  $\frac{1}{16}$  lb. of powdered talc is well stirred in. The mixture when cold is pressed and made

into cakes, balls, or "cartridges," which are dipped into melted paraffin, and thus become covered with a protecting shell of paraffin.—W. L. C.

*Improvements in the Manufacture of Soap.* C. R. Alder Wright. Eng. Pat. 14,681, January 12, 1885.

DR. WRIGHT proposes to counteract the evil effects on the skin or on fabrics, of the free caustic soda or potash often to be found in soap, by mixing with the soap some ammoniacal salt (usually sulphate or chloride), the acid of which combines with the free caustic alkali, while the liberated ammonia gradually passes away into the air during the subsequent operations of cutting, stamping, etc. Even if a little free ammonia remain in the soap, it is not nearly so deleterious as the fixed alkali.—W. L. C.

*Improvements in Obtaining Glycerine and Fatty Acids from Animal and Vegetable Substances.* J. W. Freestone. Eng. Pat. 7573, February 10, 1885.

THE fat is heated in an autoclave for four or five hours at a pressure of 100 to 125 lb. per square inch, with one-half its volume of water, and from  $\frac{1}{2}$  to 1 per cent. of hydrated oxide of magnesium, prepared by precipitating magnesium chloride with milk of lime or caustic soda, and washing the precipitate. The mixture of fatty acids and magnesium soap may be at once saponified, or treated first with a mineral acid.—W. L. C.

*Improvements in Extracting Grease from Soap-water, and its Subsequent Bleaching and Purification.* Benjamin Davy. Eng. Pat. 4679, February 23, 1885.

THE soap-water in calico printing works is treated, in tanks at 50° F. or upwards, with sulphuric or hydrochloric acids; the clear liquid is decanted, and the fat separated by filtration. The fat is then hot-pressed, and the grease from the hot-presses is clarified and bleached with "sulphuric or hydrochloric acid and common soda."—W. L. C.

## XII.—PAINTS, VARNISHES, AND RESINS.

*Rubber Compositions.* J. J. C. Smith, Passaic, N.J., U.S.A. Eng. Pat. 15,150, November 18, 1884.

THIS specification relates to the production of a vulcanisable composition of india-rubber or caoutchouc combined with ozokerit, mineral wax or paraffin and sulphur. The ozokerit is first melted with rosin, and the caoutchouc and sulphur are added, the mixture then being removed to a regular rubber mill, after which it is ready for working into articles in the same manner as other rubber compounds. The inventor states that by the addition of rosin, together with ozokerit, a perfect union of the rubber and sulphur with the mineral wax is effected, and a much stronger and more elastic composition produced.—E. G. C.

*Improvements in the Manufacture and Preparation of Drying Oils.* Miles Williams, Wigan. -Eng. Pat. 579, January 3, 1884.

ACCORDING to this invention, a drying oil "medium" for paints, etc., is prepared by distilling colophony in an iron still. Pyroigneous acid and water first pass over, and the temperature is maintained at 315-320° F. until the resin is freed from these compounds. The temperature is then raised, until the resin boils and crude resin oil distils over. The oil, if required to be very pale, is rectified by redistillation, or by being heated for about ten hours to a temperature of about 300° F., and is finally mixed with a suitable dryer, such as the oxides of lead, manganese, etc. The resulting oil is transparent, free from bloom, has good drying properties, and forms a hard, tough, glossy surface, which, when dry, does not contract or crack. It moreover possesses a sweet smell, and will mix in any proportions with other boiled and drying oils; it is soluble in turpentine, and is a good solvent for gum-resin or varnish gums.—E. G. C.

*An Improved Mode of Treating Certain Resins for obtaining a New Elastic Substance.* A. Germot and L. Riviere, Paris. Eng. Pat. 2630, February 2, 1881.

As the result of numerous experiments, the inventors have proved that oleic acid from stearin works will entirely dissolve solid and semi-solid resins. The degree of solubility varies with the nature of the resins to be dissolved, and the temperature required from about 50-150° Centigrade. The product of the solution thus effected is soluble in spirits of turpentine and in oil, and can, therefore, be used for the manufacture of oil varnishes. Solid and semi-solid gums are also soluble in ethylic and benzoic aldehyde, liquid or melted camphor and chloroform. "The solution of gum in the above-named aldehydes, and liquid or melted camphor and chloroform forms an elastic material, having equivalent properties to those of the material (elastine) produced by the solution of the gums in oleic acid. The integral solution of copal gums in oleic acid (effected in a similar manner to that hereinbefore described) gives a product which is applicable not only to the manufacture of varnishes, but also of new plastic materials. Products varying in consistence may in fact be obtained by altering the proportions of the oleic acid and gum, as well as by varying the kind of gums employed." The product of the solution of the gums in oleic acid has sometimes the elasticity and consistence of india-rubber, and the inventors have given to this substance the name of "elastine." It is suitable for the manufacture of varnishes, of coatings of all kinds for cloth, wire, etc., and for making insulating cloth by the incorporation of cork, fibrous or textile material, or mineral substances, with the elastine. The ordinary process of dissolving solid and semi-solid copal resins in oil and in spirit of turpentine is somewhat dangerous and difficult, and it has to be carried out at a temperature at which about 25 per cent. of the resin to be dissolved is lost. This loss of resin is avoided if the inventors' process be adopted.

—E. G. C.

*Manufacture of Weatherproof Oil Colours or Paints.* Otto Wolf, Saxony. From August Then Bergh, of Dresden. Eng. Pat. 2896, February 7, 1884.

A PROCESS for making oil colours or paints which are to be employed in cases where such preservation is deemed necessary. "Oil colours or paints have up to the present time not been manufactured with sufficient care." "The process of the conversion of the oil varnish into a resinous substance, and the facilitating of the said process so as to prevent the penetration of dampness, has not received sufficient attention; and, on the other hand, the hardening of the colour or paint by adding exceedingly hard substances has been overlooked, but is necessary to enable the colour or paint to withstand the injurious effects of the continuous friction of rain, dust, and sand." The inventor adds to the oil varnish a powder consisting of ground and calcined lead or silver slag, which is a very hard material. The said substance contains about 25 per cent. of  $\text{SiO}_2$  and small quantities of

$\text{PbO}$ ,  $\text{ZnO}$ ,  $\text{SnO}_2$ ,  $\text{FeO}$ ,  $\text{CuO}$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{MnO}$ ,  $\text{CaSiO}_3$ , and S. "The said substance contains the above in such favourable proportions for the preparation of weatherproof oil colours, that in the opinion of competent experts, the so prepared oil colours or paints, with the addition of burnt colours in the various requisite shades, are perfectly able to withstand dampness and all atmospheric influences or effects of the weather, as the resinous process is not only facilitated by the addition of the aforesaid silice compounds, but the paint or colour is also rendered hard or indestructible."—H. A. R.

*Priming and Anti-fouling Compositions.* P. Layden and W. McLean, Jarrow. Eng. Pat. 4796, March 12, 1884.

The priming composition of the inventors consists of the following ingredients:—

1. Gum guaiacum in powder.....	3 parts.
2. Teak varnish.....	3 "
3. A varnish known as knotting varnish	2 "

4. Yellow resin or other resinous gum....	12 parts
5. Benzoline or other spirit.....	20 "
6. Stockholm or other tar.....	3 "
7. Black varnish.....	5 "
8. Colouring matter.....	30 "

No. 4 is reduced to a fine powder and dissolved in part of No. 5; Nos. 1 and 3 are then thoroughly mixed together; Nos. 2, 6, 7, and 8 are next placed in a properly constructed mixing vessel, to which are lastly added gradually Nos. 1, 3, 4 and the remainder of No. 5. The whole is then briskly stirred for twelve hours, at the expiration of which period the composition is ready for use. The anti-fouling composition is prepared from the following ingredients:—

1. Metallic bronze powder, known as gold	1 part.
2. Gum catechu in powder.....	2 parts.
3. Teak varnish.....	7 "
4. Schweinfurt or Vienna green.....	3 "
5. Yellow resin or other resinous gum....	15 "
6. Benzoline or other spirit.....	30 "
7. Stockholm or other tar.....	3 "
8. Black varnish.....	6 "
9. Pure Prussian blue.....	3 "
10. Colouring matter.....	37 "

Nos. 2, 3, and 4 are thoroughly mixed together; No. 5 is reduced to a fine powder and dissolved in part of No. 6; Nos. 1, 7, 8, 9, and 10 are next placed in a mixing vessel, Nos. 2, 3, 4, and 5 and the rest of No. 6 being then gradually added. The mixture is now briskly stirred for a period of twelve hours, after which it will be ready for use. The compositions may be applied to surfaces with a brush in the ordinary manner; the anti-fouling is applied when the coating of priming has dried.

—E. G. C.

*Improvements in the Preservation of Moist Colours.* H. F. Brousson. Eng. Pat. 4778, March 14, 1884.

THIS invention relates to a simple device for protecting the contents of the pans in which artists' moist colours are kept from becoming dry by exposure or useless through dust, etc.—H. A. R.

*Improvements in the Manufacture of Red Pigments or Paints.* John Cowdery Martin. Eng. Pat. 5192, March 20, 1884.

THE improvements consist in treating red oxide of lead, or the oxide known as "orange lead," or a mixture of these, with white lead, as follows:—Inventor treats with a weak solution of carbonate of soda or potash, the quantity of alkali being from 1 to 2 per cent. of the other materials. Either acetic, nitric or other suitable acid, or else acetate or nitrate of lead is added in quantity sufficient to neutralise the alkali used, and the mass, which has assumed "a brilliant vermilion tint," is dried. The red colouring used other than lead compounds is that known in commerce as "aniline scarlet," and the proportions of lead compounds and "aniline scarlet" vary according to the shade required. The lead compounds are made into a thin paste with water, the alkali added in solution, and the whole heated in a pan. After addition of the other ingredients, and when a thick paste has been formed, the colour is dried in a stove. The pigment resulting is ground into an oil paint in the ordinary way. Red pigments, termed "vermillionettes," are made by combining cosine with white lead and "white zinc," but the colour of this material is extremely fugitive, and pigments made with it partake of this character. "The colour produced as above does not fade, and resists as an oil-paint long exposure to atmospheric influences equally well with genuine vermilion."—H. A. R.

*Improvements in the Production of Compounds containing Nitro-Cellulose, suitable as Varnishes, and for making Leather Cloth.* William Virgo Wilson and Joseph Storey. Eng. Pat. 6051, April 7, 1884.

THE inventors claim the use of acetate of amyl as a solvent for nitro-cellulose. Such a solution can be used as a varnish for an indefinite variety of articles. When 200 parts nitro-cellulose are mixed with 600 parts acetate of

amyl a mass of a doughy consistency is obtained, which can be used for any of the purposes for which celluloid is used. With the addition of castor oil, China clay, and a small proportion of certain essential oils, a compound suitable for the production of artificial leather may be produced.—E. J. B.

*Improvements in the Manufacture of Euphorbia Paints.* S. R. Hooper. Eng. Pat. 39, Jan. 1, 1885.

IN the utilisation of euphorbia juice with pigments it has been the practice simply to mix the same with ordinary paints. The said juices become more or less dissolved out or impaired by moisture, and thus the paints in a great measure lose their preservative properties. Inventor adds certain water-repellent materials previous to mixture with colours or pigments. For general use it is proposed to combine equal parts of euphorbia juice and a solution of gum resin,—e.g., shell-lac.—H. A. R.

## XIV.—AGRICULTURE, MANURES, Etc.

*Proceedings of Convention of Agricultural Chemists, Philadelphia, 1884.*

THE Convention proceeded to formation of an "Association of Official Agricultural Chemists," for which analytical chemists connected with State Agricultural Departments, Experimental Stations, and Boards are alone eligible as members. The object is to secure legislative uniformity by the different States for the sale of, and uniformity and accuracy in the analysis of, commercial fertilisers. The Association adopted methods for—

1.—Determination of phosphoric acid in fertilisers, as, Total, water-soluble, and citrate-insoluble, phosphoric acid, the sum of the last two deducted from the total to give the citrate soluble, neutral ammonium citrate solution to be used of 1.09 density, the  $P_2O_5$  to be precipitated by molybdiic solution, and converted by magnesia mixture into ammonio magnesic phosphate, burnt, and weighed. Solutions of ammonium citrate, magnesium nitrate, magnesia mixture, ammonium nitrate, and molybdiic acid to be prepared and used as directed.

2.—Potash in fertilisers is to be determined by aliquot part of 10grm. in 1000cc., representing 0.5 to 1.0grm., precipitated first by barium chloride, filtered, then barium hydroxide. Careful removal of all excess of baryta by ammonium carbonate, evaporation, re-solution, and soda and potash weighed as pure dry chlorides, the potash then precipitated by excess of platinum tetrachloride. The atomic weights adopted are:—

Platinum .....	197.18	Chlorine .....	35.46
Potassium .....	39.13	Oxygen .....	16.00

—J. R.

*Improvements in Silos.* J. B. A. McKinnel, Dumfries. Eng. Pat. 6008, April 5, 1884.

THIS specification is accompanied by drawings, and "the improvements consist in forming the ordinary built up or earth-embedded chamber with a hollow cover or casing, which serves to cover the fodder, and when filled with water or liquid, to apply pressure to the material within the chamber." The hollow cover is formed to correspond with the shape of the silo, and the upper end of the cover is fitted with a broad flange, which rests on the containing-walls of the silo, when the lower or piston-like part of the cover is fully down, it can then be cemented or fitted air-tight. The silo chamber is first filled with the grass or fodder, and the cover brought to bear on it. The hollow casing is filled with water until the weight compresses the material sufficiently. This process of filling and compressing is repeated as often as is necessary. To facilitate raising and lowering the cover it is suspended by chains passing over pulleys on carrying columns, fitted with counterbalancing weights or water-tanks.—W. M.

*Improvements in Obtaining Certain Solutions containing Free Phosphoric Acid.* E. Packard, Jun., Ipswich. Eng. Pat. 6176, December 19, 1884.

THE liquid portion of the product obtained by acting upon phosphate of lime with dilute sulphuric acid (mixed or not with phosphoric acid) is separated from the solid residue, and this latter washed at least twice in wooden filterpresses. The first wash, mixed with strong sulphuric acid, is used for treating a further quantity of phosphate, while the second wash is utilised as the first wash for the next lot of solid residue. If more than two washings are given the same principle applies.

—A. R. D.

*Improvements in Obtaining very Pure and Rich Superphosphates of Lime.* E. Packard, jun., Ipswich. Eng. Pat. 6750, December 19, 1884.

NATIVE or other phosphate of lime is treated with sulphuric acid in the presence of sufficient water to obtain a solution of monoalcic phosphate and free phosphoric acid. This solution is separated from the solid sulphate of lime, etc., and evaporated to a density of from 1.125 to 1.300. This causes almost the whole of the sulphate of lime and phosphates of iron and alumina originally existing in the solution to precipitate, while arsenic, if present, is removed by a current of sulphuretted hydrogen, or the addition of a suitable sulphide such as alkali waste. One filtration may serve to remove these impurities, and the filtrate may be evaporated to any required degree of dryness.

—A. R. D.

*Improvements in Obtaining from Native or other Phosphates of Lime, Products Rich in Phosphoric Acid and of a High Degree of Purity.* E. Packard, jun., Ipswich. Eng. Pat. 6751, December 19, 1884.

PHOSPHATE of lime is treated with sulphuric acid and water in such proportions as to yield the greater portion of the phosphoric acid in the free state. The solution is separated by filtration, and evaporated to a sp. gr. 1.125-1.300. Sufficient phosphate or carbonate of lime, or free lime, is then added to leave only about 30 per cent. of the phosphoric acid (not combined with iron and alumina) still in the free state. This causes the deposition of the sulphate of lime, and phosphates of iron and alumina contained in the phosphoric acid solution. The liquor filtered from these precipitated impurities is concentrated as required.—A. R. D.

*Improvements in Obtaining from Native or other Phosphates of Lime Products Rich in Phosphoric Acid.* E. Packard, jun., Ipswich. Eng. Pat. 6752, December 19, 1884.

TO a solution obtained by treating phosphate of lime with sulphuric acid in such proportions that nearly the whole of the phosphoric acid (exclusive of that combined with iron or alumina) is obtained in the free state, lime, or carbonate of lime is added in such quantity as will combine with about two thirds of the free phosphoric acid. The resulting product is evaporated to the degree of dryness required.—A. R. D.

## XV.—SUGARS, GUMS, STARCHES, ETC.

*On Raffinose (Melitose?), a Kind of Sugar of High Rotating Power derived from Molasses.* B. Tollens, Ber. Chem. Germ. 1885, pp. 26-28.

SOME molasses which had been treated with strontium hydrate in the usual manner were allowed to stand for two years, when they appeared to be intersected by numerous needle-shaped crystals. Alcohol of 80 per cent. was added in such quantities that the mass could be filtered. After pressing and repeated crystallisation white needles were obtained, containing about 15 per cent. of water. An elementary analysis showed C = 42.46 % and H = 6.50 % for the substance dried at 100° C., which corresponds to the formula  $C_{12}H_{22}O_{11}$  +

3 H<sub>2</sub>O for the hydrated crystals. The polarisation of a 9.5986 % solution showed in the Landolt Laurent apparatus a rotation ( $\alpha_r$ ) = 102.5°-103°. By heating this solution with a little sulphuric acid, the angle of rotation was reduced to less than half—viz., ( $\alpha_r$ ) = 45°. The matter is indifferent to Fehling's solution, but after heating with sulphuric acid it reduces an alkaline copper solution. Treated with dilute nitric acid it yields a substance similar to mucic acid and fusing at 210°-214°. These properties do not agree with any of the known compounds of the formula C<sub>12</sub>H<sub>22</sub>O<sub>11</sub>, but they correspond well with a kind of sugar prepared from molasses by Loiseau and termed "rallinose." This substance offers all the more interest at present as the sugars which were produced in the last few years showed a higher polarisation than could be expected from their percentage of pure cane-sugar. Rallinose having a higher power of polarisation than cane-sugar, it appears probable that since the introduction of the strontium process the sugar of commerce contains a certain amount of rallinose, which would, of course, raise the rotating power of the sugar. Furthermore, it does not seem unlikely that rallinose exercises an influence on the crystallisation of sugar by causing the crystals to take a longish shape. Tenne and V. Schaaf have made the same observation with sugar prepared by the strontium process. The investigation of this interesting body not being finished, the author refrains from pronouncing an opinion whether his and Loiseau's substance are identical. —S. H.

*Experiments in the Manufacture of Invert Sugar from Saccharose.* F. W. Thompson, Burton-on-Trent. Eng. Pat. 8686, June 7, 1884.

ANY commercial saccharose is dissolved in water in suitable proportions, and the solution is heated to from 95° F. to 160° F., preferably 130°. Whilst the solution is at that temperature, yeast, ordinary pressed brewer's yeast by preference, is added in the proportion of 1 part of yeast to 100 parts of saccharose, and allowed to stand for five hours. At the end of that time the saccharose is completely inverted. It is claimed that by using the yeast at this temperature, or even by heating the yeast before use to 120° F., it still retains its inverting power, though it can no longer produce fermentation or convert the sugar into carbonic anhydride and alcohol as it would do under ordinary circumstances.—A. J. K.

*Improvements in the Process of and Apparatus for Treating Megass for Extracting Sugar therefrom.* G. W. Parbury, London. Communicated from Gustav Kottman, Sydney, N.S.W. Eng. Pat. 17,092, December 31, 1884.

BY this invention the sugar is extracted as completely as possible from the canes by the old process of squeezing through mills, and then the megass which is left is afterwards exhausted by the application to it of the diffusion process in a modified form invented by the authors. The apparatus designed for carrying out the process receives the megass either directly from the mills or after it has been more or less disintegrated by a special cutting or tearing machine. The diffusion apparatus (the construction of which cannot be exactly explained without reference to the diagram) is so arranged that the megass is made to rotate round a large cylinder in the opposite direction to a stream of hot water, until when the exhaustion is complete the megass passes out to another mill to receive a final squeeze, and the sweet water is separately drawn off and taken to the factory for treatment.—A. J. K.

XVI.—BREWING, WINES, SPIRITS, Etc.

*On the Presence of Choline on Hops.* Dr. Griess, F.R.S., and Dr. G. H. Harrow. Abstr. Proc. Chem. Soc. 1884-5 [5], 35.

THE authors have separated choline—

from hops by adding to a concentrated extract, acidified with hydrochloric acid, a solution of iodine in hydriodic acid. The semi-solid precipitate obtained—a choline periodide—was boiled with water to expel iodine, and the resulting solution of choline iodide treated with silver oxide; the impure choline in the solution was then converted into the auro chloride, which was recrystallised. In this manner they have not been able to obtain more than  $\frac{1}{5}$  per cent. of choline from hops. They consider it not improbable that it exists in loose combination with resin, as they find that a very dilute aqueous solution is capable of dissolving comparatively large quantities of hop resin, the liquid being then of intensely bitter taste. Employing the same method, they have also extracted choline from beer.—W. S.

*Analysis of Two Californian Wines.* J. L. de Fremery. Ber. 18, 426.

THE author has obtained the following results on analysis of a red wine "Zinfandel," and a white wine "Gutedel." 100cc. of wine gave in grms. :—

	Gabinet Gutedel.	Zinfandel.
Extract .....	2.0609	2.127
Alcohol .....	10.45	9.8
Mineral constituents .....	.0978	.2218

—A. G. G.

*Fuchsin in Wine.* R. Kayser. Rep. Analyt. Chem. 4, 296-301.

100 CUB. CENTS. of the wine to be tested are shaken with 20 cub. cents. of colourless amyl alcohol, and then after diluting with water, the solution is examined with the spectroscope. If the characteristic absorption bands between the lines D and E of rosaniline compounds are observed, then the author recommends adding excess of ammonia solution to the sample of wine, and again shaking with amyl alcohol. If the alcohol solution is coloured red, then ordinary rosaniline has been the colouring matter employed; but if the alcoholic extract remains colourless, then the spectroscopic reaction is due to magenta S (rosaniline sulphonate). If these tests have given negative results, 100 cub. centimeters of the wine is warmed with excess of finely-powdered barium hydrate for two hours on the water-bath, and after cooling, the precipitate is filtered off and washed with water till the filtrate has a volume of 100 cub. cents. The filtrate is then evaporated to 10 cub. cents., acidulated with weak acetic acid, and examined spectroscopically for rosaniline salts and sulphonate. The precipitate may contain fuchsin, to obtain which lead acetate and ammonia are added, and the mixture well shaken with amyl alcohol, and the alcoholic extract again tested with the spectroscope. The sediment deposited by the wine may contain the rosaniline in combination with tannic acid, and can be examined in the way above described.—S. R.

*Examination of Wine for Cane-Sugar.* L. Medicus, Rep. Analyt. Chem. 4, 327-329.

THE author has examined pure white wines for cane-sugar before and after warming with hydrochloric acid, and finds that there is a greater quantity of reduced

copper after inversion. The method used was that of Soxhlet-Alilin. This increase he attributes to the inversion of a gum in the wine which he has succeeded in precipitating by the addition of alcohol, and by inverting the viscid precipitate obtained with hydrochloric acid and then reducing with copper solution has proved that the increased power of reduction of the wine after inverting is entirely due to this body. In estimating the sugar in wine the author finds it necessary to heat for the same length of time in all cases. With light-coloured wines it is not necessary to decolorise. With red wines animal charcoal must be used with caution; lead acetate, however, removes the colouring matter without carrying down the gummy substance along with the precipitate.—S. R.

*Estimation of Glycerine in Wine.* M. Barth. Pharm. Centraltb. 25, 458-458.

THE amount of sand and lime added for the estimation of glycerine has an influence on the preciseness of the results. The author finds that with a quantity of wine which would yield 2 grm. of extract, 1.3-1.5 grm. of calcium hydrate should be added, and in ordinary wines 2 grm. of sand, but with sweet wines it is best to have as much as 5 grm. of sand to the same quantity of calcium hydrate. If these proportions of lime and sand are adhered to, no marked influence on the result is observed, whether the wine is evaporated almost or quite to dryness, if one takes care to dissolve all the residue off the dish. By observing these conditions one can obtain with 100 cub. cent. of the hot alcoholic filtrate 97 per cent., and with 150 cub. cent. about 90-99.5 per cent. of all the glycerine.—S. R.

## XVII.—PRESERVING FOOD, MEATS, Etc.

*Improvements in the Manufacture of Meat Powder, and Methods for using the same.* M. Bauer, Paris. Eng. Pat. 16,700, December 19, 1884.

THE object of this invention is to manufacture a new description of meat powder, without using a higher temperature than 167° F., from which all danger arising from bacteria has been removed, and which, although not subjected to boiling, is suitable for consumption as food. The meat, cut into thin slices, is placed in hot water for several minutes, then removed, and placed in a water bath, which is kept boiling for one or two hours. The meat is now minced, and the broth from the former process is evaporated and added gradually to the minced meat, which is heated to 160° F., until all the water is driven off.—W. M.

*Improvements in the Manufacture of Pressed Meat and Vegetables, and Method of Packing the same.* M. Bauer, Paris. Eng. Pat. 16,701, December 19, 1884.

THIS specification gives a detailed account of the manner in which certain preparations of meats and vegetables are to be prepared, steamed and stewed together, and finally hermetically sealed in tin cans.—W. M.

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

*On Eucalyptol.* E. Jahns. Ber. 17, 2941.

ACCORDING to Cloëz, *Compt. Rend.* 70, 687 the ethereal oil of the leaves of eucalyptus globulus consists, for the most part, of a substance, eucalyptol, which boils at 175°, and has the composition  $C_{10}H_{16}O$ . Faust and Homeyer (*Ber.* 7, 63), on the other hand, obtained a liquid boiling at 171-174°, which contained no oxygen, and appeared to be a mixture of eucal and a terpene. They considered their product, however, to be identical with that of Cloëz. The author points out that Cloëz obtained his oil by the distillation of the leaves of eucalyptus globulus grown in Paris; while that of Faust and

Homeyer was bought from a druggist in Leipzig; and he doubts whether they worked with the same substance. The author subjected some oil, obtained from Hr. Tromandorff, in Erfurt, to fractional distillation, and found that the greater part came over between 170 and 180°, the residue consisting of terpenes and traces of phenols. It was not found possible to obtain a constant boiling product from this oil, nor from samples supplied by Merck, in Darmstadt, and Schimmel & Co., in Leipzig. Analyses were made of the different fractions between 171 and 175°; and it was found that the composition of the lowest boiling portion agreed with the formula  $C_{10}H_{16}O$ , while Cloëz's formula approximately represented the composition of the highest boiling fraction. That the product was a mixture was shown by the analyses, and by the different optical properties of the fractions. The substance was purified by the method of Wallach and Brass, *Ann. Chem. Pharm.* 225, 291. Hydrochloric acid gas was passed into the oil, cooled by a freezing mixture, and the crystalline mass quickly pressed and decomposed by water; the oil was again precipitated with hydrochloric acid. It was then warmed with alcoholic potash, washed with water, dried and distilled. It boiled constantly at 176-177°; its specific gravity was 0.923 at 16°; and it was optically inactive. Its odour resembled that of camphor. Its composition was found to be  $C_{10}H_{16}O$ . A study of its physical and chemical properties proved its identity with the substance to which the two names, eucal and cajepitol, have been given.—S. Y.

*On Juglone.* A. Baranzen and A. Semper. Ber. deut. Chem. Ges. 18, 203.

THIS is a lengthy paper on the preparation, properties, and probable constitution of juglone, a substance obtained by extracting nutshells with ether. Juglone seems to be a naphthalin derivative, and possibly an oxyanthraquinone having the empirical formula  $C_{12}H_6O_2$ ; it crystallises in shining red needles, is easily soluble in chloroform and glacial acetic acid, less soluble in alcohol and ether. It has acid properties, but the salts are not easy to obtain. An acetyl derivative was prepared. Oximides of juglone were obtained by reaction with hydroxylamine chloride; and juglonic acid obtained by the action of nitric acid appears to be a dinitro-oxyphthalic acid of the formula  $C_8H_4N_2O_6$ .—G. H. B.

*On the Conine Group.* A. W. Hofmann. Ber. 18, 5-23.

FOR a very long time the following formulas for conine and conhydrine were generally accepted:

The latter base was therefore considered as the hydrate of the former, and this supposition seemed to be confirmed by Wertheim's experiments, who is stated to have converted conhydrine into conine by the abstraction of a hydroxyl molecule, by means of phosphorus pentoxide. On the other hand, the author recently proved that the formula of conine was undoubtedly  $C_8H_{17}N$ , and it was then thought that conhydrine may have the composition of  $C_8H_{15}NO$ , although some observations did not quite correspond with this presumption. On repeating Wertheim's experiments, the author found that the resulting basic oil was not of a uniform composition, but at any rate it contained no conine. The oil contains two or perhaps even three isomeric but different bases, represented by the formula  $C_8H_{15}N$ , which was formerly ascribed to conine. For these bases the terms of a and  $\beta$ -conine are proposed.

1.—*Action of hydrochloric acid on conhydrine.*—Four parts of strong hydrochloric acid were treated with 1 part of conhydrine in a sealed tube at 220° C., for four hours. The resulting mass was supersaturated with an alkali, and the free bases appeared on the surface as an oily layer which after separating, was purified by distilling with steam. After removing the water and dehydrating with potassium hydrate, the oil commenced to boil at 150°, and the principal fraction distilled between 155° and 175° C. On saturating it with hydrochloric

acid two salts could be easily distinguished, which were separated from each other by converting them into picrates, one of which is only slightly soluble, whereas the other is easily soluble in alcohol. The free base of the first—a conicine—is a colourless liquid boiling at 158°, and has the same smell and physiological properties as conine. It solidifies at 25° C., and its sp. gr. is 0.893 at 15° C. Then follows a description of some derivatives.

2.—*Conversion of conine into α-conicine*.—If 1 mol. conine hydrochloride be mixed with 1 mol. bromine and an alkali be added, a bromine derivative of a conicine is formed, thus:

By treating it with sulphuric acid it is changed into hydrobromic acid and α-conicine, thus:

3.—*Reconversion of α-conicine into conine*.—On digesting α-conicine with a great excess of hydroiodic acid (sp. gr. 1.96) and a small quantity of common phosphorus in a sealed tube at 200° C., α-conicine is partially reconverted into conine.

4.—*Reduction of Conine to Octane*. Conine was heated with hydroiodic acid in a sealed tube at 300° for 8-10 hours. The hydroiodic acid turns dark, and a colourless layer of octane appears at the top, whereas large quantities of ammonia are dissolved in the acid solution, and no conine is left. The reaction seems to proceed almost quantitatively, thus:

After separating and distilling over sodium it can be obtained in a pure state, boiling at 118° to 120°, and smelling exactly like petroleum. The author for the present reserves his opinion on the constitution of this hydrocarbon.

5.—*Bases formed by treating conhydrine with hydrochloric acid*. As mentioned above, the product of the reaction of treating conhydrine with hydrochloric acid contains a mixture of bases, from which α-conicine was separated as a picrate slightly soluble in alcohol. From the alcoholic mother liquor an oily product is obtained, which after purification yields a colourless liquid boiling between 165° and 170°. This liquid, however, is a mixture of α and β-conicine, and very likely of a third conicine. By converting it into the chlorhydrate and frequent recrystallising a salt was produced which is a derivative of β-conicine. From this salt the free base was prepared. It forms white crystals, melting at 41° C., and smelling like conine. Its physiological properties are far weaker than those of α-conicine.

6.—*Action of hydroiodic acid on conhydrine*.—On treating one part conhydrine with four parts hydroiodic acid and some phosphorus in a sealed tube at 150° C. for three to four hours, a quantity of colourless prismatic crystals is produced, which are easily soluble in hot water. The analysis showed them to be hydroiodate of conine iodide, thus:

This salt is therefore a source of preparing conveniently α-conicine. The iodine can be easily separated by boiling the salt with silver nitrate. On digesting it with silver chloride the hydrochlorate of conine iodide is obtained, which readily combines with platinum chloride to 2(C<sub>8</sub>H<sub>16</sub>IN.HCl)PtCl<sub>4</sub>. By boiling hydroiodate of conine iodide with silver chloride all iodine is replaced by chlorine forming hydrochlorate of conine chloride, C<sub>8</sub>H<sub>16</sub>ClN.HCl. Reduced with tin and hydrochloric acid the iodised compound is converted into free conine. Wertheim's idea of the relation of conine to conhydrine is thus proved to be a mistake. The latter cannot be converted into the former by means of dehydrating agents, but this conversion can be really effected by the use of hydroiodic acid.—S. H.

*Researches on the Conine Group.* A. W. Hofmann. Ber. 18, 109.

THE fundamental reaction of the research is the action of bromine on conine, and the products obtained are very

various and depend on the relative quantities of the reagents employed. On account of the simpler character of the resulting reaction, bromine was caused to act on a salt of conine. A brominated compound is thereby formed of the formula C<sub>8</sub>H<sub>15</sub>N.HBr.BrBr. By the regulated action of sodium hydrate, the compound C<sub>8</sub>H<sub>16</sub>NBr is obtained, and this gives rise to distinct isomeric bases by the different methods employed for the removal of HBr from this compound. These isomers are named α, β and γ-conicine, of the general formula C<sub>8</sub>H<sub>15</sub>N; α-conicine is formed from the brominated compound by the action of sulphuric acid, and is a tertiary amine; β-conicine is a secondary amine and is described in a former paper along with the α-compound as products obtained from conhydrin; γ-conicine is obtained by the action of an alkali on the brominated compound, and is also a secondary amine. It is noted that there are six possible isomers of C<sub>8</sub>H<sub>15</sub>N according to present views. γ-conicine is a colourless liquid base, lighter than water, in which it is little soluble, but sufficiently so to impart a strongly alkaline reaction. It smells like conine and is very poisonous. It boils very constant at 173° and forms volatile crystalline salts with acids. The formation of a definite double salt with tin tetrachloride is very characteristic. It is worthy of remark that the different conicines could not be converted from one isomeric form into the other. Further products were obtained in the reactions giving rise to the conicines. Dimethylhydroxyconine was obtained as a colourless liquid base of peculiar odour, little soluble in water but with an alkaline reaction, and a boiling point of 225°. It forms very soluble, not easily crystallisable salts, and has the probable formula C<sub>8</sub>H<sub>15</sub>(CH<sub>3</sub>)<sub>2</sub>NO. TRIBROMOHYDROXYCONINE is a bye-product obtained in the preparation of γ-conicine. It is obtained in crystals which decompose spontaneously in the free state, but forms more permanent crystalline salts and also double salts with platinum and gold chlorides. It seems probable that this compound was a derivative of conhydrin, but the latter could not be obtained from the brominated base. Dibromohydroxyconicine is obtained from the tribromohydrate by the regulated action of sodium hydrate. It is an oily body, and also liable to spontaneous decomposition, but its hydrochloride is not crystallisable. HYDROXYCONINE is obtained from the dibromohydroxyconicine by the action of tin and hydrochloric acid. It is a colourless liquid which boils between 210 and 220°, and forms a crystalline hydrochloride. It corresponds to the formula C<sub>8</sub>H<sub>15</sub>NO. CONICIDINE is the name given to a base containing no oxygen, and obtained from hydroxyconicine by long distillation with inverted condenser in presence of alcoholic potash, during which the elements of water are eliminated. It crystallises in colourless needles, which melt at 55.56° and boil above 300°. The analyses of the crystalline hydrochloride and platinum salt determine its formula as C<sub>8</sub>H<sub>14</sub>N<sub>2</sub>, and its formation from hydroxyconicine corresponds to

This body is dibasic and may be provisionally viewed as a homologue of nicotine.

The latter part of the paper is devoted to a discussion of the possible constitution of the bodies of the conine group, which renders further experiments necessary before definite conclusions can be arrived at.—G. H. B.

*Synthesis of Homo-quinine.* O. Hesse. Annalen, 226, 240-242.

PAUL and COWNLEY have shown that homoquinine, when heated with caustic soda and then ether added, is resolved into a mixture of 52 per cent. of quinine, which dissolves in the ether, and 45 per cent. of cuprine, which remains dissolved in the soda. The cuprine can be thus obtained by crystallising from ethereal solution in colourless prisms aggregated together, and melting at 191°. Cuprine forms compounds with both acids and bases. If cuprine and quinine in the above proportions be dissolved in excess of weak sulphuric acid, then ammonia

added and shaken with ether, homoquinine dissolves out, and can then be crystallised from the ethereal solution.—S. R.

*Trimethylquinoline.* L. Berend. Ber. 18, 576.

The author has prepared this compound from pseudocumene (m. p. 63°) by Skraup's method. Trimethylquinoline melts at 42-43° C., and boils at 285-287° C. Owing to its extreme solubility in the ordinary solvents, it cannot be purified by recrystallisation. The analysis of the substance itself and also of the nitrate and the platinum salt, confirmed the formula  $C_{12}H_{13}N$ , and being derived from 1, 3, 4, 6 trimethylamidobenzene, its constitution may be expressed thus:—

—J. B. C.

*On β-Naphthoquinolinesulphonic Acid I.* C. Gentil. Ber. 18, 201.

β-NAPHTHYLAMINESULPHONIC acid in cohobated with glycerine, nitrobenzene and concentrated sulphuric acid, when a violent reaction sets in. β-naphthoquinolinesulphonic acid  $C_{10}H_7(SO_3H):C_3NH_3 + aq?$  is formed and is prepared in a pure state after previous conversion into the barium salt. The acid crystallises in groups of white needles, and is difficultly soluble in cold but easily in hot water. By fusion with potash a β-oxy-naphthoquinoline  $C_{10}H_6(OH):C_3NH_3$  is obtained.—G. H. B.

*Separation and Estimation of Methyl-Alcohol in presence of Ethyl-Alcohol.* Dingler's Polyt. Journ. 254, [12], 500.

C. DE PONCY describes in the *Génie civil*, 1884, v. 5, p. 353, the following method:—Both alcohols combine readily with oxalic acid in presence of gaseous hydrochloric acid. The methyl-oxalate is readily soluble in water, the ethyl-oxalate only difficultly soluble; the aqueous or alcoholic solution of both ethers, when treated with ammonia, gives amides quite insoluble in water. On these facts the estimation of the methyl-alcohol is based. 10·8grm. oxalic acid are dissolved in 10cc. of the alcohol to be examined, and hydrochloric acid gas is passed in to saturation. After standing for 24 hours in a closed flask, 2cc. of this solution are diluted and shaken with 10cc. water, and then filtered. As the methyl-oxalate is completely soluble in water, more oxamide will be obtained on the addition of ammonia, than would be the case if pure ethyl-oxalate only were present. A series of experiments establishes that the mean quantity of oxamide obtained from the wash-water is 6·6 per cent. for absolute ethyl-alcohol. For methyl-oxalate the number lies between 14·65 and 15 per cent. of the quantity of methyl-alcohol. If a mixture of ethyl- and methyl-alcohol be treated as above described, and the precipitated amides weighed, the percentage of methyl-alcohol present can be calculated. For every one per cent. methyl-alcohol from 0·14 to 0·15 per cent. more than 6·6 per cent. of oxamide is obtained.—G. H. B.

*Process for the Estimation of Etheral Oils.* Dingler's Polyt. Journ. 255 [5], 216.

A. LEVANDLOIS (*Comptes Rendus*, vol. 99, p. 977, 1884) estimates the etheral oils in vegetable matters by distilling the latter with water in a short-necked distillation apparatus, and then adding bromine water until after energetic shaking a faint yellow colour remains. He finds that all the etheral oils come over in the first portion of the distillate.—W. M.

## XXII.—GENERAL ANALYTICAL CHEMISTRY.

*New Laboratory Apparatus.* H. Landolt. Ber. 18, 56.

(1.) A COMBINATION of water-bath and hot-water funnel. It consists of a box of copper (Fig. 1) whose bottom is 38cm. long and 25cm. wide, with a back 11cm. high and a front 9cm. high. The top is made of brass. The higher portion serves as a water-bath for beakers, wash-bottle, etc., which stand on a perforated plate 1cm. above

FIG. 1.

the bottom. The front part has three openings for funnels. The apparatus stands on four legs, 20cm. high, one of which is provided with a set screw. At the bottom is a vertical screen to keep the gas flame from the funnels. The filtration and drying proceeds very quickly in using these hot funnels. (2.) Arrangement for concentrating very dilute solutions. A sloping box of copper (Fig. 2) is supported on three legs and provided with a corrugated and rimmed top, made either of silver-plated copper or thin platinum. At alternate ends of the gutters passages are provided in order to compel the liquid to proceed in a zig-zag way. By means of set screws the inclination of the apparatus can be altered.

FIG. 2.

The box is filled with water through a gauge tube at the lower end, where it is also heated, whereas the steam escapes at the top end. The vessel containing the solution to be concentrated is placed in a high position, and by means of a syphon and a screw clip the feed is so regulated as to cause only a concentration and not the complete evaporation of the liquid. A part of the latter must therefore continually run off at the small overflow tube, which forms the continuation of the lowest gutter. A box, 38cm. long, 20cm. wide, and 10cm. high, with a total surface area of 850 square cm. evaporated more than one litre of water per hour. (3.) Apparatus for subliming. It consists of a thin platinum pipe 1·0mm. long by 18mm. wide, closed at one end and provided at the top with a stopper through which two glass tubes are inserted. Through one tube, reaching nearly to the bottom, cold water is allowed to flow into the pipe, which escapes through the second. The apparatus is inserted into the flask, which contains the mass to be

work at  $o$ ,  $p$  and  $q$ . A part of the water enters at  $o$ , then flows along the tube  $b$  and enters through a small canal at  $r$  into the water vessel  $E$ . A second stream enters at  $p$ , passes along the barometer tube  $D$  and  $s$  into the water vessel through  $t$ . The small wide tube  $u$  hangs by threads on  $t$  and is useful in preventing the spitting occasioned by the air bubbles passing down  $t$ . A third stream enters at  $q$  into the double rubber tube  $g$  and goes towards  $E$  through the rubber tube  $ac$ . In this way all parts of the apparatus are kept at the same constant temperature. The gas is measured in the glass ball  $C$ , at constant volume, determined by a mark on the neck, and is transferred for absorption of oxygen to the gas pipette  $B$  which contains pyrogallate of potash.

—G. H. B.

On a Lacmoid. M. C. Traub and C. Hock. Ber. 17, 2615.

THE authors prepare a colouring matter closely resembling litmus in the following manner:—100 parts of resorcinol, 5 parts sodium nitrite, and 5 parts of distilled water are slowly heated in an oil-bath to  $110^{\circ}\text{C}$ . A vigorous reaction sets in, and the contents of the flask become red; when the reaction has moderated the mixture is heated to  $115-120^{\circ}$ , till the evolution of ammonia has ceased and the melt has become blue. It is then dissolved in water and precipitated by  $\text{HCl}$ . The product is a glistening reddish-brown powder, which is insoluble in chloroform, benzol, and petroleum spirit, easily soluble in methyl-, ethyl-, and amyl-alcohols, less soluble in ether and water. In all its properties it closely resembles the colouring matter of litmus, with which it is possibly identical. It can be conveniently used as a substitute for the latter as an indicator.

—A. G. G.

The Lacmoid as an Indicator. M. C. Traub. Arch. d. Pharm. [3], 23, 27-29.

THE lacmoid prepared from resorcinol is a very useful indicator, being more delicate than ordinary tincture of litmus, and capable of more general application than phenolphthalein, whilst it can be very readily prepared. The indicator solution is prepared by dissolving  $\frac{1}{2}\text{gm.}$  of the lacmoid in a mixture of 50cc. of alcohol (96 per cent.) and 50cc. of water. Blue test paper is prepared from a solution containing  $\frac{1}{2}\text{gm.}$  of the lacmoid dissolved in a mixture of 500cc. of alcohol and 500cc. of water and five drops of a solution of  $\text{KOH}$ .—A. G. G.

An Improvement in the Apparatus used for Precipitating Copper by Electrolysis. H. C. Foote. American Chem. Journ. vol. 6, No. 5.

THE author has devised a piece of apparatus for electrolytic determinations of copper, which possesses the advantage of maintaining a regular current of proper

wires sunk into it, so that no wires are visible above the board save the ones connected to the platinum strips dipping into the dishes. The current enters at  $a$  and passes to  $c$ , where it enters a switch, from which it may be made to pass directly to a switch at  $g$ ; or it may be made first to traverse either one of the coils  $m$ ,  $n$ , on its way, by a simple movement of the switch handle above the board. From  $g$  it may be made to pass through  $h$  to the switch at  $r$ ; or by connecting the switch with  $i$ ,  $k$  or  $l$ , the current will first traverse one, two or all of the coils  $o$ ,  $p$ ,  $q$ , and when it reaches  $r$  it will have the required strength. The coils have the following lengths of fine iron wire respectively:  $m$ ,  $1\frac{1}{2}$  meters;  $n$  and  $o$ , 3

FIG. 2.

meters each;  $p$  and  $q$ ,  $4\frac{1}{2}$  meters each. More coils may be added if it is desirable; but with the arrangement shown in the cut a resistance of  $1\frac{1}{2}$  meters may be obtained, which may be increased, by additions of  $1\frac{1}{2}$  meters each, up to 15 meters, by properly manipulating the switches  $e$  and  $g$ . For example: If the switch  $e$  be connected with  $c$ , and the switch  $g$  with  $i$ , the current will pass through  $4\frac{1}{2}$  meters of the iron wire. The board shown in the cut is arranged for only three dishes, but it will be readily seen that any number might be added. As the battery grows weaker, or as dishes are removed or added to the circuit, the strength of the current is kept uniform by manipulating the switches. This might be made to work automatically. The switch  $r$ , with its connections  $s$ ,  $t$  and  $u$ , make it possible to use one, two or all of the dishes. If only one dish is to be used, the connection is made with  $s$ , and the current passes through the cylindrical copper connection  $v''$  (see also Fig. 2,  $v$ ) to the platinum, and finally through  $x'$  to  $b$ . If two dishes are to be used, the switch  $r$  is connected with  $t$ , and the current passes first to the dish over  $v'$ , thence through the platinum strip to  $x'$ , and then to the second dish over  $v''$ . When all the dishes are to be used, connection must be made with  $u$ . The method of automatically regulating the current in the case of removing a dish from the circuit, is shown by Fig. 2—a coil of fine iron wire  $w$ , equal to the resistance of the solution in a dish placed under the board, and near each dish. Through the centre of the piece of platinum  $3, 4$ , upon which the precipitating dish rests when in connection with the current, is a small hole, which is continued down through the board, and lined with a piece of copper pipe  $v$ , which is soldered to the platinum to make the connection. A short stick of wood  $5, 6$ , passes through

FIG. 1.

strength for several days, without a change of the battery fluids becoming necessary. The platinum dishes are arranged on a board, as shown in section by Fig. 2. The current from the battery is made to pass through a certain number of coils of fine insulated iron wire before it passes to the platinum dishes. Fig. 1 shows the under side of the board with the resistance coils and connecting

the pipe, and is so arranged with a spring  $1, 2$ , that when the resistance coil  $o$  is in the circuit, the stick protrudes slightly above the platinum foil. When, however, a dish is placed upon the board it pushes down, by its weight, the stick  $5, 6$ , removing the strip  $1, 2$ , from contact with  $r$ , thus disconnecting the resistance coil, and at the same time causing the current to pass

from  $v$ , through the solution and platinum strip to  $r$ . When a dish is removed, the current through  $s$ ,  $r$ , is, of course, broken, and the spring 1, 2, comes in contact with  $r$ , making the connection with the resistance coil, which, being equal to the resistance in the dish, keeps the current the same in the other dishes. If two dishes are to be used, and the solution is only ready for one, the switch  $r$  is connected with  $t$ , and the dish which is ready is placed on the platinum above  $r'$ . The current will then pass from  $t$  to  $r'$ , and through the strip 1, 2, to the resistance coil  $w'$ , and then through  $x'$  to  $r'$ , and finally through the liquid to  $x''$  and  $b$ . When ready to add the second dish to the circuit, it may be done by simply placing the dish in its place over  $r'$ , when it will automatically disconnect the resistance coil  $w'$ ; and the strength of the current will remain the same, and sufficient for both dishes. Either one of the two dishes may now be removed at any time without altering the strength of the current, or in any way interfering with the work of the other dish in the circuit. The third dish may also be added at any time, by simply changing the switch  $r$  from  $t$  to  $u$ , and manipulating the switches  $e$  and  $g$ , so as to increase the current sufficiently. In the same manner, any number of dishes may be used. The strength of the current may be ascertained by passing it through acidulated water, in an inverted tube, graduated in  $cc$ ., and noting the amount of mixed gases liberated in a minute.—J. B. C.

*The Detection of Iodine in Presence of Large Quantities of Bromine.* P. S. Brito. Chem. News, 50, 210.

If bromine and iodine be liberated by chlorine and the solution shaken up with chloroform, the violet colour of the iodine will be masked by the brown colour of the bromine when a large quantity of the latter is present. The violet at once appears on addition of ferrous sulphate. —J. B. C.

## New Books.

NEUE METHODEN ZUR ANALYSE DER GASE. Von Dr. WALTHER HEMPEL, Professor am Königl. Polytechnikum zu Dresden. Mit in den Text eingedruckten Holzstichen. Braunschweig: Druck und Verlag von Friedrich Vieweg und Sohn, 1880.

This work, important to all interested in technical gas analysis, is an 8vo volume, bound in paper cover and containing 129 pages of subject-matter, a table of contents, and twenty-two admirable woodcuts illustrating the apparatus in detail and in combined forms so as to indicate methods of working.

The Table of Contents will best illustrate the plan and method of the whole work. **FIRST PART—ON TECHNICAL GAS ANALYSIS. I. General; II. Analysis by Absorption.**—Description of the Apparatus. THE GAS-BURETTES: A, the Simple Gas-burette; Mode of Handling the Gas-burette; The Modified Winkler's Gas-burette, B., THE ABSORPTION-PIPETTES, B., The Simple Absorption-pipette for Solid and Liquid Reagents, C, THE COMBINED ABSORPTION-PIPETTES—The Combined Absorption-pipette, C<sub>1</sub>. The Combined Absorption-pipette for Solid and Liquid Reagents, C<sub>2</sub>. Handling the Absorption-pipettes. General Details concerning the Conducting of Absorption-analyses. Recorded Analyses. Special Details on the Estimation of the Simple Gases: 1, Carbonic Acid; 2, Carbonic Oxide; 3, Oxygen; 4, Heavy Hydrocarbons. **III. Analysis by Combustion.**—1. The Combustion by Explosion. General Description of the Apparatus. The Explosion-pipette. 2. The Absorption of Hydrogen with Palladium. 3. Fractional Combustion. **SECOND PART—ON AN EXPEDITIOUS AND EXACT GASOMETRIC METHOD. IV. General Description of Apparatus.**—The Measuring Bulb. The Adjustable Mercurial Niveau C. The

Gas-pipettes. Handling the Apparatus. Measuring. The Absorptions. Recorded Analyses. V. The Mercurial Trough without Barometric Tube.

ACETIC ACID AND VINEGAR, AMMONIA AND ALUM. (Churchill's Technological Handbooks.) London: J. & A. Churchill, 11 New Burlington Street, 1885.

SMALL 8vo volume bound in cloth. As the preface shows, the work is edited by Mr. JOHN GARINER, F.I.C., F.C.S. It contains 193 pages of subject-matter, short table of contents, and an alphabetical index, and is illustrated with twenty-eight woodcuts.

The first chapter of the book is devoted to ACETIC ACID AND VINEGAR, and this includes a description of the process of carbonising wood in close retorts and obtaining pyroigneous acid. The second chapter deals with AMMONIA, and the third with ALUM AND ALUM-MARKING.

## Monthly Patent List.

### ENGLISH APPLICATIONS.

1885.

#### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

3397 L. H. Pearce, London. Improved means for heating liquids, applicable also for vapourising and distilling the same. March 20

3731 E. B. Petrie and A. S. Fox, Manchester. An improved composition to be applied to straps, belts, ropes, and brakes used in and in conjunction with machinery, which composition is also applicable to other articles for the purpose of protecting and preserving them from injury arising from moisture or exposure to the atmosphere. March 23

3736 W. R. Lake. Improvements in and relating to steam-boiler and other furnaces. Communicated by L. Broussas, France. March 23

3896 J. H. Johnson, London. Improvements in furnaces for burning pulverulent materials. Communicated by M. Perret, France. March 26

3921 L. W. Sutcliffe, London. Improvements in self-feeding and smoke-consuming furnaces and appliances for heating muffles and drying stoves and for other like purposes. March 27

4018 F. W. Gordon, London. Improvements in hot blast stoves. Complete specification. March 31

4270 G. H. Lilley, London. Improvements in mills for reducing solid crystalline substances to powder. April 7

4377 T. W. Barber, Ulverston, Lancashire. Improvements in hot blast apparatus. April 9

4580 J. McInnes, Glasgow. An improved tube for transmitting air or other fluids under pressure. April 11

4613 R. McQueen Weir, Boone, Iowa, United States. Furnaces. April 11

4619 A. M. Clark, London. Improvements in stone and ore crushers. Communicated by D. Brennan, jun., and G. G. Young, United States. Complete specification. April 11

4695 J. S. Booth, London. Improvements in the construction of boiler and other furnaces. Complete specification. April 13

4710 M. Keenan, London. An improved non-conducting composition for protecting boilers, cylinders, pipes, and other objects against radiation. April 16

4711 M. Keenan, London. Improvements in means for protecting boilers, cylinders, pipes, and other objects against radiation. April 16

4834 C. Jones, London. Improvements in apparatus used when heating vessels or chambers by steam-heated jackets. April 18

4835 P. Jensen, London. A system or combination of pumps for producing vacuum. Communicated by L. A. Riedinger, Germany. April 18

4889 F. Maxwell-Lyte, London. Improvement in crucibles, muffles, and other refractory apparatus. April 20

#### II.—FUEL, GAS, AND LIGHT.

3683 S. Clarke, London. Improvements in the manufacture of night-lights. March 21

3776 A. H. Reed, London. An improvement in the manufacture of hydrogen gas. Communicated by G. E. Moore, United States. Complete specification. March 21

3790 W. Black, Glasgow. Improvements in the manufacture of briquettes or fuel blocks. March 21

3870 R. Dempster, jun., Manchester. Improvements in the construction of condensers used in the manufacture or purification of gas. March 26

3808 A. T. D. Berrington, Ebbw Vale, Monmouthshire. An improved method of regenerating waste gases. March 27  
 1882 G. Brownen, London. Improvements in the manufacture of candles and night lights, and in the preparation of oil or spirit, to cause disinfecting or deodorizing vapours to be given off from them when burnt. March 31

4119 G. L. O. Davidson, Manchester. Improvements in the construction of apparatus for washing or purifying smoke. April 2

4111 W. Black, Glasgow. An improved process of treating coal dust and other carbonaceous substances. April 9

4164 A. Klonne, London. The improvement in gas-washers called column-washers. April 10

4153 J. Roots, London. An improved method of treating illuminating oils to increase brilliancy of flame. April 13

41616 A. M. Clark, London. Improvements in, and in furnaces for, manufacturing illuminating gas. Communicated by F. F. Fisher, United States. April 11

4178 S. Butler, London. Improvements in the manufacture of artificial fuel, and in machinery employed therein. April 18

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, ETC.

4011 J. A. B. Bennett, Birmingham. Improvements in the method of introducing steam and other vapours and gases into carbonaceous matter during the process of distillation. March 31

### IV.—COLOURING MATTERS AND DYES.

3803 H. J. Haddon, London. Colouring matters obtainable by the combination of tetrazoditoyl or tetrazodixilyl-salts with alpha- and beta-naphthylamine or their mono- and disulpho-acids, and process for the manufacture of the same. Communicated by F. Bayer & Co., Germany. March 21

3889 J. Murray, London. Manufacture of blue and violet colouring matters by oxidation of the thio-bases of diamines. Communicated by J. Housbousson, France. March 23

4156 J. H. Johnson, London. The preparation of alkalisal oxy-derivatives of a base resembling a chinoline base. Communicated by Dr. A. Scheidel, Italy. April 13

### V.—TEXTILES, COTTON, WOOL, SILK, ETC.

3632 P. Frankenstein, Manchester. Improved finish in colours on waterproof fabrics. March 21

3628 C. Moon, London. Making textile fabrics fireproof, and at the same time waterproof, yet allowing free ventilation. March 23

### VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

3718 W. Mather, London. Process for bleaching cotton yarns and fabrics. Complete specification. March 23

4115 J. Farmer, Manchester. Improvements in the construction of apparatus employed for washing, coloring, scouring, soaping, dunging, and dyeing woven fabrics. Partly communicated by A. Lalancé, Germany. April 2

4251 J. Barnes, Manchester. Improvements in dyeing cotton and other vegetable fibres, and yarns and fabrics composed thereof. April 7

### VII.—ACIDS, ALKALIS, AND SALTS.

3761 W. P. Thompson, Liverpool. Improvements in the extraction of phosphorus from phosphide of iron or ferro-phosphor. Communicated by L. Imperatori, Germany. March 21

3846 R. Biggs and T. Terrell, London. Improvements in decomposing sulphate of iron and in obtaining sulphuric acid, sulphurous acid, and red oxide of iron thereby. March 25

3865 J. Anderson, Dundee. Improvements in the manufacture of sodium. March 26

3886 J. J. Hood, London. Improvements in the manufacture of chromates and bichromates. Complete specification. March 26

3833 F. S. Newall, London. Improvements in the treatment of alkali waste by other materials in order to obtain useful products. March 27

3834 F. S. Newall, London. Improvements in obtaining sulphur from sulphuretted hydrogen. March 27

4092 E. F. Trachsel, London. An improved method or process of producing carbonate of sodium. March 31

4101 D. H. Lowry, Liverpool. An improved caustic drum lid or appliance for closing small hand holes. April 1

4138 F. Maxwell-Lyte, London. Improvements in the manufacture of sodium aluminate and other aluminous compounds, and in the utilisation of gases resulting therefrom, and in the construction of furnaces used in the manufacture of sodium aluminate. April 1

4163 H. W. Todd, Liverpool. Improvements in or pertaining to caustic or other drum lids or closers. April 2

4175 F. J. B. Raken, London. An improved method of manufacturing carbonic acid (dry) under any desired pressure. Communicated by Dr. J. H. Fiebig and J. F. Beims, Holland. Complete specification. April 2

4261 A. McDonald Graham, Lewisham, Kent. Improvements in the manufacture of the sulphates of manganese and ammonia. April 7

4274 H. Gaskell, Jun., London. Improvements in the treatment of bicarbonate of soda for obtaining useful products therefrom. April 7

4285 G. Attwood, London. An improved method and means for the continuous oxidising and desulphurising of ores or minerals. April 7

4290 W. J. Chrystal, Glasgow. Improvements in the manufacture of chlorides and bichlorides. April 7

4136 C. Wigg, Liverpool. Improvements in apparatus for the manufacture of carbonate of soda. April 10

### VIII.—GLASS, POTTERY, AND EARTHENWARE.

3886 R. Boote, London. Improvements in the manufacture of pottery ware. March 26

3897 J. H. Johnson, London. Improvements in the manufacture of artificial stone. Communicated by I. Brandstatter, Austria. March 26

4181 G. F. Redfern, London. Improvements in or applicable to flating furnaces employed in the manufacture of cylinder glass. Communicated by E. Masquelier, Belgium. April 2

### IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

3916 E. Ormerod and W. C. Horne, London. Improvements in rendering cements luminous and damp proof. March 27

3932 J. Loman, London. Improvements in fireproof floors. March 27

4151 W. E. Heys, Manchester. Improvements in the manufacture of fire and waterproof boards or paper from asbestos. Communicated by E. Ladewig, Germany. Complete specification. April 2

4308 C. H. Murray, London. Improvements in means or apparatus for making bricks or other forms of clay or plastic materials. April 9

4111 W. Tapp, Bristol. A new or improved construction of tiles for stairs. April 10

4186 E. Ormerod, London. Improvements in apparatus and mode for the production of paving slabs, blocks, sinks, man-holes, roofing tiles, and other similar articles in concrete, in terra-cotta and other similar materials. April 11

### X.—METALLURGY, MINING, ETC.

3361 J. Smith, Stoke-upon-Trent. The manufacture of a new method for polishing or brightening metal. March 20

3823 P. M. Parsons, London. Improvements in the manufacture of ordnance. March 20

3721 W. H. Tooth and J. E. Rooke, London. Improvements in furnaces and apparatus employed in the manufacture and refining of iron and the conversion of iron into steel. March 23

3737 E. Morewood, London. Improvements in the manufacture of iron or other metal into sheets, plates, or other forms, and in stretching or extending or improving the surface of such sheets, plates, or other forms. March 23

3758 E. Morewood, London. Improvements in coating with tin, terne, or other coating metal, sheets, plates, or pieces of iron or other metal. March 23

3808 W. E. Wynne, London. A new and useful improvement in the manufacture of steel. Communicated by H. W. Oliver, Jun., and J. P. Witherow, United States. Complete specification. March 24

3830 W. L. Wise, London. A method or process for the extraction of precious and other metals from millstone and other analogous stones or rocks. Communicated by V. Popp, France. March 25

3923 H. Wiggins (M.P.), H. A. Wiggins, A. S. Johnstone, and W. W. Wiggins, London. Improvements in the manufacture of nickel and cobalt. March 27

3889 R. A. Gilson, W. J. Boor, and G. Smith, London. Improvements in ovens applicable for heating iron castings preparatory to annealing them, and for other purposes. March 28

4016 M. Vescemayer, London. Improvements in the method of collecting "float gold" in mining operations. March 30

4088 E. Matheson, London. Improvements in the manufacture of tinned or galvanised metal plates and like articles. Communicated by E. V. McCandless, United States. March 31

4228 T. Bayley, Birmingham. A method of manufacturing oxide of iron and obtaining other useful products. April 7

4164 G. F. Redfern, London. Improvements in treating auriferous and other metalliferous sand and dust and apparatus therefor. Communicated by A. Clement and G. Perret, Italy. April 7

4371 W. R. Lake, London. Improvements relating to the electrolysis of vegetable, tanning, and other substances. Communicated by E. Quintallet and A. T. Mabu, France. April 8

4117 A. Lavroff and A. Schensnovich, London. Improvement in anti-friction metal called Lavroff's phosphorous anti-friction metal. April 9

4174 C. D. Abel, London. Improved mode of and apparatus for utilising the waste gases of puddling and reheating furnaces. Communicated by F. C. Glaser, Germany. April 10

4178 W. E. A. Hartmann, Swansea. Improvements in treating waste liquors from the manufacture of tinplates. April 10

4198 W. A. Thoms and H. F. Oddy, London. An improvement in the coating of metals with an electro deposit of platinum. April 11

4263 F. W. Gardner, Wolverhampton. Improvements in utilising blast furnace slag. April 11

4374 W. P. Thompson, Liverpool. Improvements in processes applicable for extracting phosphates from phosphatic slags. Communicated by G. Hoyermann, Germany. April 11

4063 P. Thompson and M. H. Simpson, London. Improvements in machinery for breaking pig-iron. April 11

4706 W. E. Gedge, London. Improvements in the manufacture of metallic lead from the sulphurous ores thereof. Communicated by S. Trayner, Spain. April 16  
4711 F. J. P. Cheesbrough, Liverpool. An improved process for the manufacture of iron and steel direct from the ore with gaseous fuel, and apparatus employed therein. Communicated by A. Hansen, Germany. April 17  
4752 T. Cooper, London. Improved apparatus for the manufacture of chilled castings. April 17

# XI.—FATS, OILS, AND SOAP MANUFACTURE.

3703 T. Rowley, II. Grimshaw, and J. H. Kidd, Manchester. Improvements in the treatment of oils used in the manufacture of floorcloths, and for other purposes. March 23  
3855 C. T. Kingzett, London. Improvements in the production of compounds or mixtures to be used for the destruction of insects, also for washing animals, and generally as soaps or detergents, and for purifying purposes. March 25  
3891 C. T. Kingzett, London. Improvements in the production of liquid soaps and other liquids which may be usefully employed as insecticides, also for washing animals, and for preserving and general purifying purposes. March 26  
3977 L. A. Groth, London. A new or improved method of scouring or removing the oil from animal and vegetable substances by means of infusorial earth and heat. Communicated by A. Eberz, Germany. March 28  
4090 G. Payce, London. An improved process of refining glycerine. March 31

# XII.—PAINTS, VARNISHES, AND RESINS.

3839 E. V. Gardner, London. Improvements in the manufacture of white lead, and in apparatus to be employed therefor. March 25  
4313 H. J. Allison, London. An improved substance for lining or covering steam boilers, pipes, and other objects. Communicated by S. Hollman, Mann & Co., Hamburg. April 8  
4415 P. Dennison, Glasgow. An improved anti-fouling and anti-corrosive composition for ships and submerged structures. April 9

# XIII.—TANNING, LEATHER, GLUE, AND SIZE.

4778 H. S. Barrow, J. Bostock, and G. A. Hardy, London. An improved finishing machine for leather. April 15

# XIV.—AGRICULTURE, MANURES, ETC.

4748 T. H. Selater, Kirkwall, Orkney. A new or improved combined insect destroyer and soil fertilizer. April 17

# XV.—SUGAR, STARCH, GUM, ETC.

3751 W. Walker, London. Improvements in apparatus for extracting the water of condensation from sugar boiling apparatus. March 21  
4322 A. Cook, Glasgow. Improvements in apparatus for reducing or disintegrating sugar canes or other vegetable substances. April 8  
458 B. H. Remers, Glasgow. Improvements in the manufacture of starch and in apparatus employed therein. Communicated by L. von Wagner and A. Gyllitzer, Austria. April 17

# XVI.—BREWING, WINES, SPIRITS, ETC.

3706 J. H. Loder, Utrecht, Netherlands. Improvements in the manufacture of alcoholic beverages. March 23  
3768 J. Clayton, London. Improvements in apparatus for lifting malt liquors. March 21  
4068 W. Lawrence, London. Improvements in the manufacture of beer and malt liquors, and in apparatus for the treatment and preparation of materials for the same. March 31  
4524 J. Death, jun., Cheshunt. Improvements in grain and its preparation for use in brewing and distilling, and for feeding purposes. April 13

# XVII.—FOOD PRESERVING, MEATS, ETC.

4823 H. J. Haddad, Westminster. Process and compound for preserving eggs. Communicated by P. G. Wind and C. C. Lassen, Germany. April 15

# XVIII.—SANITARY CHEMISTRY, DISINFECTANTS, ETC.

3682 J. R. Shepland, London. An improved method of and means or apparatus for purifying sewage and other liquids. March 21  
4046 A. Engle, Liverpool. Destroying and utilising sewage in buildings, towns, and cities. Complete specification. March 31  
4082 G. Brownen, London. Improvements in the manufacture of candles and night-lights, and in the preparation of oil or spirit, to cause disinfecting or deodorising vapours to be given off from them when burnt. March 31  
4207 W. H. Beck, London. Improvements in processes for treating sewage and other waste waters for obtaining the fats, fatty acids, and fibrous matter contained in the same, and in apparatus to be employed therewith. Communicated by JI.

Wagener and Prof. Dr. A. Muller, Germany. Complete specification. April 2  
4473 E. Langen, London. Method of and apparatus for treating semi-liquid substances with purifying or other liquids. April 10  
4532 J. W. Slater, London. Improvements in the treatment of sewage and water polluted with organic matter. April 13  
4677 T. Stoer and J. Turton, Bradford. A combined disinfecting and fumigating compound. April 16  
4711 H. J. Haddon, London. A method of disinfecting. Communicated by G. Langbein, Saxony. April 16  
4802 J. B. Austin, London. Improvements in the manufacture of disinfecting powder. April 18

# XIX.—PAPER, PASTEBOARD, ETC.

3921 G. P. Barnes, Dulwich. Improvements in the manufacture of paper and in machinery therefor. March 27  
3980 D. C. Simpson, Glasgow. A new or improved process of preparing paper or similar materials to render indelible writings or other markings thereon. March 28  
3982 H. H. Lake, London. An improved method or process of sizing paper pulp. Communicated by L. Lacoste, France. March 28  
4176 W. Manning, London. Improvements in the process of treating gypsum or sulphate of lime for use in the manufacture of paper, and for other purposes. April 2  
4569 A. McDougall, Penrith. Improvements in the construction of boilers or other vessels used in the conversion of woolly or other fibres into pulp for the manufacture of paper or other articles prepared from pulped fibres. April 11

# XXI.—EXPLOSIVES, MATCHES, ETC.

3202 R. Punshon, London. Improvements in safety blasting cartridges and detonators. March 20  
3918 W. F. Ruston, London. Improvements in detonating gas signals for railways. March 27  
4547 C. D. Abel, London. An improved manufacture of nitrate of ammonia explosives. Communicated by F. Barbe, France. April 13  
4833 J. Paulin, London. Improvements in caps or apparatus for exploding dynamite. Complete specification. April 20

# ENGLISH PATENTS PUBLISHED,\* APPLIED FOR DURING 1881.

# I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

5034 W. R. Lake. Improved method of distillation and apparatus therefor. Communicated by F. König, Italy. 6d  
8320 J. P. Jackson. Apparatus for filtering liquids. 6d  
857 H. H. Lake. Communicated by Schulz, Knaut & Co. Gas-generating furnaces. 1d  
8777 J. H. Johnson. Process and apparatus for producing cold. Communicated by J. C. Rossi, United States. 10d  
15099 L. A. Groth. Communicated by W. Backer. Improvements in gas-producer furnaces. 1d

# II.—FUEL, GAS, AND LIGHT.

7156 D. Tildesley. Apparatus for injecting fuel and hot air into furnaces, and for injecting liquid and solid matter into retorts for gas-making, etc. 6d  
8408 B. and W. P. Gibbons. Fire-clay gas retorts. 6d  
8633 W. S. Sutherland. Improvements in and applicable to gas-producers. 6d  
8341 H. E. Newton. Preventing stoppages in the ascension pipes in the manufacture of coal-gas. Communicated by Klönne. 1d  
8751 J. Cort. Adjustable dip pipes for the manufacture of gas. 6d  
12457 L. A. Groth. Treatment of petroleum. Communicated by T. N. Fiesch. 2d  
1885.

915 F. J. Jones. The production of combustible gases from finely-pulverised coal, peat, wood-sawdust, etc. 1d  
2169 A. Dempster. Purifying coal-gas. 1d

# III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, ETC.

6995 B. J. B. Mills. Apparatus for carbonising bones and turf, and for coking and distilling brown-coal, pit-coal, and other carbonaceous materials by means of superheated steam. Communicated by A. Zwillingner, Vienna. 6d

# IV.—COLOURING MATTERS AND DYES.

6311 C. D. Abel. Violet colouring matter. Communicated by Lucius and Brüning, Germany. 2d

\*Any of these specifications may be obtained by post, by remitting the cost-price, plus postage, to Mr. H. Reader Lusk, Controller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 2s.	1d.
Above 2s. and not exceeding 1s. 6d.	1d.
1s. 6d. " "	1d.
" 2s. 4d. " "	2d.
" 3s. 4d. " "	2d.

874 C. D. Abel. Manufacture of colouring matters suitable for dyeing and printing. Communicated by Lucius and Brunn, Germany. 1d

8806 A. M. Clark. Process of combining certain diazo compounds with phenols and their sulphoacids for the production of colouring matters. Communicated by R. Krueger and the Farbwerke vormals Bronner, Frankfurt. 4d

1885.

275 E. Passbury. Process and apparatus for drying colour paste and other strongly aqueous materials. 6d

## V.—TEXTILES: COTTON, WOOL, SILK, ETC.

8893 R. S. Moss. Waterproof materials for wearing apparel and other purposes. 2d

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

5887 J. Welter. Manufacture of antioxidant compounds suitable as mordants in dyeing and printing. Communicated by M. H. Vogel, Leipzig. 4d

8699 W. Mather. Improvements in bleaching, and in apparatus for the purpose. 6d

8179 F. A. Gatty and F. A. Gatty. Bleaching certain classes of cotton fabrics. 1d.

1885.

86 H. Gieseler. Apparatus for washing, scouring, bleaching, dyeing, etc., fibrous material in the form of slubbing slivers, rovers, or yarn. 6d

1912 W. Mather. Apparatus for steaming in the bleaching of fibres, fabrics, and yarns. 1d

## VII.—ACIDS, ALKALIS, AND SALTS.

5898 W. R. Lake. Manufacture of ammonia, and apparatus therefor. Communicated by La Societe Lorraine Industrielle. 8d.

7258 E. Solvay. Manufacture of chlorine. 4d

7259 E. Solvay. Manufacture of chlorine and chloride of lime. 4d

7260 E. Solvay. Manufacture of hydrochloric acid. 1d

7253 C. Wigg. Manufacture of carbonate of soda. 1d

8296 T. Higgin. Apparatus for disintegrating and removing impurities from lump salt. 6d

8240 H. J. Hadden. Process for the partial separation of Schaffer's monosulpho acid from the alpha-monosulpho acid of beta-naphthol. Communicated by Bayer & Co., Elberfeld, Germany. 1d

11886 J. Meikle, jun. Purifying sulphuric and sulphurous acids and their salts. 2d

1885.

1868 W. R. Lake. The protection of nitrate of ammonia against deliquescence. Communicated by R. S. Penniman. 2d

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

7111 J. Watson and J. L. Spoor. Kilns employed in the manufacture of Portland cement. 4d

8296 G. Walker. Asphalting for road-paving, etc. 2d.

8317 J. Fottrell. Hygienic concrete for paving, etc. 4d

1885.

897 A. J. Bonit. Manufacture of tiles and other articles from plastic materials, and apparatus therefor. Communicated by F. C. A. Meite. 6d

2161 H. Faija. Means or apparatus for treating slurry or slip in the manufacture of Portland cement and bricks. 6d

## X.—METALLURGY, MINING, ETC.

5166 A. W. Anderson. Facilitating the dissolution of metallic lead. 6d

7206 J. Hargreaves and T. Robinson. Treating ores and substances containing antimony to obtain metallic antimony and other products, and appliances employed therein. 1d

7194 W. E. Thomas. Purification of iron ores and of iron by the basic process. Communicated by R. Schliwa, Dortmund. 4d

7707 H. J. Hadden. Manufacture of castings from furnace slag. Communicated by L. Perin, St. Arnaud. 6d

8013 A. Atwood and T. W. Barber. Charging blast furnaces. 6d

8053 S. J. Coxeter and H. Nehmer. Manufacture of silico-carbon. 1d

8093 G. Bischof. Manufacture of spongy iron, and apparatus employed therefor. 1d

8295 J. A. Mays. Method of amalgamating or separating metals from their ores. 6d

8355 A. M. Clark. Preparing or treating copper. Communicated by W. Braun, Germany. 1d

8490 F. Siemens and J. G. Gordon. Reduction of iron ores and production of iron and steel. 2d

8192 F. Siemens and J. G. Gordon. Manufacture of iron and steel. 2d

8627 W. A. Vêrel and P. Stewart. Obtaining copper, silver and gold from copper matte or regulus. 2d

8679 J. Mason. Treatment of the oxides of iron from iron pyrites or other sources, so as to render them more suitable for employment in the blast or other furnace. 6d

13071 J. Simpson and E. W. Parnell. Obtaining gold and silver from antiferrous and argenteriferous sulphide of antimony ores. 2d

16651 F. W. Gerard and J. Smith. Depositing magnesium and its alloys. 2d

16652 F. W. Gerard and J. Smith. Depositing calcium and its alloys. 2d

16653 F. W. Gerard and J. Smith. Depositing aluminium and its alloys. 2d.

1885.

1917 W. R. Lake. Process for annealing copper or its alloys. Communicated by I. Wallace. 2d

1951 R. Schliwa, L. Gildencrout, and R. Feldmann. Treating iron in the Bessemer converter or similar apparatus, for the elimination of silicon, phosphorus, and sulphur, and for the formation of slags containing phosphoric acid soluble in water. 2d

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

4679 B. Davy. Method for extracting grease from soap water. 2d

7573 J. W. Freestone. Separating glycerine from animal and vegetable substances. 4d

9012 W. Rodiger. Manufacture of soap. 1d

9575 A. Domicer and B. Nickels. Manufacture of soap. 1d

13512 J. Seeger. Improvements in lubricating oils. 2d

16106 M. Kerr. Washing and cleansing liquid. 2d

1885.

1399 W. G. Radley. Preparation of oils for medicinal purposes. 2d

2100 H. H. Lake. Process of purifying fat and oil. Communicated by J. P. A. Larson. 1d

## XIV.—AGRICULTURE, MANURES, ETC.

7502 F. W. Harbord. Manufacture of phosphates. 4d

7963 P. M. Justice. Treating or enriching phosphates of calcium or lime. Communicated by W. H. Kenn, Luxembourg. 2d

8680 R. R. Kelly and A. C. L. Weigel. Manufacture of sulphate of ammonia and by-products resulting from the process. 1d

## XV.—SUGAR, STARCH, GUM, ETC.

7982 C. D. Abel. Obtaining sugar from saccharine substances. Communicated by Dr. L. Harperath, Cologne. 4d

8036 A. M. Clark. Process for hardening balsams, resins, and resinous compounds or products. Communicated by A. K. Kissel and C. Zimmer, Germany. 1d

8502 J. Murray. Apparatus for osmotic treatment of saccharine liquors. Communicated by H. Leplay, Paris. 6d

1972 C. A. Day. Means and apparatus for bleaching sugar. Communicated by E. O. Foster. 4d

2553 H. J. Chapin. Apparatus or devices for the treatment of sugar-cane. 6d

## XVI.—BREWING, WINES, SPIRITS, ETC.

7178 M. Hedicke. Utilisation of hops in the manufacture of intoxicating beverages other than beer. 2d

7881 A. Schriber. Treatment of malt and other grain. 6d

7881 R. E. Ratlock. Treatment of alcoholic spirits. 2d

1885.

2208 W. R. Lake. Preparation of food for animals from the refuse of breweries or of starch and glucose factories, and apparatus therefor. Communicated by F. W. Wiesebroek. 5d.

## XVII.—PRESERVING FOOD, MEATS, ETC.

1885.

1531 C. Russell. Preserving meat. Communicated by A. Losasco, Calcutta. 2d

## XVIII.—SANITARY CHEMISTRY, DISINFECTANTS, ETC.

7198 S. K. Page, C. E. Robinson, and W. Stevens. Apparatus for use in the treatment of sewage, etc. 6d

7731 E. H. Cook. Preventing the emission of metallic vapours, compounds of metal, sulphur dioxide, or other vapours, from the chimneys and flues of chemical or other works. 1d

8212 E. and A. Ashby. Process and apparatus for deodorising the fumes of cement and other kilns. 6d

14561 J. Y. Johnson. A new or improved disinfectant. Communicated by E. O. Beck, Paris. 4d

## XIX.—PAPER, PASTEBOARD, ETC.

7511 J. H. Johnson. Bleaching paper pulp or other materials. Communicated by J. B. Jessy, St. Etienne. 6d

11887 T. G. Young and J. Pettigrew. Treating vegetable substances in order to obtain pulp for making paper, etc. 4d

## XXI.—EXPLOSIVES, MATCHES, ETC.

7133 A. Schröder. Apparatus for manufacture of nitro-glycerine. 6d

12292 E. Luck and F. B. W. Roberts. Manufacture of explosives and treatment of materials employed therein. 4d

1885.

1171 J. H. Johnson. Marine torpedoes, etc. Communicated by—Howell. 10d

#### NOTICES.

In accordance with the provisions of Rule 18 of the Bye-laws, notice is hereby given that those members of Council whose names are placed in italics in the annexed list, will retire from their respective offices at the forthcoming Annual General Meeting.

Mr. Edmund K. Muspratt has been nominated to the office of President, and Dr. W. H. Perkin, F.R.S., has been nominated Vice-President under Rule 11.

Mr. I. Lowthian Bell, F.R.S., Dr. Peter Griess, F.R.S., Mr. John Spiller, and Mr. E. C. C. Stanford have been nominated Vice-Presidents under the provisions of Rule 8; and Sir Bernhard Samuelson, Bart., M.P., and Dr. S. A. Sadler have been nominated ordinary members of Council in the place of Dr. Peter Griess, F.R.S., and Mr. John Spiller, nominated Vice-Presidents under the provisions of Rule 17.

The Treasurer and Foreign Secretary have been nominated for re-election.

Members are hereby invited to nominate fit and proper persons to fill the four vacancies thus created among the ordinary members of Council, in accordance with the provisions of Rule 18. Nomination forms for this purpose can be obtained from the General Secretary upon application.

Members are hereby informed that the Annual General Meeting (1885) will take place in London, on Tuesday, the 7th July, at 11 o'clock, in the Lecture Theatre of the City Guilds of London Central Institute, Exhibition Road, South Kensington, adjoining the International Inventions Exhibition.

The order of business will be:—Report of Council, Election of Office Bearers, and President's Address.

After an adjournment for luncheon, Mr. Frederick Siemens will read a paper—"On heating regenerative gas furnaces by radiation from flame, and on a producer to supply gas specially suitable for that purpose, and for the recovery of bye-products." Discussion on this important subject is invited.

In the evening the members will dine together at the Freemason's Tavern, Great Queen Street. Application for tickets should be made at an early date on the form inserted.

On Wednesday, 8th July, a visit will be paid to Messrs. Joynton & Co.'s Paper Mills, St. Mary's Cray (L.C. & D. Ry.). Messrs. Joynton & Co. will kindly provide luncheon. If possible, and prior to this, arrangements will be made to enable members to inspect Messrs. Orlando Jones & Co.'s Starch Factory, Battersea.

In the evening there will be a *Conversazione* and Reception by the President of the Chemical Society, Dr. Hugo Müller, F.R.S.; the President of the Institute of Chemistry, Dr. W. Odling, F.R.S.; and the President of the Society of Chemical Industry, Dr. W. H. Perkin, F.R.S., at the Galleries of the Royal Institute of Painters in Water Colours, Piccadilly.

On Thursday, 9th July, visits will be made to the Beekton Gas and Chemical Works of the Gas Light and Coke Company; to the Disinfectant Manufactory, at

Barking, and the Pumping Station at Crossness, belonging to the Metropolitan Board of Works; and to the Great Docks now being constructed at Tilbury, subject to the consent of the Directors. A commodious river steamer will be engaged for this excursion.

A time-table and detailed programme will be issued with the ballot papers and notices of the number of the Journal for June.

Friday has been left unoccupied to afford members an opportunity to visit the International Inventions Exhibition. Season Tickets, price 10s. 6d., can be obtained from the General Secretary of the Society. Members only are entitled to this privilege.

Members are hereby advised that the Subscription for 1885 falls due at the beginning of the year, and should be paid as soon afterwards as possible. The Council has decided that after January 1st, 1885, the 29th Bye-law will be strictly enforced, so that Members whose subscriptions are more than four months in arrear, will not continue to receive the Society's Journal.

Inquiries having been made as to the transactions of the Newcastle Chemical Society, the Committee of the Newcastle Section have to state that a very few complete sets are remaining, and will be sold to members at £2 10s. per set. A number of separate volumes can also be had by members wishing to complete their sets, at 10s. per volume (generally three years' Issue). Application for these should be made to the Local Secretary of the Newcastle Section.

#### LIST OF MEMBERS ELECTED MAY 23rd, 1885.

J. M. Anthony, c/o E. G. Marks, 9, Nelson Street, Bristol, metal merchant.

Alex. J. Atkinson, 41, Loudoun Square, Cardiff, analyst.

F. J. Barr, 15, Garden Reach, Calcutta, and 13, London Street, Edinburgh, soap manufacturer.

Jas. Bell, 118, Southwark Street, S.E., asbestos manufacturer.

J. H. Bickett, Medical College, London Hospital, E., chemist.

L. Briant, The Laboratory, Crosswells Brewery, Oldbury, analyst.

William Brathly, Pott Street, Ancoats, Manchester, aerated water plant manufacturer.

T. Lynton Briggs, Star Chemical Works, Wandsworth Bridge Road, Fulham, S.W., chemical manufacturer.

J. H. Brinjes, Whitechapel Engine Works, Fieldgate Street, E., engineer.

A. M. Cheyne, c/o Messrs. Burgoyne, 16, Coleman Street, E.C., chemist.

W. Christie, 222, Brunswick Road, Bromley, E., sulphate ammonia manufacturer.

H. S. Collins, Messrs. Langton & Co., 230, Upper Thames Street, E.C., chemist.

Wm. Dawson, 79, Burlington Street, Liverpool, analyst.

J. H. Darby, Pen-y-Garth, near Wrexham, ironmaster.

Geo. Dobson, Hanishen, near Cardiff, chemical manufacturer.

Henry Doulton, Lambeth Pottery, S.E., potter.

Rog. G. Durrant, Marlborough College, Wilts, schoolmaster.

T. Elborough, 59, Mark Lane, E.C., chemical manure manufacturer.

Judoo Money Ghose, City College, 13, Mirzapore Street, Calcutta, chemist.

F. M. Haig, Carnforth Lodge, Hammersmith, W., distiller.

T. W. Hand, Public Library, Oldham, librarian.

W. H. Heaton, University College, Nottingham, professor of physics.

J. Wm. James, University College, Cardiff, demonstrator or chemistry.

H. A. B. Leipner, 8, Loftus Street, Sydney, New South Wales, analyst.

Jas. Longshaw, 7, Park Place, Cross Lane, Salford, manufacturing chemist.

T. D. Perkin, Greenford Green, Harrow.

W. H. Richardson, High Field, Southwram, Halifax, science student.

Hugh T. Spencer, Park House, St. Helen's, manager of plate-glass works.

Claude M. Thompson, University College, Cardiff, professor of chemistry.

E. E. H. Thorne, Denia Lodge, West Croydon, chemist.

H. W. T. Wager, 16, Charlotte Street, Portland Place, W., science student.

W. B. Waterfall, c/o Avon Manure Company, Bristol, chemical manure manufacturer.

J. H. Williamson, Golden Hill Works, Stoke-on-Trent, colour manufacturer.

Frank Wilson, The Brewery, Castle Street, Long Acre, W.C., brewer.

#### CHANGES OF ADDRESS.

W. T. Alexander, 20, Booth Street, Mosley Street, Manchester; and Crummock Bank, Victoria Crescent, Eccles, Jno. Anderson (d/o Glasgow), Carnbroe Ironworks, Coatbridge, N.B.

R. Bindschedler (d/o Bolton), c/o Société pour l'Industrie Chimique, Basle, Switzerland.

H. E. Bunker (d/o Manor Park), 28, Wetherell Road, South Hackney, E.

F. Chisholm (d/o Somerset House), The Patent Office, Chancery Lane, W.C.

H. Shugden Evans (d/o Montreal), Department of Inland Revenue, Ottawa, Canada.

A. E. Fletcher (d/o Liverpool), 57, Gordon Square, London, W.C.

And. Haddow (d/o Abbey Street), 1 Keith Place, Easter Road, Edinburgh.

W. Hibbert (d/o Marylebone), 8, St. Dunstan's Road, Margrave Gardens, West Kensington, S.W.

S. Horrocks (d/o Manchester), 50, Prince's Street, Southampton, Lancashire.

J. H. Irvine (d/o Strathbungo), North British Chemical Company, Clydebank, Glasgow.

W. H. Laik (d/o Jersey), Burton Dasset, Knight's Hill, Lower Norwood, S.E.

T. H. Leach (d/o Lee Terrace), Burneston House, Barking Road, Plaistow, E.

Jas. Mackenzie, 21, Shuttle Street, Glasgow.

E. K. Mitling (d/o Leyton), Faversham, Kent.

J. H. Payne (d/o De Beavor Road), New Hill Hall, West Milton, Rutland.

Legh S. Powell (d/o St. James' Square), 5, Notting Hill Square, Camden Hill, W.

T. C. Sanderson (d/o New Cross), 21, Glengall Grove, Old Kent Road, S.E.

A. Seckendorf (d/o Ashley Place), 16, Mark Lane, E.C.

S. Scillon (d/o Kensington), Palace Club, Westminster.

V. Peromet Sells (d/o Redhill), The Grannar School, Bradford, Yorks.

Dr. A. Studer (d/o Manchester), Olten, Switzerland.

G. C. Thompson (d/o Garnet Hill), 39, Kersland Terrace, Hillhead, Glasgow.

Geo. Tunbridge (d/o Belgrave Road), 7, The Crescent, King Street, Leicester.

M. W. Williams (d/o Kensington), Queenwood College, near Stockbridge, Hants.

P. J. Witsor (d/o Higher Broughton), Bank Quay, Warrington.

#### CHANCE OF ADDRESS REQUIRED.

J. A. Graham, 1 o Sherborne Lodge, Wexler Road, Putney.

F. T. Schreiber, 1 o Hampden Street, Bolton.

#### London Section.

##### CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE.

Chairman: David Howard.

##### Committee:

Sir F. A. Abel.	B. E. R. Newlands.
H. E. Armstrong.	B. Redwood.
W. Crowder.	T. Royle.
C. Graham.	John Spiller.
S. Hall.	G. C. Trewhy.

R. Messel.	J. Williams.

Local Sec. and Treasurer: Thos. Tyer, Garden Wharf, Church Road, Battersea, S.W.

MEETINGS, SESSION 1885—First Monday in each month (unless otherwise indicated).

June 1.—Messrs. Salamon and W. de Vere Mathew—"The Influence of Phosphates upon Fermenting Worts." Mr. H. B. Vardley—"Additional Note on Alumina in Superphosphate." And other papers.

July.—The Annual General Meeting. Notices of papers and communications for the meetings to be sent to the Local Secretary.

Meeting held May 4, 1885.

#### COMPOSITION AND MANURIAL VALUE OF FILTER-PRESSED SEWAGE SLUDGE.

(Paper by Prof. Munro, D.Sc., read Jan. 5, 1885.)

##### DISCUSSION.

THE manurial value of filter-pressed sewage, as estimated by Professor Munro, was in no sense

disputed. The discussion by Messrs. Stanford, Coleman and Tyer, was chiefly on the condition of the cake when turned out, and on the fact that the manual value was so low as to preclude its use where much expense had to be added to alter its physical conditions of cloginess and moisture (the latter being put at 50 per cent.), or in transporting the product considerable distances. Messrs. Johnson and Hutchinson contended that it was at least as valuable as farm-yard manure under ordinary conditions, and that the mere mechanical question of comminution was practically accomplished by new modifications of disintegration machines which they were applying.

#### ON THE PERCENTAGE OF SULPHUROUS ACID IN AQUEOUS SOLUTIONS OF VARIOUS SPECIFIC GRAVITIES, AND ON ITS DETERMINATION THEREIN.

BY WM. B. GILES AND A. SHEARER.

IN the course of last year, we had the honour of bringing before the notice of the Society some researches we had made with the view of arriving at a more accurate and speedy method of estimating the amount of sulphurous acid when in combination with bases, and the general result of our work may be briefly summed up as follows:—We found that it was necessary that the sulphite should be added to the iodine solution, and *not* the iodine to the sulphite, and that instead of diluting with water down to the percentage of .05 per cent. of  $\text{SO}_2$ , as recommended by Bunsen, it was inadvisable to use any water at all, but simply to place the weighed solid or liquid body straight into an excess of decinormal iodine solution. The results we obtained in this manner were so satisfactory, and so concordant with those obtained by the much more tedious gravimetric process, that we resolved to make a further research as to whether the same method could be applied to the estimation of the acid itself in the free state. A considerable number of preliminary trials having shown us that the determination was as correct in the latter as in the former case, we finally resolved, as a crucial test, to use the pure condensed sulphur dioxide as a means of comparison. The gas ( $\text{SO}_2$ ) employed, was deprived of moisture by passing it through a tube 10ft. long, filled with small flints continually kept wetted with concentrated sulphuric acid, and after being liquefied it was redistilled under pressure in glass vessels, and sealed up in small glass bulbs previously tared without any exposure to the air. In this form the sulphur dioxide appears to be almost chemically pure, the only impurity that could be found being a mere trace of hydrocarbon oil derived from the lubrication of the pump with which its condensation was effected. The glass bulbs, holding from three to four grammes, being weighed, were broken under a slight excess of pure decinormal iodine solution, contained in a stoppered bottle to avoid any possible loss of gas, the amount of excess being then determined as usual with thiosulphate. The mean percentage of  $\text{SO}_2$  obtained was 99.68 per cent., and as this entirely confirmed our previous results, we resolved to construct a table showing the amount of this acid in its solutions of varying specific gravity, especially as from various cogent reasons we were led to doubt the accuracy of the only tables we have been able to find as having been made by previous observers. These tables, which are subjoined for the sake of comparison, are three in number—viz., those given by Anthon, Gautier and Wagner, and H. Schiff. As regards the first of these,

it appears probable from Anthon's remarks that he prepared his acid by suspending calcic sulphite in water, adding the theoretical amount of sulphuric acid to it, and agitating till decomposition was perfect, after subsidence of the calcium sulphate the supernatant clear fluid was decanted; if this is the case, it is not wonderful that his figures are wide of the truth. With regard to Gautier and Wagner's figures, we have not been able to find what method of estimation was adopted; it may have been a gravimetric one, or Bunsen's mode may have been employed. They agree, however, better with our own results than the others, though there seems to be a constant error throughout them, leading to nearly all the figures for the amount of  $\text{SO}_2$  being too low for the respective specific gravities. This might be expected if Bunsen's method was adopted, the free oxygen in the large amount of water, even when long boiled, tending to lower the actual percentage of  $\text{SO}_2$ . A glance at Schiff's figures will show that they are simply absurd. They appear to be derived from some erroneous theoretical calculations founded—or rather unfounded—upon data given by Bunsen. The results of a very large number of trials, conducted with every precaution that offered itself to our consideration, lead us to propose the following very simple law of the ratio between any given percentage of sulphur dioxide in an aqueous solution at 15.4 C., 760mm, and its specific gravity—viz., that under the foregoing conditions, the percentage of  $\text{SO}_2$ , multiplied by 5, gives the specific gravity of the solution over and above 1000. Thus, for instance, a solution containing 1 per cent. of  $\text{SO}_2$  has a gravity of 1.005, one of 5 per cent. a gravity of 1.025, one of 10 per cent. a density of 1.050, and so on; so that, on the other hand, if we know the specific gravity, we can of course at once tell the percentage of  $\text{SO}_2$ , provided that this is the only body present to influence the density. Whether this law be *absolutely* correct or not, is, of course, uncertain; but it is undeniable that the experimental results exhibit an extraordinary agreement with the theoretical figures, and that for all *practical* purposes it may be assumed to be so.

The following details of the preparation of the varying specific gravities of the acid solutions, and the volumetric solutions employed, will serve to indicate the precautions that were observed by the authors:—1. The purest re-sublimed iodine obtainable was rubbed to a fine powder with excess of pure potassiumiodide, and re-sublimed in the usual manner. It was then fused into a solid cake, and allowed to cool in a closely stoppered vessel. This fusion occasioned considerable loss, but it is the best way of obtaining the iodine in an absolutely dry condition, and the compact fused pieces are less subject to change during the operation of weighing than the micaceous scales which ordinary re-sublimed iodine usually occurs. The titre of the iodine was but slightly altered by this treatment; in fact, the only impurity in the original iodine appeared to be traces of insoluble matter and moisture. Still, when this iodine was titrated in the usual way, it was always found that the weight indicated was slightly less than the actual amount. The cause of this was investigated, and found to consist in the fact that the purest obtainable potassium iodide contains a trace of caustic potass or potassium carbonate, or at any rate destroys a trace of iodine. When this was compensated for, the iodine was found to agree absolutely with sodium thiosulphate, which was always found recrystallised, specially granulated and air-dried till no adherence was observable in the particles of the salt. Two grams of potassium

bicarbonate were added to each litre of the thiosulphate solution, as recommended by Mohr, and the solution will, with this addition, keep for months with its titre absolutely unaltered if it be preserved in a cool place and in the dark. If kept in the light it speedily changes. A daily experience, extending over some years of work, enables us to speak confidently as to the unalterability of the iodine solution when pure materials are made use of. Verified burettes, with Erdmann's floats, reading easily to less than  $\frac{1}{10}$  of a cc., were employed. The observers worked simultaneously, but with different balances, weights and burettes. Each observation was made at least six times, and the mean taken, in many instances—*i.e.*, in those about the specific gravity of 1040, as many as fourteen to fifteen different trials were made. The specific gravities were all obtained by direct weighings in 100-gramme flasks on Regnault's principle, no hydrometers being trusted to. (The small hydrometer seen inside the flask in the engraving, served merely as an approximate guide to the progress of the saturation.) Particular attention was given to the distilled water employed, as it

the neck. After boiling strongly for nearly three hours, it had decreased till it occupied a space about represented by the dotted lines in the figure, the steam passing away freely from the tap W, which was disconnected from the second flask C. At this period, without stopping the boiling, the sulphur dioxide was turned on from the syphon F, and not till this had saturated the boiling fluid was the lamp removed from under the flask A. The tap W was then connected to the second washer G, and the stream of gas maintained without the least intermission till the desired degree of saturation was attained at the normal temperature. This was reached in about twelve hours, when the lamp was replaced by a vessel of water supplied from the main, which enabled the temperature to be kept constant. This was noted by means of the thermometer B. The small delicate hydrometer C gave the approximate specific gravity. The stream of gas still continuing, the upper part of the vessel A was of course full of gaseous  $\text{SO}_2$ . To preserve the aqueous acid during the experiments, light purified petroleum oil was now allowed to flow in upon the surface of the acid

had long been observed by the authors that an extremely small quantity of a base increases in a remarkable manner the apparent solubility, and hence the percentage of sulphurous acid. As an instance of this, it may be mentioned that if an excess of barium sulphite be suspended in water, the solution, under the influence of a stream of  $\text{SO}_2$ , rapidly attains a specific gravity of 1060,  $15.4^\circ \text{C}$ ., yet this solution was found to contain only 0.16 grm. of  $\text{BaO}$  in 100cc., which represents the maximum solubility of barium sulphite in sulphurous acid at  $15.4^\circ \text{C}$ . The water used was the middle portion of a distillate from a thirty-gallon copper still heated by steam, and it was boiled for three hours in the absorption vessel itself to get rid, as far as possible, of any dissolved oxygen before passing the stream of  $\text{SO}_2$ . The same water was used for diluting. The sulphurous dioxide was evolved from the pure liquefied acid contained in glass syphons with regulating screws. The water issuing hot from the still was introduced into the 5-litre flask A, nearly up to

through the stoppered-tap funnel E to a depth of about half-an-inch, after which the stream of  $\text{SO}_2$  was discontinued, and the tap W also closed. By this method of procedure, all access of air from beginning to end of the operation was entirely prevented, and the contents of the vessel could be raised or lowered to any required temperature. A large flask of the same water was used for diluting the strong acid down to the lower gravities, boiled in exactly the same way, and allowed to cool, petroleum being floated on the surface to exclude air. By means of the stopcock H, with a drawn-out point, the acid was then run into the Regnault specific-gravity flasks and weighed, the flasks being tared before each weighing. After weighing, the flasks were then cooled in a freezing mixture, and the acid when sufficiently cooled was transferred to small, very accurately tared and stoppered bottles, which, after re-weighing, were first cooled to about  $5^\circ \text{C}$ ., in the same freezing mixture, to avoid any loss of gas when the stopper was raised, as it was

invariably found that without this precaution the results were low from loss of gas, and then dropped into a slight excess of decinormal iodine, contained in a stoppered bottle, the excess of iodine remaining being estimated in the usual manner with thiosulphate.

The authors do not attempt to obtain any exact given percentage of sulphurous acid, or to arrive at round numbers in the determinations of the specific gravities, their attention being directed to obtaining correct results with the least possible exposure of the solutions to the air. Finally, they would remark that none of the figures in Table I. are interpolations, but all are results of absolute experiment.

TABLE I.—*Experimental Determination of Percentage of SO<sub>2</sub> in Solutions of various Specific Gravities.*

#### DISCUSSION.

The CHAIRMAN congratulated the authors upon having furnished results which, from their reputation for accuracy and care, could be considered reliable; and the precautions taken to ensure this, especially in the more concentrated, and therefore more volatile solutions, commended themselves to his judgment. He also remarked that as a manufacturer of iodides the authors' observations were well founded, the presence of the traces of free alkali being not accidental, but essential, if stability of this salt was desired.

Mr. TYLER, endorsing these remarks, observed how fully the authors' numbers agreed with those of Mr. Umney, and confirmed by himself when examining the sulphurous acid of the then newly published edition of the *British Pharmacopoeia*. These figures were given in the *Pharm. Journal*, March, 1863, as follows:—

Specific Gravity.	Percentage SO <sub>2</sub> .
1.005	1
1.011	2
1.017	3
1.022	4
1.027	5
1.032	6
1.037	7
1.042	8

Careful precautions were taken to secure uniformity of result, but he (Mr. Tyler) must bear testimony to the superiority of those used by the authors.

SIR H. E. ROSCOE IN THE CHAIR.

## THE PRODUCTION AND FIXING OF COLOURING MATTERS BY MEANS OF ELECTRICITY.

BY J. J. HUMMEL.

SINCE the beginning of this century, when Nicholson and Carlisle discovered the decomposition of water by means of the electric current, electrolytic phenomena have engaged the attention of scientists to a greater or less degree.

In the hands of Davy, as you know, their study led to the analytical production of the alkali metals, and although some attention has been devoted to the electrolysis of organic compounds, that of inorganic substances has generally been the chief attraction.

In 1862, Dr. Letheby, of London, discovered in two cases of poisoning by nitrobenzene that this body was changed in the animal organism into aniline, and this could be distilled from the contents of the intestines and from the tissue of the body.

Letheby sought after the most delicate test for the presence of aniline, and found it in nascent oxygen, which caused mere traces of aniline to give a deep blue colour.

A single drop of a dilute aniline solution, say one gramme aniline in a litre of dilute sulphuric acid ( $\text{H}_2\text{SO}_4 + 7\text{H}_2\text{O}$ ), is placed upon a piece of platinum foil attached to the + electrode of a Bunsen cell. If the liquid is then touched with the - electrode, a deep blue coloured body is gradually deposited on the platinum. Half a milligramme of aniline can by this means be readily detected.

Thirteen years afterwards—viz., in 1875—Coquillon studied the electrolysis of aniline salts.

Coquillon, first of all, repeated Letheby's experiment, and confirmed his observations. After passing an electric current from two Bunsen elements through a concentrated solution of aniline sulphate for twenty-four hours, the + pole became coated with a greenish or bluish-black mass, which could be readily detached. When dry it formed an amorphous black substance possessing a metallic lustre.

Coquillon proved that the presence of a metal, or metallic salt, was not necessary to its production, for he employed carbon electrodes which had been perfectly cleansed by treating with chlorine, nitric acid, &c.

The account of Coquillon's results, in the form of a paper read before the Academy of Sciences in Paris, caused Goppelsroeder to publish in the same year, before the Société Industrielle de Mulhouse, a

resumé of his independent work in the same field, with which he had been occupied since the autumn of 1874; and in 1876 appeared a detailed account of the same in his "Études Electrochimiques des Dérivés du Benzol," a paper read before the same society.

A pupil of Schoenbein, Goppelsroeder seems to have early interested himself in ozone and its possible industrial applications—e.g., in bleaching, ageing, &c. Eventually, he concentrated his attention on the study of the action of nascent electrolytic ozone on substances capable of yielding colouring matters by oxidation, and, in the first instance, upon a solution of aniline sulphate.

In his numerous researches on electrolytic aniline black, he noticed that the liquid in which the + pole was immersed varied in colour during the experiment, becoming yellow, orange red, and violet, at different periods, and only colourless when the aniline salt was fully decomposed. Filter-paper, cotton, wool, or silk, which was employed to conduct the current from one decomposing cell to the other, became also variously coloured, showing the presence of different colouring matters in the solution. Goppelsroeder showed, indeed, that electrolytic black is a mixture of aniline black with other colouring matters which could be extracted by successive treatment with various solvents, especially water and alcohol. The purified electrolytic aniline black formed a velvety black powder, which, according to analysis, seemed to be the hydrochloride of a base  $\text{C}_{21}\text{H}_{20}\text{N}_2$ . It may be noted, in passing, that this empirical formula does not agree with that of the aniline black base produced by other methods, which is given as  $\text{C}_{18}\text{H}_{15}\text{N}_3$ , but it is quite conceivable that there may be blacks of different composition.

From the beginning, Goppelsroeder has continued his researches with great zeal and earnestness, and has indeed made the field practically his own.

He has succeeded in obtaining most interesting results, and a resumé of these I now wish to place before you, illustrated by the series of specimens and elegant album of patterns dyed and printed by the electrolytic method, which Professor Goppelsroeder has kindly lent for the purpose. I am also greatly indebted to him for the liberal manner in which he has supplied me with his various original papers on the subject.

The several chapters of Goppelsroeder's work in which the employment of the electric current is the characteristic feature, are as follows:—

- I. The production of colouring matters.
- II. The simultaneous formation and fixing of colouring matters upon the different textile fibres.
- III. The production of white and coloured discharge patterns upon dyed fabrics.
- IV. The production of oxycellulose.
- V. The preservation of printing colours liable to be destroyed by oxidation during the printing process.
- VI. The reduction of colouring matters for the preparation of so-called vats (indigo, aniline black).

### I.

The idea of producing various coal-tar colouring matters by means of electricity originated in the formation of the electrolytic aniline black already alluded to. The electric current was passed through solutions of various salts analogous to aniline hydrochloride, and in each case colouring matter, or a mixture of several colouring matters, was obtained.

It being necessary to prevent the effect of one pole from influencing that of the other, various forms of apparatus were employed, some of which are shown in the diagram.

The solution may be, for example, contained in a simple U-tube, loosely packed with glass wool in the bend, the poles of the battery being inserted in each limb; or the solution may be contained in two separate glass vessels, and the current conducted from one to the other by means of several sheets of filter-paper moistened with the solution; or the solution is placed in the inner and outer cell of an ordinary Bunsen element.

The electrodes employed may be of carbon or platinum; in some cases the negative electrode may be of lead.

The + electrode, which is the principal seat of the production of colouring matter, may be conveniently wrapped in calico. In this case the precipitate formed is deposited between the electrode and the calico, also in the pores of the latter, from which, after washing in water, the colouring matters formed can be removed by means of alcohol or other solvents. In making a qualitative examination of the colouring matters produced, advantage is taken of the fact that if a strip of blotting-paper is partly immersed in a solution containing several colouring matters, the latter rise by virtue of capillary attraction to different heights on the paper. Numerous filter-paper specimens, showing what information may be gained in this manner, are shown in the album exhibited.

The best yield of colouring matter is obtained when the solution surrounding the principal electrode is kept in constant motion.

In most cases the production of colouring matter, or other effect obtained, is to be ascribed mainly, if not entirely, to the decomposition of the solvent employed—viz., water. Oxygen gas is given off at the + pole, and hydrogen at the - pole. The oxygen, either in the nascent state, or as ozone, or by the production of hydrogen dioxide, acts upon the substance in solution, and converts it into colouring matter either by oxidising it or by removing a portion of its hydrogen.

The following is a brief resumé of Goppelsroeder's results relative to the production of colouring matter from various substances under the influence of the electric current:—

1. Aniline hydrochloride in acid and in neutral solution gives emeraldine and aniline black.

2. Aniline salt, with the addition of aniline and ammonia, gives only an insignificant deposit of a brown colouring matter soluble in alcohol, while the liquid acquires a deep red colour, and contains red and violet colouring matters, and these can be obtained by evaporating the solution to dryness and extracting the residue with ether and alcohol.

3. Salts of para-toluidine yield, as the main product, a brown colouring matter; also a little red and yellow colouring matter. Salts of ortho-toluidine yield, on the contrary, a violet colouring matter, similar to that produced by the action of bleaching powder; also small quantities of red, green, and brown and yellow; also emeraldine or aniline black.

4. A solution containing a mixture of 1 mol. aniline hydrochloride, and 2 mols. paratoluidine hydrochloride, gives a red-coloured solution at the + pole.

By employing a solution of commercial "aniline for red," imperfectly saturated with HCl or  $H_2SO_4$ , and with the addition of  $NH_3$ , a red and also a violet colouring matter is produced.

It is well known from the researches of Runge, Hofmann, and Perkin, that blue, red, and violet colouring matters are produced by oxidising aniline, or mixtures of aniline and toluidine, and it is not at all improbable that the colouring matters obtained by Goppelsroeder's method may be identical with those obtained by the older methods of oxidation, though I believe this has not yet been proved.

5. Solutions of aniline and toluidine salts, in the presence of potassium-nitrate, -nitrite, and -chlorate, yield at the + pole products from which rose-red and violet-red colouring matters can be extracted, which in their behaviour towards mineral acids remind one of the colouring matters of the safranin group.

6. Salts of methylaniline yield at the + pole a violet, and, under certain conditions, also a blue colouring matter. It will be interesting to know if the violet is identical with the well-known methyl-violet obtained by oxidising dimethylaniline according to Lauth's method.

7. Diphenylamine salts, with or without those of ditolylamine and phenyltolylamine, yield at the + pole a blue colouring matter soluble in alcohol. This may, of course, be identical with the diphenylamine blue produced according to the ordinary methods.

8. Salts of methyl-diphenylamine give blue and violet colouring matters.

Salts of naphthylamine give a violet colouring matter, accompanied by small quantities of brown, yellow, and red colouring matters.

Turning now to the results obtained from the phenols:—

9. An aqueous acidified solution of phenol itself gives a brown colouring matter, and, under certain conditions, also traces of yellow and orange-red. An ammoniacal solution of phenol gives, under certain conditions, at first a blue, afterwards brown and pink colouring matters, with traces of violet and yellow. With certain additions—e.g.,  $NH_4Cl$ ,  $KHO$ ,  $K_2SO_4$ ,  $KNO_3$ , the principal colouring matters formed are reddish orange, brownish yellow, and brown and yellow colouring matters, sometimes with traces of violet or red.

10. An acidified solution of naphthol gives as the principal product—a golden yellow colouring matter, possessing a green fluorescence, also a brown and a small quantity of red.

Goppelsroeder has also passed the electric current through solutions containing several substances, partly organic, partly inorganic, in order that by the interchange of certain atoms or atomic groups under the influence of the electric current, new compounds might be obtained.

A solution of magenta containing methyl-alcohol,  $H_2SO_4$  and KI, gave at the positive pole Hofmann's violet.

Very interesting is the electrolytic production of alizarin from anthraquinone.

When the electric current is passed through a boiling solution of caustic potash containing finely-powdered anthraquinone in suspension, a deep red colouration is produced at the pole, due to hydro-anthraquinone, but it is rapidly decolourised under the influence of the air. Only when the caustic potash is extremely concentrated, and the temperature very high, is there a production of alizarin; in this case, during the passage of the current, the melted mass becomes first red (oxyanthraquinone), then bluish-violet (alizarate), then reddish-violet (mixture of alizarate and purpurate), and then again red (purpurate). If the experiment is continued still longer, the mass becomes brown, then gradually lighter in colour, and finally white (potassium salts of organic acids and carbonate).

The alizarin is obtained by stopping the current whenever the deep bluish-violet colouration is attained, allowing the mass to cool, extracting it with water, and precipitating the alizarin from the solution by adding dilute acid. The yield of alizarin is always small.

At first sight it might be thought that at the high temperature employed, the transformation alluded to

would take place without the aid of the electric current, but experiment shows that this is only the case when the heating is continued for a very long time, and even then only traces of alizarin are produced. Further than this, it is noticed that if, when the red colour due to purpurate appears, the current is reversed, the mass becomes again violet, then red, and lastly greyish yellow, since alizarate, oxanthraquinonate, anthraquinone, and even anthracene are probably reproduced.

## II.

As to the simultaneous formation and fixing of colouring matters on textile fibres, the best examples are those of aniline black and canarin yellow.

The following is the arrangement which Goppelsroeder has found suitable for the purpose of printing or writing in aniline black by electrolysis on textile fabrics:—

A lead plate insulated by resting on a sheet of indiarubber serves as the negative electrode. On this rest a dozen folds of calico suitably moistened with dilute sulphuric acid (1 : 10) in order to conduct the electric current, and on these the piece of cloth (silk or cotton) on which the colour is to be produced. The latter is impregnated with a strongly-acidified solution of aniline hydrochloride (about 125 grm. per litre).

A second metallic plate, preferably of platinum or gold, serves as the + electrode; this is gently pressed upon the prepared fabric, and the electric current is passed through for one or two minutes. On removing the + electrode, a fixed and permanent impression in aniline black is produced.

If the - electrode is in the form of a stencil plate or an engraved plate, a pattern corresponding to the design upon it is of course produced. Goppelsroeder has also made experiments in printing continuously by means of engraved cylinders.

So rapid, indeed, is the production of the black, that by making the + electrode in the form of a rod of carbon, gold, or platinum, it is possible to write indelibly upon the fabric in aniline black as rapidly as in the ordinary manner.

The characters or design thus produced, after washing with alkaline solution, are perfectly fast, since the fundamental law governing the fixing of colouring matters is properly fulfilled: the coloring principle or chromogen is presented to the fibre in a soluble condition, and is there rendered insoluble.

Goppelsroeder suggests that the electro-chemical method here described might be utilised in printworks, bleach-works, etc., for marking indelibly the piece-ends; also in the customs and telegraph departments.

*Dyeing* with aniline black may be accomplished by first depositing on the textile fibre a thin metallic layer. This rendered a good conductor of electricity, the fibre itself may serve as the + electrode, and be placed in the aniline salts solution; the dyeing would then at once take place on plunging the - electrode into the solution.

*Canarin*, or perthiocyanogen  $C_2N_3S_2H$  is a deep yellow amorphous powder, produced ordinarily by the action of nitric acid or chlorine upon a boiling solution of potassium thiocyanate. It has recently been introduced as a dyestuff for cotton, since it resists the action of light and soap solutions extremely well, and also acts as a mordant for basic coal-tar colouring matters.

By treating the thiocyanates of aluminium and potassium as if for aniline black, and then steaming, "canarin" yellow is at once developed and fixed upon calico; and very probably the remembrance of this process of H. Schmidt caused Lidow and also

Goppelsroeder to submit ammonium and platinum thiocyanate to electrolysis.

On passing the electric current through a cold solution of either of these salts, little or no action takes place; but if the solution be heated (preferably to the boiling point), an orange-yellow flocculent precipitate of persulphocyanogen is produced at the + pole, the thiocyanate being entirely decomposed.

Canarin yellow may also be simultaneously produced and fixed upon textile fibres by the method adopted for aniline black. A piece of calico, for example, is impregnated with an aqueous solution of potassium thiocyanate, then spread out upon a number of folds (8-16) of calico, similarly moistened, and resting upon a piece of platinum foil which serves as the - electrode. On placing another piece of platinum acting as the + electrode, upon the prepared calico, and passing the current, the cloth immediately beneath the + electrode is permanently dyed from a canary-yellow to a dark orange, according to the intensity and duration of the current.

## III.

Although many colouring matters, as we have seen, are produced by oxidation, most of them are destroyed if submitted to excessive oxidation. This fact is made use of by the calico-printer in the production of so-called discharge patterns—e.g., on Turkey-red and indigo blue grounds. Such discharges may also be readily produced by the electrolytic method.

A piece of Turkey-red or indigo-blue calico is impregnated with a solution of sodium or ammonium chloride or nitrate. Beneath are a number of folds of calico similarly moistened, resting on an insulated sheet of platinum serving as the - electrode. If the positive pole, in the form of a platinum sheet, etc., is pressed on the prepared cloth, there is at once a production of chlorine or  $HNO_3$ , according to the salt solution employed, which attacks the colouring matter, colourless oxidation products are formed, and a white discharge on a red or blue ground is the result.

With a view of accelerating the reaction, Goppelsroeder acidified the salt solutions with sulphuric acid. Without such acidifying there was always a production of caustic alkali at the - pole. Albert Scheurer has recently shown that the bleaching action of chlorine gas is considerably more powerful in the presence of caustic alkali, and by substituting caustic soda for sulphuric in his experiments Goppelsroeder also finds the bleaching action to be stronger, and has obtained most excellent discharges, whether the salt used was sodium chloride or nitrate (*Journ. Soc. Chem. Ind.* 478, 1884).

In order to obtain a sharp impression it is necessary to protect the cloth, not covered by the + electrode, by means of glass plates. These prevent the spreading of the liberated gases.

If such salts are chosen whose bases are liberated by electrolysis, and can act as mordants, it may be possible, by dyeing the cloth subsequently, to produce coloured discharges. Such might, of course, be at once produced if the liberated oxides were themselves coloured, or became so through being oxidised still further by the electrolytic oxygen.

These ideas thrown out by Goppelsroeder have been partly submitted to the test of experiment, and he finds that by impregnating calico with the usual iron and aluminium mordants, and passing the current through them, as already described, they become mordanted in contact with the + electrode, and produce impressions darker than the surrounding tissue, when subsequently dyed up with alizarin.

He has further attempted, but with what success I know not, what might be called an electrolytic topical style of printing—namely, to produce simultaneously,

in presence of the fibre, mordanting oxides, and such colouring matters as would combine with these to form coloured lakes. Under the conditions imposed, this seems an extremely difficult problem.

Black discharge patterns, on red or blue grounds, are readily produced by fixing the electrolytic aniline black on Turkey-red or indigo-blue. It would appear that there is not a mere superposition of the black, but a simultaneous destruction or discharging of the red or blue beneath.

Yellow discharge patterns, on blue and red grounds, are produced by means of the electrolysis of potassium thiocyanate; but they seem to be less successful.

A very good yellow pattern, on blue or red ground, however, is obtained by first producing a white discharge, according to the method already described, then impregnating the whole cloth with potassium thiocyanate, and going over the discharged places with the + electrode, when, of course, yellow canarin is produced.

#### IV.

It is impossible to imagine that in the discharging or production of colouring matter by such a powerful oxidiser as the electrolytic oxygen, the fibre itself should remain unaffected. A few experiments suffice to show that by lengthened action of the electric pen, holes in the fabric are produced, the fibre being destroyed just as it would be by the action of strong bleaching powder.

Before, however, this extreme condition has been attained, Goppelsroeder has proved that in the case of cotton the fibre becomes changed into oxycellulose, just as it is, according to the researches of Witz, under the action of hypochlorous acid.

The most characteristic property of oxycellulose is that it readily attracts and becomes dyed with the basic coal-tar colouring matters without the aid of a mordant, whereas cellulose requires to be prepared with tannic acid to give a similar result.

If a piece of cotton or linen cloth be impregnated with a neutral, acid, or alkaline solution of sodium -chloride, -chlorate, or -nitrate, and be placed upon 8-16 folds of similarly moistened cloth resting upon a sheet of platinum as the - negative electrode, and if it be then impressed with a platinum plate, serving as the + electrode, after the current has passed through for some time, the products given off at the + pole will so change the fibre immediately in contact with it, that after washing, that portion will dye up in a solution of methylene blue or other basic coal-tar colouring matter, exactly as though it were mordanted with tannic acid. The effect is due to the oxycellulose produced.

On discharging Turkey-red and indigo-blue by the electrolytic method, the cellulose is similarly modified in the discharged portions, so that by dyeing afterwards in various basic coal-tar colouring matters, one may obtain coloured discharge patterns on an indigo-blue ground.

#### V.

Hitherto, except in the case of the electrolytic production of alizarin, I have referred to experiments in which the positive pole plays the principal part. Let me now refer to other instances in which the negative pole is the most important.

There are several printing colours which, by reason of too rapid oxidation, present difficulties to the calico-printer during the printing process—e.g., the aniline-black printing mixture, reduced indigo, etc. Goppelsroeder proposes to prevent the premature oxidation of such during printing, by putting into the colour-box the - electrode of a small battery or dynamo, and connecting the contents of the colour-box by means of a porous diaphragm, tube, etc., with a smaller

supplementary box, filled with the same printing colour, in which the - electrode is placed. The hydrogen given off at the - pole would prevent the oxidation of the colour.

Another service which he thinks might be rendered by the - pole would be that of precipitating, on the textile fibres, the heavy and noble metals, several of which are used in printing. The fabric would require to be impregnated with a thickened solution of the metallic salt, and the - electrode caused to act upon it in order to precipitate and fix the metal.

#### VI.

The hydrogen of the - pole can also be used for the conversion of the nitro compounds of the aromatic group of bodies into amido compounds. Nitrobenzene can be changed into aniline, for example, and a patent seems already to have been taken out for this purpose; also for the reduction of such colouring matters as aniline black and indigo, to form vats suitable for purposes of dyeing.

In the case of indigo, for example, this dyestuff is finely ground and mixed with a somewhat concentrated solution of caustic alkali. This mixture is placed in a porous earthenware cylinder, resting in a copper vessel, also half-filled with the same alkaline mixture. The copper vessel is connected with the - pole of a galvanic battery; while a strip of platinum attached to the + pole is inserted in the contents of the porous jar. It is well to heat the contents of the copper vessel to the boiling point to accelerate the reduction.

Although hydrogen gas is given off in large quantities at the - pole, in the cold the reduction is very incomplete; but when the alkaline mixture is heated, the evolution of hydrogen ceases, since it then reacts upon the indigo-blue and changes it into indigo-white, which dissolves in the caustic alkali. The characteristic colour of the ordinary indigo-vat is soon perceptible, the solution in the copper vessel acquires a greenish yellow colour, becomes covered with the usual indigo "flurry" or scum, and may serve for dyeing according to the ordinary method.

It is, however, not at all necessary to wait till the indigo is completely reduced, it suffices to allow the current to pass through the mixture for a short time, and then at once alternately to immerse the fibre in the liquid and to expose it to the air.

It is possible even to reduce the indigo upon the fibre itself, so that in the moment of reduction the fibre shall be at once impregnated with a solution of indigo-white, and it requires then only to be exposed to the air to become permanently dyed.

To this end the fabric to be dyed is impregnated with a solution of caustic alkali, mixed with finely-ground indigo, and placed between two metallic plates, one of which forms the +, the other the - electrode. After passing the current through for a short time, and exposing the fabric to the air, it is dyed blue.

With a current of suitable intensity, it might even be possible to dye calico pieces continuously, by passing them (previously impregnated with the mixture of alkali and indigo) through a pair of metal rollers, which formed the + and - electrodes of an electric battery. The cloth would, of course, require to be exposed afterwards to the air and washed.

It is worthy of note that if the passage of the current be too prolonged, the indigo is gradually destroyed, which is quite in harmony with the fact that the indigo is also destroyed in the woad-vat by excessive fermentation.

And now, gentlemen, the first question which is no doubt ready to escape from the lips of many of you is :

Is it possible to apply the electric current in practice in the manner described, and is there any advantage in so doing over the older methods of obtaining the results desired?

In answer, let me quote from a letter I have recently received from Professor Goppelsroeder. He says:—

"After having opened up this new field of research, as one fact after another comes to view, I become more and more convinced that the seed sown will gradually develop into a plant which will sooner or later bear fruit, and that this new use of electrolysis will some day belong not only to pure but also to applied science. The greater the number of workers in the field the more rapidly and abundantly will fruit be obtained.

"At present I give to science the simple facts just as I find them, without asking whether or not they will find a use to-morrow or only after many years. If in making scientific researches one were always to consider carefully what difficulties might stand in the way of practically applying results obtained, research would often be hindered, if not entirely paralyzed.

"In this special electrolytic domain, the question is, whether the new process of producing and fixing colouring matters by electrolysis possesses any advantages over the old method as regards cost and simplicity. Of course the more dynamo machines are improved, and the price of the necessary current is lowered, the more likelihood there will be of the subject passing from the laboratory to the workshop, at first possibly only in a modest degree, but afterwards, perchance, quite universally.

"Should this end ever be attained, there seems to me to be the possibility of electricity being used for the following varied purposes:—

- "1. The production of colouring matters and their intermediate products.
  - "2. The bleaching of textile fabrics.
  - "3. The dyeing and printing of textile fabrics.
  - "4. The discharging of dyed colours.
  - "5. Heating and illumination.
  - "6. Chemical telegraphy.
- "The future alone will show whether electricity is capable of playing such a many-sided rôle."

#### DISCUSSION.

Mr. LEVINSTEIN: As Professor Hummel has already stated in his interesting paper, none of Goppelsroeder's efforts to produce colouring matters by electrolysis have passed the precincts of his laboratory. It may, therefore, be interesting to mention a patent which has been taken by Ewer and Pick in Berlin for the production of colouring matters containing sulphur (XXII. E. 1258), which, as far as I am aware, has not yet been printed. The method which these chemists propose, combined with the very ingenious apparatus for carrying it into effect on the large scale, appears to me not at all unlikely of being introduced into practice. Ewer and Pick insert two platinum plates or rollers, which form the two poles of an electric current, into a diluted sulphuric acid solution of paramidodimethyl-aniline, containing hydrogen sulphide. As soon as the evolution of hydrogen takes place, the liquor round the anode is coloured blue—this colouration, however, soon disappears, while the anode is covered with a grey precipitate. When this precipitate is removed, the liquor close to the anode again becomes blue, then disappears, and a precipitate is once more formed. This process of colouration of the liquor and formation of colouring matter continues, until at last all the hydrogen sulphide is used up, and the whole liquor becomes dyed an intense blue. The precipitate is the leuco base of the methylene blue. As I already stated, the process appears to me practical, not alone on account of the ingeniously contrived apparatus proposed by the inventors, which you will

soon have an opportunity of seeing fully described in our Journal, but also on account of the present unsatisfactory mode of producing methylene blue, by which method useless bye-products are formed, and the yield of valuable blue colour is far short of what theoretically it ought to be. Ewer and Pick claim the avoidance of the production of bye-products, and, as I assume, a quantitative yield of colouring matter

#### NOTE ON TITANIC ACID AS A MORDANT.

BY J. BARNES.

THE property possessed by titanic acid of combining with colouring matters presented itself to my notice during the course of some experiments to discover if alizarin is a reliable reagent to distinguish alumina from other white precipitates which may be thrown down by ammonia—*e.g.*, hydrated silica, phosphates of the alkaline earth metals, etc. I found that precipitated titanic acid gave a reaction very similar to that produced by alumina. This induced me to prepare some cloth with titanic acid, with the view to ascertain whether it would act like alumina as a mordant for colouring matters. The cloth, which had been previously oiled as for Turkey red, was soaked in an aqueous solution of titanium chloride containing some sodium acetate, dried off, and then passed through a bath heated to about 160° F. containing a little sodium phosphate. Prepared pieces of cloth were dyed with various colouring matters, and finally soaped. The colours yielded were as follows:—

*Alizarin*.—Full red, duller, and of a bluer shade than when alumina acts as the mordant.

*Alizarin Orange*.—Full orange, considerably redder than with alumina.

*Cerulein and Alizarin Blue*.—Dark green and full blue respectively, very similar to the colours produced on an alumina mordant.

*Preparation of Persian Berries*.—Brownish orange.

*Tannic Acid*.—Buff; very like an iron buff.

*Logwood Extract*.—Dark grey—almost black.

[In reply to a question by Mr. W. THOMSON, as to the mode of carrying out the alizarin test for alumina, Mr. BARNES continued]: The well-washed precipitate is mixed with water, one drop of a mixture of alizarin and water containing not more than 1 per cent. of pure alizarin is added, and the whole boiled for a short time. The precipitate, if consisting of hydrated alumina, assumes a bright red colour, which is more conspicuous if the precipitate be allowed to subside; if one drop of weak acetic acid, containing about 1 or 2 per cent. of the pure acid, is then added the colour will not be destroyed. If a red-coloured fluid has been formed owing to the presence of traces of alkali, the addition of the acetic acid immediately destroys the colour. I have sometimes made use of this test to remove any doubt as to whether a precipitate was alumina or hydrated silica. [In reply to a question by Mr. SIMS, as to whether the production of the colour was due merely to the oiling]: When pieces of the oiled cloth containing no titanic acid were heated with the dye materials, there were practically no colours formed. I have, moreover, obtained similar colours on yarn which had not been submitted to any oiling treatment.

*Meeting held April 23, 1885, in the Durham College of Science.*

### DISCUSSION ON MR. WELDON'S PAPERS READ AT THE LAST MEETING.

DR. HEWITT: There is one point, which in justice to English industrial chemistry should be stated, and that is in reference to a remark which Mr. Weldon made as to the possibility of making strong bleach from dilute chlorine. He omitted, unintentionally, I am sure, to state that without any mechanical means whatever, that question had been solved in England more than ten years ago. It will be known to every member that about that time Mr. Henry Deacon invented a direct process for the manufacture of chlorine by the decomposition, or, as I should prefer to call it, the combustion of hydrochloric acid with air at a high temperature in presence of a copper salt. That process yields an extremely dilute gas; it has been successfully worked, and it has been clearly established on a manufacturing scale that strong bleach can be made from very dilute chlorine. In order to give some idea of how dilute the chlorine may be, I have myself frequently made bleach testing 26 to 37 with a gas containing 26 or 27 grains of chlorine per cubic foot of inert gases—a degree of dilution far greater than any that M. Péchiney is likely to have used. I think it is due to the memory of Mr. Deacon that this should be stated.

### ON A NEW FORM OF CHLORIMETER.

BY J. FLEMING STARK, F.C.S.

SPECIAL attention has lately been directed by Her Majesty's Inspector under the Alkali Acts, to the amount of chlorine left unabsorbed in the chambers in the manufacture of bleaching powder. A notice thereon by Mr. Fletcher will be found at p. 39 of his last annual report. Immediately following the publication of that report, a system of testing was instituted at Messrs. Tennant's Works, at Helburn, which has been continued ever since, and by which each day, the amount of chlorine remaining unabsorbed in each chamber is ascertained prior to packing. The process first used was as follows:—40cc.  $\frac{1}{10}$  arsenite of soda solution was introduced into a bellows aspirator of 0.1 cubic foot capacity; 0.1 cubic foot of gas was then drawn from the bleach chamber, the aspirator well shaken, and the contents then carefully washed out. The amount of arsenite of soda left unacted on was then determined by titration with  $\frac{1}{10}$  iodine solution, and the grains chlorine per cubic foot of gas calculated therefrom. A careful examination of this method of testing was made, and its accuracy satisfactorily established.

A short time after this, Ballard's chlorimeter, as exhibited by Mr. Payne at the December meeting of this Section last year, was introduced on the Tyne. This apparatus consisted of a glass jar with attached indiarubber finger-pump, and was a modification of the apparatus described in 1864 by the late Dr. Angus Smith at p. 48 of his first annual report.

The process used was a development of Dr. Angus Smith's "minimetric system or method of analysis." A known quantity of hyposulphite of soda was introduced into the jar along with a little iodide of potassium and starch liquor. Gas from the bleach chamber was then drawn through the solution till a blue colour was obtained. The printed instructions, along with table for calculation of results, are published by Messrs. Mawson & Swan. The results obtained thereby, however, I have found to be considerably under the actual, and this, in view of the possibility of future legislation on the subject, has to be carefully guarded against, as thereby an erroneous idea might be established of the degree of absorption practically obtainable in ordinary working. As regards the reason for the discrepancy referred to, I have not investigated.

Returning then to the bellows test described above, an extended experience proved it to be, though accurate in careful hands, rather cumbersome in working. Each test necessitated a journey from the laboratory to bleach chambers and back again, thus entailing too great an expenditure of time. I accordingly designed the apparatus as shown below, which has now been in daily use for several months. The ease and speed

with which it can be worked, and the close degree of accuracy of the results obtained thereby, form my excuse for bringing it under your notice this evening. It consists of a burette *a* for measuring the gas. This is filled with water and connected by indiarubber tubing with the reservoir *b*. Between the burette and reservoir, a tap *c* is inserted, having two holes drilled through the plug at right angles to each other, one of large diameter and the other of small diameter. This admits of either the full flow of water through the tube while the burette is being filled with water, or of a restricted flow while gas is being drawn through the solutions. The four tubes *d, d, d, d*, contain solution of iodide of potassium in water, and can each in turn be brought in connection with the measuring burette by means of the glass taps shown. These absorbing tubes have each two tubes inserted through an indiarubber cork. One tube reaches nearly to the bottom of the solution, and is contracted at its lower end so as to break up the bells

of gas, and at its upper end connected with the interior of the bleach chamber by indiarubber and glass tube *e*. The second tube just goes through the cork and connects with the burette. Between the absorbing tubes and the burette a small wash-bottle *f* is fixed containing solution of iodide of potassium and starch. Between the wash-bottle and burette there is a two-way tap *g*, which admits of the air in the burette being forced out in refilling without having to pass backwards through the wash-bottle.

In using the apparatus, 3877cc. of gas are drawn through the solution in one of the absorbing tubes. Certainty of the absorption of all the chlorine is obtained by the solution in the wash-bottle remaining colourless. The contents of the tube are then carefully washed out into a beaker and titrated with  $\frac{5}{8}$  arsenite of soda solution. The number of cubic centimetres of this solution used multiplied by two gives the grains of chlorine per cubic foot of gas in the chamber.

### ON A PRACTICAL METHOD FOR RECOVERING TIN FROM TIN SCRAP BY ELECTRICITY.

BY JOHN HENRY SMITH, PH.D. (ZÜRICH),

*Associate of the Royal College of Science, Dublin.*

OWING to the vast accumulation of the above-mentioned material in canister, button, and other manufactories where tinned iron plate is extensively employed, considerable attention has been devoted to the utilisation of the same, chiefly with a view to the recovery of the tin, either in the metallic form or that of one of the various salts of tin used in commerce.

It would be interesting and amusing, although not instructive to an equal degree, to glance at the various methods, patent or otherwise, which have been suggested from time to time to effect this purpose. The separate actions of acids, alkalis, and chlorine gas have been utilised; friction and fusion have been resorted to; and more recently electricity has been pressed into service.

Of these methods I am only aware of three which have been employed on any large scale—viz., dissolving in a mixture of hydrochloric and nitric acids, and subsequent precipitation of tin by metallic zinc; treatment with caustic soda and litharge, forming stannate of soda; and the formation of tetrachloride of tin by the action of dry chlorine gas.

The last-named process is worthy of special mention. It has been described by Prof. Lunge in his report of the chemical section of the Swiss National Exhibition, held in Zürich in 1883.

Some time ago I was requested to recommend some practical method for the utilisation of these tin cuttings, in a district where they could be collected in large quantities. After reading all the literature at my disposal relating to the subject, I was induced to make some experiments, and amongst others, actuated by a knowledge of certain electrolytic processes employed for the precipitation of metals from their ores, I tried the effect of a current of electricity in passing through an acid solution in which a quantity of cuttings were suspended forming the anode, a copper plate serving as cathode. These experiments proved that not only is tin dissolved at the anode, but that it is also deposited in a pure form at the cathode, very soon after the commencement of the action. After continuing these experiments, and making the necessary calculations, I came to the

conclusion that this might form the basis of a practical method for the recovery of tin from tin scrap on a large scale.

I recommended that a trial should be made of this process; this was undertaken; the ceremony of obtaining a patent was duly observed, and I was intrusted with the supervision of the erection of the plant, an account of which, and of the results obtained therefrom, I now propose to give you in a brief form.

Although ignorant at the time, I am now aware that at least four English patents have been granted for the same object, effected by very similar means; still, as there are important differences in the process about to be described, and especially as, to the best of my knowledge, it was under my direction that the first plant was erected for the employment of an electrolytic method on any large scale, I venture to hope that the following details may interest the members of our Society:—

*General.*—The cuttings with which we had to deal varied considerably in value. Some of the thicker ones contained little more than 3 per cent. of tin, while some of the thinner kinds contained 8 or 9 per cent. I considered 5 per cent. as about an average. The quantity obtainable was calculated at about 6 tons per week, and the plant was designed to accommodate that quantity, charging twice a-day. The iron was designed to be converted into sulphate, a large quantity of which could be disposed of at a high price; the remainder was to be converted into "iron mordant"; the tin was to be converted into stannous chloride, and other salts of tin employed as mordants, and largely used by the dyers of that neighbourhood.

*Source of Electricity.*—No doubt could exist as to the best source for the production of such a strong current as that required, the difficulty was to select the dynamo machine which would be most suitable for the purpose. The machines manufactured by Siemens and Halsk of Berlin had been very highly spoken of as yielding good results in the precipitation of copper on a large scale at Oker in Germany. This firm was appealed to, and one of their small machines was recommended, which, although calculated to perform only about one-half the work required, was deemed sufficient to commence with. This machine is numbered C<sub>1</sub>, and it is stated to give a current of 240 Amperes with an electromotive force of 15 Volts, and an expenditure of 7 horse-power. (Of course this is considerably higher than the calculated power required.)

*Baths.*—From the given capacity of the machine it is easy to calculate that the best result would be obtained, without danger of over-heating the machine, by arranging the total resistance to be equal to  $\frac{1}{10}$  Ohm. As the subject of the resistance of various liquids to the passage of the electric current has been so imperfectly investigated, and data respecting other factors being likewise unobtainable, it was impossible to determine the best form, number, and arrangement of baths for the purpose in question. The best plan was evidently to make the resistance of each bath as little as possible, consistent with facility of working, and then to arrange them parallel, or in series, or both, so as to include the resistance mentioned above. Eight baths were decided upon. These were made of wood, lined with indiarubber, and each had the following internal dimensions. (I preserve the metrical measurements, not to shirk the trouble of converting them into English equivalents, but because I think every English chemist should be as familiar with the metric system as with our national system of weights and measures.) Length 150cm., breadth 70cm., depth 100cm. The thickness

of the wood was 5cm., that of the indiarubber 3 to 4mm. Each four baths were formed by the division of one large tank, 3m. x 14m., and the two tanks were firmly secured by iron bolts running from side to side. Placed longitudinally they occupied exactly the breadth of the building, and they were fixed at the end of the same, at an elevation of one metre from the ground. In front was a platform, at one side of which was a door for the admission of the cuttings, after being washed and packed. The dynamo was situated in the engine room just behind the baths, and communication was made by two copper cables passing through a hole in the wall. At either side wall, and on a level with the baths, was a dissolving tank capable of accommodating half the cuttings after the removal of the tin. A little farther on, and nearly on a level with the ground, were the evaporating down tanks. The crystallising tanks were situated beneath the ground level, so that the solution could be run off from one stage to another without any pumping arrangement.

**Anodes.**—These, of course, were composed of the tin scrap. Baskets were obtained to pack the cuttings in. These, at first, were made of wicker-work, but as they were too flexible, and soon rotted by the action of the acid, their place was supplied by strong wooden baskets, whose sides were formed of stout upright wooden bars, 2cm. thick, with spaces between them sufficient to allow the solution to circulate freely, while preventing the exit of the scrap. The internal dimensions of the baskets were:—Length, 120cm.; breadth, 30cm.; depth, 85cm. Great care was required in packing the scrap, because, if it were packed too closely, the metallic surfaces thereby united, and preventing the circulation of the electrolyte between them, necessarily retained their coating of tin. These baskets held from 60 to 70kilos. of the scrap, the 8 being capable of accommodating about half the total quantity required. Long and narrow strips of the same material were employed to complete the communication with the conductor. As the resistance of iron to the current is comparatively great, a large number of these were required to prevent excessive heating. At one end they were soldered together, and connected with the copper conductor by means of binding screws; the other extremities were distributed throughout the scrap.

**Cathodes.**—Copper plates were employed. These had a thickness of 13mm., were 120cm. long, and 95cm. in breadth. There were 16 in all, two for each bath, placed one on either side of the baskets. To keep these thin plates of copper as plane as possible, each was surrounded by a framework of copper rod of square section. They were coated with tin to prevent corrosion, as well as to avoid solution by any accidental reversal of the current. These plates rested in grooves at the sides of the tanks, placed at a distance of 10cm. from the sides of the baskets. They were provided, as also were the baskets, with indiarubber rollers extending to the sides of the baths, enabling them to be raised out of the same with ease, and without injury to the indiarubber coating.

**Electrolytes.**—Dilute sulphuric acid formed the electrolyte. This was employed, not only on account of its comparatively small resistance to the current, but also because it was convenient to turn the solution into the sulphate of iron tanks, as soon as it became saturated with that salt, and all the tin had been precipitated from it. Commercial acid of 60° B. was diluted with 9 volumes of water.

Above the tanks was a pulley arrangement for raising the baskets and plates out of the baths as required; there was also an arrangement of levers and eccentrics constructed, whereby the baskets were kept in gentle motion in the baths,

thus exciting circulation in the liquid, and tending to prevent polarisation. The horizontal axis upon which the eccentrics were disposed made about two revolutions per minute, thereby raising the baskets a distance of about 5cm. Levers were fulcrumed into the wall, these passed over the eccentrics, and at their extremities ropes were fixed communicating with the baskets.

The current was conducted by thick copper wires of several plies. Although already coated, they were enclosed in indiarubber tubing as an additional protection.

One of Crompton's indicators, registering up to 250 Amperes, was obtained for measuring the strength of the current, and detecting flaws or breakages in the same. Some such instrument is invaluable for such work, and this proved very reliable.

**Results obtained.**—The arrangement of the plant having been detailed, it remains to give the results of the working of the same. The critical point had been arrived at: the working capacity of the structure was to be determined; that which calculation could not indicate was about to be demonstrated. Acting in accordance with the principle, "Aspire high," the baths were first arranged in series. The connections being complete, the engine of horse-power was set in motion; the dynamo increased rapidly in speed, while the needle of the indicator followed tremulously until it stood vacillating within a few degrees of 240 Amperes, the dynamo then making about 900 revolutions per minute. Thus the most economical conditions of working had luckily been hit upon; the machine bore the current bravely, showing no signs of overheating.

**Quality of Tin deposited.**—This was at the first of a spongy nature, owing to the great acidity of the bath. Soon, however, it began to be precipitated in a more dense, extremely fine, granular, and partially crystalline state, which indeed was preferable, as it fell to the bottom of the bath, and was not in danger of forming a communication with the anode. I will not say that the tin was "chemically pure," but it was purer than commercial tin, and, when thoroughly washed, contained no trace of iron. It fused readily, and almost completely, and that without any addition, provided it had previously been thoroughly washed and dried. The rapidity with which it dissolved in hydrochloric acid was not to be compared to the slow action of that liquid upon granulated tin, and this rendered it peculiarly suitable for the production of stannous chloride.

**Quantity of Tin precipitated.**—From the data already given, the theoretical amount of tin deposited can readily be calculated. The electro-chemical equivalent of tin as a dyad, compared with silver, is  $117.8 \div 2$

$\frac{107.66}{3694} = 0.546$ , and this is equivalent to the precipitation of  $67.65 \times 0.546 = 36.94$  m.gms. of tin per minute per Ampere. For 240 Amperes, working through 8 baths arranged in series, we obtain a total precipitate of  $\frac{36.94 \times 240 \times 8 \times 60}{1,000,000} = 4.25$  kilos. per hour.

As a matter of fact, little more than half this quantity was obtained, the discrepancy being due to part of the current being absorbed in dissolving the iron as well as the tin, as soon as the former began to get bare. This, together with the natural solution of the iron in the acid, led to the rapid accumulation of sulphate of iron in the baths. The acid here employed took about seven weeks to become saturated. On analysis, the baths were found to vary in a very remarkable manner, first one and then another containing the largest quantity of iron. The tin, on the contrary, remained very constant in amount, both in the

individual baths and in the total, the average being 1.5 grm. per litre. Pure tin was deposited until the acid was saturated and no more tin was present in solution, then hydrate of iron began to form. This might be avoided for a time by the addition of more acid, but it was better to run the liquid into the "green vitriol" tanks, and add fresh solution. It was not at all necessary to continue the action of the current until all the tin had been removed; in fact, after a certain time, the action on the iron was even stronger than that on the tin. It was found in practice that, after the passage of the current for the space of 5 or 6 hours, the quantity of scrap referred to was sufficiently free from tin to be dissolved in the sulphate of iron tanks with the greatest ease; the tin remaining unacted upon in the presence of the large excess of iron always provided for, and it was not difficult to recover that tin, and utilise it with the rest.

*Cost of Plant and Expense of Working.*—These, of course, would depend upon the neighbourhood fixed upon, and other circumstances; but, in any case, they would be little compared with the value of the tin capable of being recovered. I think I have given sufficient details for any one to be able to calculate approximately their amount for any particular locality. Generally, this scrap is obtained for a mere nominal sum, frequently just for the expense of transport. One stoker and two or three labourers would be quite sufficient to work three tons per week, using one of the small dynamo machines manufactured by Messrs. Siemens Bros. The three cwt. of metallic tin obtained therefrom, at £3 18s. per cwt., will compare favourably with the cost of fuel necessary to maintain the production of 7 or 8 horse-power, wages of workmen, interest on the plant, and occasional repairs. If it were worked on a larger scale, and the tin and iron further worked up into salts, as in the instance detailed, the profits would be increased in a much greater ratio. When we consider that in Paris alone 3000 tons of this scrap are produced annually, it is no unimportant matter to determine the best method of utilising it.

*Advantages of this System.*—In addition to the consideration of economy, this method possesses advantages which are well worthy of attention, especially where sulphate of iron and "iron mordant" are marketable products. As has been observed, the tin is precipitated in a pure form, and in a state of fine division. It may, therefore, be either fused and sold in the metallic form, or it may be converted into stannous chloride, or other salts, for which it is exceedingly well suited, owing to the ease with which it is dissolved. In the process in which the scrap is acted on by chlorine gas, no choice exists as to the form in which the tin shall be sent to the market, tetrachloride being the constant product. The same remark applies to the method where caustic soda and litharge are employed, and in other respects this latter method has little to recommend it, judging from my own observations. The other process which I mentioned is also unsatisfactory. In employing a mixture of hydrochloric and nitric acids, considerably more iron than tin is dissolved, and when the tin is precipitated by metallic zinc, the contamination of the chloride of iron with zinc chloride renders it of little value. I do not claim perfection for the method I have advocated. It is capable, however, of considerable modification; and I am sorry I have not been able to follow the matter up as I should have liked. A better electrolyte could doubtless be found; probably a solution of stannous sulphate would be the best. I think, however, I have proved that this process is practical, simple, and economical; and further, that it presents the additional advantages of purity of product and variety of utilisation, thus rendering it well worthy of a wider application.

## DISCUSSION.

MR. GATHERAL said: This question of the recovery of tin was one to which a great deal of attention had been devoted, there having been taken out since 1857 no less than about forty English patents on the subject. The question of cost was the thing on which they had chiefly broken down, and he feared this would be the case, too, with Dr. Smith's process if attempted here. In this country the mere cost of collection of tin scrap often amounted to 25s. or 30s. per ton.

DR. SMITH said that the cost of the tin scrap at the locality spoken of in the paper was only 2 francs per ton.

## JAMESON COKING PROCESS.

BY J. JAMESON.

I HAVE been asked to say something to-night as to the coking process associated with my name. I admit that some explanation is required as to its position. A little more than a year ago, and indeed up to a much later time than that, it was considered a highly successful process, and one of immense importance to the coke and coal trade everywhere. At the present time little is heard of it, and that little is sometimes, unhappily, not satisfactory.

In regard to the truthfulness of representations made by the holders of my patents, there is not a word to retract. The results obtained were published far and wide; coals were carried to Felling from nearly all parts of the country and coked in the ordinary oven, usually in the presence of the owner or his representative; the products were carefully weighed and measured; many independent analyses were obtained, samples were sent in all directions, and the fullest inquiry was courted.

When the process was practically adopted, it fell into good hands. Messrs. Bell Brothers converted three ovens, and after some experience with them, seven more; then, with a further experience of many months, another range of seven. The Weardale Iron and Coal Company converted three, then added seven more, and after many months' trial, made a new conversion of twenty, with plant adequate for considerable extension. The results of these trials were reported to us as follows:—That the cost of the process was less than one penny per ton of coal coked; that the yield of coke was increased; that the time required in the oven was shortened; that the quality of the coke was improved as regards sulphur; and our coke, being carefully tried in the blast furnace by itself, was pronounced quite equal to the best Beehive coke. No wonder the use of the process was extended, and that we had very soon installations in a number of different places.

The results, unhappily, were in many cases by no means such as we had anticipated, and complaints began to rise, and, as time went on, to increase. The defects discovered, not of course all at one place, but some at one place and some at another, were the following:—

The yield of ammonia was almost *nil*. The yield of oil was much less than was expected; its quality was depreciated; the suction pipes stopped up; the scrubbers became clogged with a pitchy oil; the passages below the oven floor became filled up with coke dust, or the perforations in the brick bottom through which the gas should pass, closed up; the gas became unburnable or explosive. The Directors of the Company found themselves embarked upon a sea of troubles with no autocrat to direct, and no absolutely certain programme to follow.

I am, I confess, greatly tempted here to indulge in some personal explanations; but they would have little general interest, if any, and I refrain.

The Directors of the Company did not cease to believe in the process. Most excellent results had been obtained, and the difficulties arising appeared to be mechanical and not inherent in the invention itself. The falling off in results for the reason that it was due in one place to one cause, and in another place to another cause, was not unhelpful; and without dividing a penny, the Directors (being at the same time the largest shareholders) have been content to spend, in the prosecution of the enterprise of the Company, upwards of five thousand pounds, independently of the cost of all preliminary experiments.

Now, as to the present position of affairs. I do not propose to take you through all the tedious steps of our discoveries. Alterations in ovens or apparatus involve the expenditure of considerable time, and often a much longer time is required for practical demonstrations of their effect; but, perhaps, the longest time of all is occupied in localising the exact cause of failure where there may be several causes.

The first and great cause of all our trouble, after many experiments, was conclusively proved to be ingress of air at the oven bottom, and the first requisite to success, therefore, is that the oven bottom be air-tight, or as nearly so as possible. This point was strongly pressed in all our circulars and in all our directions for installation, but, as it proves, not sufficiently so. Any ordinary building of bricks and fireclay or (unless carried to both a great depth and width) of bricks, fireclay, and tar, becomes after use porous, and admits air. The effect of leakage of air is extremely bad in many ways. The air is heated in its passage through the hot brickwork, and meeting with the warm gas from the oven (dependent upon degree of admixture and temperature) it decomposes the ammonia, and the oil or it makes an explosive gas; or the air may burn in the gas atmosphere, just as gas does in air—it produces a heat in the pipes which is very undesirable, causing a distillation of the oil deposited on the sides of the pipe, with the result that the lighter fractions of the oil are carried forward with the gas, and the heavier part is formed into pitch on the pipe, and gradually stops it up. There is a further injury caused by the ingress of air—namely, that all useless air tends to carry away ammonia and oil, by hurrying the gas dealt with through the scrubber and condenser. If the gas be mixed, for instance, with its own bulk of air at equal temperature, it is clear that the condensing apparatus must be double the size, and that scrubbers and exhausters possess only half the efficiency they would have if the air were excluded. A simple method of discovering the tightness of an oven bottom is to cover the whole of the perforated floor with papers wet with oil, and then to apply considerable suction, and estimate the quantity of air passing. But, as defects may arise in this respect at any time, it is also of great importance to have a simple means of ascertaining how much gas is passing from every oven to the main when in regular work; and to accomplish this we put a regulator valve in the pipe of each oven between the oven and the main. This regulator is a valve so marked as to indicate exactly the amount of opening through it, and there is a syphon water-gauge coupled to the pipe at one end on one side of the regulator, and at the other end to the pipe on the other side of the regulator, so that the indicated difference of level shall show the exact pressure tending to pass gas through the restricted opening. Within very narrow limits, this enables us to estimate the exact quantity of gas passing from each oven.

If from a 5-ton oven, burning its charge in 72 hours,

there is a passage of gas of about 1000 feet per hour, with a good suction on the oven, it may be presumed that the process is working well; but if the passage of gas be much more or less than this it points to some defects which should be investigated and remedied.

Next to the tightness of the oven bottom, I think I should attach importance to the construction of the oven floor; and the best floor, in my judgment, is one formed of alternate firebricks and T irons; the bricks being shaped so as to take in the T iron, and form a level floor. I show a piece of T iron which has been in an oven continuously worked for four months. It is practically as good as new.

I show a drawing of the special brick and of the oven floor with T irons in place. To provide for expansion and prevent the T iron from rising into the charge, we cut these into pieces not more than 18 inches long, and bevel the ends as shown in the drawing, so as, while affording room for expansion, to prevent actual opening for the passage of coal into the channels below; or the floor may be constructed in accordance with plan No. 2. The T irons prevent an action which has caused a great deal of trouble—namely, when the openings through or between the bricks enlarge downwards, as they must do to prevent stopping up, any chipping of the top makes an opening equal to the size of the enlargement at the depth to which the chip extends. The heavy rakes in use for drawing coke chip the bricks, the openings become much too large, and coal and coke dust get down and impede or stop up the passages below. The T iron, however, will bear a heavy blow of the rake and distribute it on a large solid body of brickwork so as to do no harm to it.

Next in importance to the points already referred to, I attach value to an improvement effected by a slight cooling of the gas of each oven separately before passing into the main.

It is very easy to reduce the temperature of gas at 400° to 150°, a very short pipe will do it; but if gas at 400° be mixed with gas at, say, 150°, so as to make the resultant temperature 160°, it requires a great surface of pipe to extract the 10° thus added and bring the temperature to 150°. There is, however, a still stronger reason for the partial cooling of the gas of each oven separately—namely, that gas and products of different quality come off at different periods of the process, and if hot gas from an exhausted or nearly exhausted oven be mixed with rich gas from a half burned oven, the products in the latter may be decomposed; the oil, which from this half-burned oven is condensable, may be so acted upon that part of it is converted into permanent gas, the remainder is injured in quality, and the ammonia may be wholly lost. With cooled gas, however, this action is stopped.

I show a drawing of the arrangement of the ovens showing the cooling pipes, details of the regulator valve, the suction pipe of each oven, and its cleaning arrangements.

I think it is well to condense the steam used for the steam jet, so as both to recover the oil and ammonia brought down by the steam, and at the same time to make the gas available for burning; but, of course, if a mechanical exhauster be used this is not necessary.

The modifications I have referred to have been practically applied at one installation, as follows. Formerly half-an-inch suction on the oven bottom overheated the pipe to the extent of sometimes making it red-hot, and as the chimney draught was a quarter-inch, the real pull on the gas was necessarily exceedingly small. With half-an-inch of suction the quantity of gas and air passing from the oven was

equal to 80,000 feet per ton of coal coked, by far the larger portion being, of course, air. Now, with the same oven,  $3\frac{1}{2}$  inches suction gives a passage of gas equal to less than 12,000 feet per ton. The temperature in the oven pipe with this great suction is usually under  $200^{\circ}$ , and rises only to  $400^{\circ}$  as the oven gets nearly burned off. The yield of oil is increased to four times what it was, and, in fact, both in ammonia and oil the Felling results have been obtained. The scrubbers, cooling pipe, and steam jet, are equal to more than six times the work they could formerly do; they can now operate six ovens instead of one with equal efficiency, and the quality of the oil is greatly improved. There is no possibility of burning the oil by reason of defect in one oven of the range; and any defect in stoppage of floor or leakage of air is at once apparent. The attention required is diminished, and I confidently believe that the application of the remedies devised will meet our troubles at every installation. That is to say, there is not any defect which has arisen, at any installation, which is not, so far as I know, met and covered by the modifications introduced. Experiments are still going on with a view to discover the best and cheapest means of making a really air-tight bottom, but as we can safely go to a depth at which the temperature never rises above a dull red, there cannot possibly be any permanent difficulty about it.

#### DISCUSSION.

Mr. JOHN PATTINSON was interested to know that the modifications spoken of were making the process a working success: he asked whether the sulphate of ammonium was recovered at any installation, and to what purposes the oil was best applied. Mr. Jameson was also asked the strength of the liquors yielded.

In reply, Mr. JAMESON said: The ammonia is not worked up into sulphate at any of our present installations. The largest number of converted ovens at one place is 54, coking about 600 tons of coal per week; these ovens are not yet modified in accordance with the arrangements described in the paper: the coal used is one yielding only small results, and the yield of ammonia is not large enough to warrant the erection of sulphate plant. The quantity of ammonia yielded depended on the coal, and varied from 2 or 3lb. to about 15lb. (expressed as sulphate) per ton. As to the oil, Dr. Armstrong, of London, is going to read a paper at the Iron and Steel Institute meeting shortly, which will I believe deal with the whole question of its nature and uses. Dr. Armstrong told me that he finds it in a very marked degree a low temperature product, and hence especially adapted for conversion into other forms by higher temperature. He suggested its application as a source of illuminating gas, and that fractions not suited for other purposes should be used as a liquid fuel for steam-ships. A good deal has been used for creosoting and found very good for the purpose. The strength of the ammonia liquor varied from 2 to 5oz. per gallon.

### THE ST. BEDE PATENT DECOMPOSING FURNACE.

BY W. L. RENNOLDSON.

This furnace, which is the invention of Mr. Thos. Larkin of East Jarrow, has been designed for the manufacture of sulphate of soda, hydrochloric acid, and other substances. In its arrangement every attention has been given to the important requirements of the present time, which are, capability to make salt-cake of first-rate quality, and to yield the

HCl in the largest possible quantity, and this of high density (so as to allow of the best results being got in the bleach department), while at the same time to admit of the escaping flue-gases being readily maintained within the standard limit of acidity.

These desiderata are all accomplished with this furnace, and not only accomplished, but with remarkable economy under every item—viz., labour, fuel, vitriol, first cost and maintenance. In its general character the furnace is not such a radical departure from the hand-worked furnace as other mechanical decomposers are, the aim having been to retain the really efficient features of the best hand system, and combine with these the several improvements which constitute the invention, and which were actually desirable.

The plant consists, in the first place, of an ordinary pan situated so that the charge of salt is dropped in from a wagon on an overhead tramway, and it (the pan) is fired by the waste heat from the roaster.

The roaster is of the close or muffle style, but with a specially low and perfectly flat inner roof (or arch), consisting of sections of iron plates supported in a very novel manner, and the space between it and the upper arch, which is also nearly flat, is divided into independent transverse compartments or channels.

The heating of this roaster is effected by a double series of small fires: one series heats the bed from its under side, the other heats the roof. Each fire has its own flue across the furnace, and afterwards all these small flues lead into a main one, from which all or any portion of the waste heat can be directed under the pan.

The mechanical appliances for working the batch in the roaster, are a vertical shaft, and horizontal radial arms with scrapers, and being very strong—i.e., strong in the proper place, but by no means ponderous—are very serviceable and efficient.

A small steam engine transmits the power from below, and the whole arrangement works smoothly and silently.

The substitution of steam-power for manual labour for working the batch in the close roaster, and the protection of every part of the steam-worked tools from the direct action of the fire, are special features of the invention. And the adoption of several small fires in place of one enormous, and more or less unmanageable fire, is an improvement of the greatest advantage.

The multiplication of the sources of heat leads to an even heating of the whole furnace, and, as the coaling and cleaning (scarring) is done at intervals, and at one fire at a time, the temperature of the whole furnace can be maintained with great regularity, and thus the great cause of destruction to the structure—i.e., expansion and contraction—is largely reduced. And as each flue, under the bed and over the arch, has its own fire, and each flue has a damper, it becomes an easy matter to manipulate the heat in any way, or even to entirely lay off any section of the arch, in the event of a failure occurring.

These flues being on the "flash" system (in contradistinction to the usual "wheel" or return system) a very slight draught to the chimney suffices, so that any leakage would not be of acid gas to the chimney, but of smoke to the condenser, owing to the (with this furnace) *undoubted* stronger draught to the condenser than to the chimney; however, the useful provision above mentioned effectually provides against leakage in either direction.

The fact that all the stirring and raking of the batch and the evolution of its HCl takes place with *closed working doors*, is a very great advantage in many ways—direct and indirect, more especially when coupled with the fact that the roaster is a close one.

There is the highly important one that it renders it a matter of ease to obtain practically all the hydrochloric acid in a highly concentrated state without any costly ranges of cooling pipes, or extravagant condensing space; this is a considerable saving in cost for plant and its maintenance, and the cost for wash towers and for their supply of water are entirely saved. The high strength hydrochloric acid means a less volume of itself, and of the still liquors, and as the loss of HCl, as free acid, in the still liquors is in direct proportion to their volume, there is a greater utilisation of the acid, and consequently a larger production of bleach per ton of salt decomposed.

From the same cause there is a saving of chalk or limestone for neutralising, while less still, etc., room and steam suffice for working such liquors.

Another advantage connected with the closed working doors is in the matter of the usual escapes of acid vapours about the furnaces—i.e., the “*low level escapes*”—which are the cause of much anxiety in many neighbourhoods; with this furnace such escapes are almost unknown.

This satisfactory state exists partly from the doors being closed, and also from the reason that a much stronger draught to the condensers is used with these furnaces than with hand-worked ones.

A strong draught on hand roasters is the cause of several evils; when the working doors are open, as they must be to a large extent, the influx of air rapidly cools the roaster, and heats the condenser, and so interferes with efficient condensation.

Then, again, the practicability of working with closed doors and strong draught prevents the possibility of any acid gas leaking into the chimney gases through any crevice that might exist in the arch, etc.

This arrangement of furnace also benefits the workmen to a very considerable extent. The drier-man is relieved of nearly all the punishing nature of his work. The steam-worked tools relieve him of the hard labour, heat and gas he had to bear with the hand furnaces, and the closed doors and strong draught keep the air about the place free from acid; and the attending to the several small fires does not give him the severe scorching that the ordinary large fire does; and when he draws the batch, it is so well worked and evenly fired that not even then is he troubled by gas.

Even the pan-man is much benefited, as he is allowed to have a stronger draught than formerly, when there was always a fear of drawing dangerous heat, etc., from the roaster through his open, or perhaps leaky partition damper. He is also relieved from the scorching which the ordinary pan-fire gave him.

The sulphate can readily be made of any strength and with great uniformity, and this uniformity of composition and of physical condition, being free from hard lumps and fine without being dusty, renders it highly suitable for the manufacture of alkali and of glass.

The following is a statement of results :—

#### RESULTS OF WORKING BY THE ST. BEDE CHEMICAL COMPANY, NEWCASTLE—AVERAGES OVER LAST THREE MONTHS.

(Three furnaces are now in constant operation.)

Salt decomposed per furnace per week (six days) (50 tons have been done in a week of six days).....	72 tons
Sulphuric acid consumed (on weight of damp salt as received).....	78 per cent.
Sulphate (salt cake) made.....	110 per cent.
Test of sulphate, 0.4 acid.....	1.3 per cent. salt
Test of gas from pan and roaster at the condenser inlet.....	175 F.

Test of gas from pan and roaster at the condenser outlet..... 0.19 gn. HCl per cubic foot  
 Test of gas, etc., in chimney... 0.07 gn. HCl per cubic foot  
 Test of hydrochloric acid produced..... 29° T. at 60 F.  
 Bleaching powder, 1 ton obtained from each... 46wt. salt

	Per Ton Sulphate
	s. d.
Labour (all at and about furnaces).....	2 0
Labour since reduced, now working at.....	1 9
Steam, fuel and labour for.....	0 14
Fuel at pan and roaster, 7½wt. small coal.....	1 3

REPAIRS.—During the fourteen months the system has been at work there have been no appreciable repairs, no renewal of arms, nor of bridge, arch, or casing of either pan or drier fires, only replacing of worn scrapers.

#### DISCUSSION.

DR. HEWITT said that he had seen the furnace at work that morning, and observed that both the method of firing and construction of the arch or roof were novel. He considered that the idea of heating with a number of small fires with separate flues was a great improvement on the one large fire system, because the latter fanned great intensity of heat in a part only of the furnace, with consequent unequal expansion and contraction. He received with reserve the statements as to cost of maintenance, owing to the short time during which the furnace had been at work; but at the same time he thought that its special construction was likely to conduce to economy in that direction. As to salt cake, he preferred its being made in two operations, as in the pan and roaster of the hand-worked furnace. But in this, mixing had to be done by hand, and the quality of salt cake produced depended on the skill of the workman. Moreover, hand mixing necessitated open doors, leading to both influx of air and escape of gas. Open mechanical furnaces, intended to replace the old “pan,” had never seemed quite satisfactory to him, owing to the dilution of the gas with air. Gaskell and Deacon’s, and Gamble’s plus-pressure furnaces had been intended to meet the objections to the second part of the operation, inasmuch as they were “close,” and permitted little, if any, dilution of the evolved hydrochloric acid. But Mr. Larkin had added to the old pan a mechanical muffle, in which thorough incorporation was effected by a mechanical stirrer with closed doors, thus effecting better condensation, and avoiding low-level nuisance. The stirrer is not exposed to a very high temperature, and its wear and tear is reduced to a minimum. Altogether, both as regards fuel, condensation, and make of bleach, he thought very highly of this furnace. Having regard to present circumstances, which rendered it desirable to make a maximum of bleach with a minimum of soda, and to obtain a more condensed, and thereby stronger gas, there was no doubt that Mr. Larkin’s furnace was a step in the right direction.

MR. STUART: It would have added materially to the value of Mr. Remondson’s interesting paper, had he mentioned the particular form of decomposing furnace over which he claims advantages for the Black and Larkin furnace, and I think it would have been well had he selected for comparison the furnace which in his opinion best suits the requirements of the present day. All other things being equal, as to cost of plant and sulphate, combined with satisfactory quality of the product, that furnace is the best, in the present condition of the Leblanc process, which produces a ton of bleaching powder

from the least quantity of salt. On the one hand we have the Jones and the Maetear mechanical decomposing furnaces, and on the other the Deacon and the Gamble plus-pressure hand furnaces. In discussing the merits of the Black and Larkin furnace to-night, it will be obviously necessary to select for comparison from these four, the furnace which is best adapted to our present requirements. The Jones and Maetear furnaces have each proved a mechanical success, and the sulphate produced by them is of excellent quality. Per ton of salt decomposed, however, the cost for these furnaces is enormous, and in connection with the now all-important question of salt consumption, per ton of bleaching powder, represented by the condensation, I venture to express the opinion that these furnaces have been superseded. Being open furnaces, the principle is wrong, the hydrochloric acid being highly heated and diluted with the products of combustion and excess air, and consequently is in that condition in which it is impossible to obtain satisfactory condensation. Heat and dilution constitute the difficulties in condensing hydrochloric acid, and of the two, dilution is the more prejudicial. The Jones furnace and the Maetear furnace have been superseded by the plus-pressure hand furnaces, which have proved so satisfactory that they have been largely adopted by alkali manufacturers. Being close and not open furnaces, the hydrochloric acid is evolved at a very low temperature, and not mixed with the products of combustion, which go direct to the chimney. The only dilution of the hydrochloric acid arises from the small amount of air that enters the doors of the roaster, when the men are working and drawing their batches. Instead, therefore, of the hydrochloric acid being evolved highly heated and diluted, as in the Jones and Maetear furnaces, it is in the plus-pressure furnaces produced at a comparatively low temperature, and being only slightly diluted, is easily condensed into acid of high density for the stills. Comparing the Black and Larkin furnace, which I have carefully examined several times, and the plus-pressure hand furnace, it will be seen, as specially pointed out by Mr. Remondson, that the sulphate is roasted with closed doors, air being only admitted for a short time when the batches are being drawn, and consequently there is less dilution of the hydrochloric acid in the Black and Larkin than in the plus-pressure hand furnace. Then, the Black and Larkin furnace is also worked with a plus pressure, got by the very simple means explained by Mr. Remondson. Excellent, therefore, as the condensation is in the plus-pressure hand furnace, it must be better in the Black and Larkin, in which also there is complete removal of the low-level gas, and the obvious advantages of mechanically worked sulphate as against hand labour. Compared with the plus-pressure hand furnace, I do not think there is any saving on plant or fuel. Wages amount to 2s. in the Black and Larkin against about 2s. 10d. in the plus-pressure hand furnace, but this will be partly at least covered by the extra repairs on the machinery. Mr. Remondson states that the consumption of O. V. with the Black and Larkin furnace is only 78 on salt, and although this is a very low figure, I am inclined to think that it must be rather less than in the plus-pressure hand furnaces. I think it would be difficult to show a direct financial saving in favour of the Black and Larkin over the plus-pressure hand furnace, which is really a very satisfactory one, but the well-recognised advantage of a really efficient machine over hand labour, the complete removal of the low-level nuisance, better condensation, combined with the durability of furnaces, which I have quite satisfied

myself about, constitute the advantages which the Black and Larkin possesses over the plus-pressure hand furnaces, and which justify me in expressing the opinion that it is the furnace by which bleaching powder can be made from the least consumption of salt, and also that it is the furnace, taken as a whole, which best suits the requirements of the present day.

## ON SECURITY OF DOCUMENTS.

BY J. JAMESON.

This paper described the importance of mordant in writing ink, and the dangers which would arise from the use of ink containing no mordant, such as a mixture of lamp black and gum water, and it then described means of protection against the use of such ink. It referred to dangers arising from the use of a film on postage stamps soluble in water, but impervious to obliterating ink, which rendered the present system of obliteration inefficient, and finally dealt with a new application of soluble films on paper for transformation advertisements, Christmas and birthday cards, etc., the arrangement being such as that washing with water removes all printed matter, which is carried on the filmed surface, leaving any printing below it intact. Some very striking examples of transformation were shown, and samples were handed to the members. The protected paper and transformation pictures are shown at the Inventions Exhibition, the latter as Reid's patented system.

MR. G. BEILBY IN THE CHAIR.

## WOOD NAPHTHA.

BY MR. C. A. FAWSITT.

As the distillation of wood and the working up of the resulting products form an important branch of the chemical industry in the West of Scotland, I thought it perhaps might be of interest to some of the members of this Society, if I read a short paper on what, in this district, is termed "wood naphtha," but elsewhere generally "wood spirit."

In the first place I shall say a few words on the composition of wood. Secondly, give some conditions on which the yield of the different products of wood distillation depends. Thirdly, dwell more particularly on the preparation, properties and uses of wood naphtha.

1st. As to the composition of wood.

Wood consists principally of cellulose, impregnated with incrusting material, such as resin, volatile oils, sugar, gum, tannin and protein bodies, besides the usual mineral constituents of plants.

The amount of incrusting material varies, being more abundant in hard and heavy varieties than in light and soft kinds; and wood which contains it in the largest proportion gives the most acid and naphtha on distillation. These incrusting materials contain more carbon than cellulose, and the greater the amount of carbon and hydrogen in wood compared with cellulose depends on a greater amount of these bodies. Beech wood was found, by Payen, to contain 40 per cent. cellulose and 60 per cent. incrusting material.

Wood is a highly hygroscopic substance, as is shown by the fact that if placed in air of ordinary temperatures, after having been dried completely at about 105° C., it takes up about 20 per cent. of water. Its average composition is as follows:—

	Carbon.	Hydrogen.	Oxygen.	Nitrogen	Ash.	Water.
Dried at 120° C.	50	6.0	42.0	1.0	1.0	0
Air-dried	39.2	4.7	34.3	0.8	0.8	20.0

2nd. Some conditions on which the yield of different products of wood distillation depends.

When ordinary air-dried hard wood is distilled in closed vessels, there results

Charcoal, which amounts to 21 to 26% of weight of wood.	
Liquid distillate	50 to 55
Permanent gas	20 to 25

You can readily understand that the weight of the different crude products depends on a variety of conditions.

The first I will mention are the species, age and condition of the wood, and also the soil it is grown in.

As regards the species, it may be said that hard woods are preferred by the wood distiller; and of these oak, beech and birch are most used in this district. The following example shows the difference in yield of acid for 100 parts oak and Scotch fir:—

	Crude Acid.	Acetic Acid.	Tar.	Charcoal.
Oak	47.6	5.4	6.1	24.9
Scotch Fir	15.0	2.7	10.0	28.0

You will notice that, although the weight of crude acid in both cases is much the same, the amount of acetic acid is very much less in the case of the Scotch fir; and I should like to mention here that the yield of acetic acid and naphtha always varies in the same direction—i.e., if the yield of acid is large, so is that of the naphtha, and *vice versa*.

The condition of the wood when distilled has an important influence, sound wood giving much better results than unsound. It should also, previous to distillation, have lain for some time, in order that a considerable proportion of the water might escape. This is then called "air-dried" wood. It appears to lose water for about 1½ to 2 years after it is cut, and should not be used, at the soonest, within one year of the time of cutting.

New beech wood contains ..... 30 to 35% H<sub>2</sub>O  
" well air-dried, contains 16 to 20% H<sub>2</sub>O  
Trunk wood gives more acid than branch wood.

We will now notice another important set of conditions—namely, temperature, size and shape of retorts.

The temperature has a most important influence, and it can be taken as an invariable rule that a low heat gives more charcoal, acid, naphtha and tar, but less permanent gas, than a high one; and this can be readily understood if we remember that at a low heat bodies are formed, rich in oxygen, such as C<sub>2</sub>H<sub>4</sub>O<sub>2</sub> and CH<sub>3</sub>O; but at high temperatures these same bodies are decomposed into compounds rich in carbon and hydrogen. For instance, acetic acid yields free carbon, benzene, naphthalene, acetone and permanent gas, whilst CH<sub>3</sub>O gives permanent gas, containing acetylene and other bodies.

The size of the retorts, likewise, has a slight effect on the yield of the products. This is more marked near the end of the distillation, when the heat of the retort is, as a rule, at its maximum; and the gas travels slowly, both through the heated mass and along the heated walls of the retort.

The aim of the wood distiller is to obtain the largest possible yield of acid; and he, therefore, regulates the heat of his retorts accordingly. Experience has proved that the most suitable temperature is 350° to 400° C.

As soon as the temperature exceeds 400° C., the per cent. of acetic acid decreases; and as acetic yields acetone on being passed through a red-hot tube, one would imagine that the per cent. of acetone would increase; but it is not the case. I made two trials, conducted under exactly the same conditions, with the exception that in one case the temperature was 300° to 350° C., and in the other low red-heat. The crude acid, from experiment at the low temperature, gave 42 per cent. of acetone, and at the high temperature 39 per cent. The yield of both acid and naphtha were, in these experiments, one-third less in the case of strong heat.

It is impossible to formulate the reactions which take place inside the retort, as you cannot establish a fixed set of conditions as regards temperature, etc. Certain compounds are no sooner formed, we will say in the centre of the retort, than they pass into a more strongly heated space, and are at once dissociated.

I have seen it stated that a sharp strong heat gives a better yield of naphtha, but my experience does not bear out this statement.

I now come, 3rdly, to speak of the preparation, properties and uses of wood naphtha.

We will assume that the wood has been distilled, and that we have the liquid distillate, containing acid, naphtha and tar, to work up for the naphtha. It is allowed to stand for some time, when the tar falls almost completely to the bottom of the vessel, and the crude acid forms a watery layer on the surface. This latter, amounting to 42 to 47 per cent. by weight of wood distilled, is drawn off and worked up for the acid and naphtha it contains, according as to what acid products are required. In this district these are,

for the most part, acetate of lime, iron liquor, and brown sugar of lead.

If acetate of lime is wanted, the crude acid gets in most cases a plain distillation, to rid it of most of the tarry matters. The distillate is then neutralised with lime, allowed to settle, and the supernatant liquor distilled. The naphtha being the most volatile, comes over at the commencement, and should be collected until the runnings have a sp. gr. '995 to '1000. A very common test in use at many works is for the stillman to throw a small quantity of the runnings upon some hot cinders, and if the gases evolved do not take fire, he concludes it is time to put off the still. It is needless for me to dwell on the unreliability of such a test, and in these days, when we hear so much about the great strides which are being made in methods of testing in chemical works, it should be replaced by a better one.

If sugar of lead or iron liquor are wanted, the crude acid is distilled, and the naphtha collected, until the runnings show same strength as in the previous case. Care is required to keep the acid from coming over. I have often worked crude naphtha, which would have paid much better to work for the acid than for the naphtha it contained; but I find dull times are the best remedy for such carelessness.

The crude naphtha, by either process, has an average sp. gr. 0.980, and varies from 0.970 to 0.990. It has a dark-brown colour and strong smell, and must, from what has previously been said, be a complex liquid.

Besides water, crude wood naphtha contains the following compounds:—

	Formula.	Boiling-Point.	Sp. Gr.
Methyl Alcohol	$\text{C}_2\text{H}_5\text{OH}$	65.0	0.79389 at 15.5° C.
Acetone	$(\text{CH}_3)_2\text{CO}$	56.3	0.814 at 0° C.
Methylic Acetate	$\text{C}_2\text{H}_5\text{O} \cdot \text{C}_2\text{H}_3$	56.3	0.90085 at 21° C.
Aldehyde	$\text{C}_2\text{H}_4\text{O}$	20.8	0.8009 at 0° C.
Ethyl Alcohol	$\text{C}_2\text{H}_5\text{OH}$	103	0.8706 at 0° C.
Di-methyl Acetate	$\text{C}_2\text{H}_5(\text{O} \cdot \text{C}_2\text{H}_3)_2$	63.61	0.8787 at 6° C.

Also small quantities mono-, di-, tri-, methylamine, acetate of ammonia, oils and tarry matters.

The wood naphtha from manufacture of sugar of lead and iron liquor almost always contains free acetic acid.

There are several methods in use for working up the crude naphtha; but the one which finds most favour in this district, and which gives a very good finished product at a small cost for plant and material, is to distil with lime, which retains the water and acid, decomposes almost entirely the methylic acetate, simple and compound ammonias, acts upon the oils in such a manner as to convert the greater part of them into solid resinous bodies of high boiling points, and has also the effect of diminishing the percentage of acetone, which, on treatment with lime, gives condensation products of high boiling points. It is important to decompose the methylic acetate, as on account of its high sp. gr. it, if present in large quantities, makes it difficult to work the naphtha down to the usual strength, 61 o.p., sp. gr. '827.

A source of considerable trouble to the rectifier of wood naphtha is the oils contained in the crude, and although they, for the most part, boil considerably over 100° C., on account of the large quantity of steam given off, are, in the distillation, easily carried over along with the naphtha. They are very soluble in strong naphtha, but can be separated again by merely diluting with water, when they usually rise as an oily layer to the surface of the liquid; in some cases they sink to the bottom of the vessel.

It is essential to remove these oils as completely as possible, as a small percentage is injurious, as I shall show farther on.

As to the composition of these oils very little is known. According to C. hours they contain, besides

other bodies, toluene, xylene, and cymene; and Kramer and Grodski found subsequently that they contain ketones, which, on treatment with  $\text{ZnCl}_2$  and  $\text{H}_2\text{SO}_4$ , give toluene, xylene and cymene.

I made a fractional distillation of a sample, and below you have the results:—

300cc. taken, sp. gr. '876 at 15.5° C.

A: Thermometer in liquid.

B: " " vapour.

Began run: A, 80° C.

" " B, 65° C.

	A.	B.
5% .....	90° C.	70° C.
10 .....	110	84
20 .....	133	120
30 .....	140	130
40 .....	146	136
50 .....	152	142
60 .....	160	151
70 .....	168	158
80 .....	178	168
90 .....	193	183
95 .....	203	191

*Specific Gravity of the Distillate.*

1st.—50cc.....	0.840 at 15.5° C.
2nd.—50cc.....	0.857 " "
3rd.—50cc.....	0.872 " "
4th.—50cc.....	0.881 " "
5th.—50cc.....	0.887 " "
Last.—25cc.....	0.901 " "

You will no doubt notice that in the case of B, a considerable proportion of the oil comes over 130-142. Within these temperatures the three isomeric xylenes boil. This fraction is almost completely absorbed when shaken with  $\frac{1}{2}$  times its volume of strongest sulphuric acid, which would be the case with meta- and ortho-xylene, as they are converted into sulphonic acids, but not if it consisted of paraffins or para-xylene. I do not say that this property of the oil proves the presence of the above-mentioned hydrocarbons, but it tends in the right direction. The finished wood naphtha, as it comes into commerce, is an almost colourless liquid, having a sp. gr. of 0.827 at 15.5° C. This sp. gr. corresponds to 61 o.p. by Sykes.

One of the principal uses of wood naphtha is in the manufacture of methylated spirit, but there are certain conditions which must be fulfilled before the Government will allow of its being used for this purpose, one of which is that it must have a pungent smell, so that it can impart the same to the spirits of wine, and so destroy its "magic" influence—i.e., render it unfit for drinking purposes.

The following is the clause in the Excise regulations which treats of the strength and proportion of wood naphtha to be added to the spirits of wine for manufacture of methylated spirit:—

"The spirit is not to be less than 50 o.p., nor less in quantity than 450 gals. at a time, and the proportion of naphtha or methylic alcohol, not less than one-ninth of the spirit. Strength of naphtha to be at least 60 o.p."

The buyer always specifies that the naphtha shall be "miscible," i.e., it shall not produce turbidity when diluted with water. This turbidity arises from the presence of the oils above referred to, and which, on addition of water, are thrown down in a finely divided state, and give the solution a milky appearance.

The method adopted in this district, and also by a large number of firms in England, for taking the strength of the finished naphtha, is simply determinative of its sp. gr. The instrument used is that of Sykes, the readings of which are tabulated with corresponding strengths. These tables were made up for spirits of wine, and are still used in all the

Government offices for that purpose, but it certainly seems a little strange that the strength of wood naphtha, consisting chiefly of methyl alcohol, should be fixed by them. It so happens that the sp. gr. of methyl and ethyl alcohols do not, for the same percentage, differ very much; but, as it is becoming more the custom to buy by sp. gr., corresponding to a certain percentage, it would be decidedly preferable to adopt a table made up for methyl alcohol. The Sykes table gives the highest strength at 60° F. to be 67 o.r., which corresponds to sp. gr. '815, but this only corresponds to 93 per cent. of  $\text{CH}_3\text{O}$ , as determined by Prof. Dittmar and myself, and you can see that by still adhering to the old tables confusion may often occur. A good average sample of finished naphtha, sp. gr. '829, at 15.5, contains—

$\text{CH}_3\text{O}$ .....	= 80 %
Acetone .....	= 6
$\text{H}_2\text{O}$ .....	= 12

Besides traces of methyllic acetate, di-methyl acetol, methylamine and other impurities, should boil as under:—

100cc. taken.

95 " .....	84.0	79.0

Not very many years ago wood naphtha was scarcely a saleable article. Its principal uses were for varnish and finish manufacture, and as a substitute for methylated spirit; but with the discovery of the aniline colours, and the large increase in the consumption of methylated spirit, the demand for this article has increased, and to-day, instead of wood naphtha being cheaper than methylated spirit, it is the reverse, the former varying from 4s. to 5s. per gallon, and the latter from 2s. 6d. to 3s. per gallon.

The principal uses for finished wood naphtha are for methylated spirit, aniline colour and varnish manufacture, the portion rich in acetone being chosen for the latter purpose, as it is a capital solvent for gums.

The quantity used for aniline colour manufacture is very small in this country compared with Germany, but the quality required for that purpose is much higher than that employed in making methylated spirit. It is to be hoped that organic chemistry will be more taught and studied in England and Scotland, so that the manufacture of articles of commerce, such as aniline colours, will be thoroughly understood and appreciated both by young chemists and manufacturers.

#### DISCUSSION.

Mr. BELBY paid a tribute to the author for his valuable contribution. He felt that it was the duty of each particular Section to bring into discussion the industries of the locality; and testified to the great want hitherto felt of technical literature bearing upon these industries, a want which such papers were intended to supply. He would like to ask the author whether stove-drying of the wood had been found to have any beneficial effect upon the yield of products? He also wished to know what method was used to

determine the percentage of methyl alcohol present in purified-wood spirit.

Mr. FAWCETT, in reply, said that stove-drying had not proved beneficial as regards increase in the yield of products. They always used the methyl-iodide test for methyl alcohol in purified-wood spirit.

In reply to questions asked by Mr. PATRICKSON, he said that naphtha was made miscible in water by extracting the oily portions by distillation, and that its so-called solvent action upon gums and resins was due to the acetone present.

Meeting held April 7.

MR. E. C. C. STANFORD IN THE CHAIR.

## A NEW SYSTEM OF COOLING OILS FOR THE EXTRACTION OF PARAFFIN.

BY GEORGE BELBY.

THE separation of the solid from the liquid paraffins in their manufacture from crude shale oil or petroleum, is essentially a process of crystallisation and filtration. By fractional distillation of the partially purified oil a concentrated solution of solid paraffin in oil is obtained. In the manufacture as ordinarily practised in Scotland, this concentrated solution of paraffin, whose crystallising point is from 90° to 100° F., is exposed to the air in large trays or tanks, from one foot to two feet deep. In from two to four days, according to the season of the year, the oil is reduced to the temperature of the air or nearly so. The separation of paraffin by such slow crystallisation makes the solution into a perfectly solid mass, so thoroughly knit together by the interlacing of crystals, that the oil, which constitutes about 75 per cent. of the whole, cannot be separated by mere draining. In order that the oil and paraffin may be separated by filtration, it is necessary to crush the mass so as to destroy the general structure, leaving the individual crystals free. The crushed mass is pumped into filter presses, the oil passes through and the paraffin is retained in the cells. The paraffin obtained at this stage is known commercially as "hard scale," but a further crop of crystals of lower melting point is obtained from the first mother-liquor by concentrating it by distillation, and again cooling and filter-pressing. As this second crop of paraffin is of lower melting point, and is, therefore, more soluble in oil, it is the custom to cool the solution by means of artificial refrigerators, so as to crystallise and extract the paraffin at a temperature of 32° F., or as much below that point as possible. The apparatus most commonly used for this purpose consists of a drum or cylinder of cast iron, kept at a low temperature by a current of cold brine led through it from a refrigerating machine. This drum revolves on a horizontal axis, its lower side dipping slightly in a tray containing the oil to be cooled. The cold surface of the drum, as it revolves, picks up a layer of oil from the tray, which layer, as it is carried round on the cold surface, is reduced to its temperature. After the layer has travelled round on the drum for about three-fourths of its revolution, it is scraped off by a steel knife which is pressed against the surface of the drum by springs and set screws. The cleaned surface in the course of its revolution again passes through the oil in the tray, taking up a fresh layer of solution to be cooled, solidified and scraped off. Thus the process is a rapid and continuous one, the warm oil is continually running into the tray, passing over the drum, and being scraped off and dropped into a suitable

receptacle, from which it is drawn by pumps and forced into filter presses. Various modifications of this form of paraffin cooler have been designed by Mr. A. C. Kirk, Mr. Southby, Mr. N. M. Henderson, and Mr. William Baxter, in every case the object being the rapid cooling of a large quantity of oil. Owing to the very low conducting power of paraffin for heat, quick cooling can only be obtained by bringing the oil in thin layers in contact with cold metallic surfaces; this principle was recognised and acted on in all of the coolers enumerated. Looked at simply as appliances for cooling, the maximum quantity of oil through the maximum number of

or powdery form, whereas slow regular cooling produces large well-defined crystals. In solutions of paraffin in oil these effects of cooling are particularly well marked. When a hot saturated solution is suddenly cooled, the paraffin is deposited in an amorphous or only faintly crystalline condition, and is consequently very difficult to separate from the oil. On the other hand, if the solution is kept in repose, and under such conditions that the cooling is slow and regular, the paraffin deposits in large well-defined crystals, which are easily separated from the oil. These effects are most apparent in oils of high viscosity, and for two reasons: (1.) The viscous oil

FIG. 1.

degrees in the shortest possible time, these coolers are all really efficient. It is only when the desired object is, not merely the cooling of a solution of paraffin to a given temperature, but the efficient separation of the paraffin by crystallisation, that the principle of rapid cooling in thin layers is seen to be unsound.

The crystallisation of paraffin from solution in oil is in many respects analogous to the crystallisation of salts from aqueous solution. The size of the resulting crystals in both cases is very largely determined by the rate of cooling and deposition. A hot saturated solution of sulphate of sodium suddenly cooled to the atmospheric temperature deposits the salt in a granular

on being cooled to a low temperature itself becomes gelatinous or semi-solid, and in this state tends to retain the paraffin in an imperfectly crystalline state.

(2.) The methods of refining which are necessary for the production of the most viscous oils, also tend to produce viscous or amorphous paraffin. Vaseline when properly prepared shows no trace of crystalline structure, and is, therefore, an excellent example of an amorphous paraffin mixed with a viscous oil. As the whole tendency of paraffin and petroleum refiners is to produce lubricating oils of maximum viscosity, the difficulty of separating the paraffin tends also to increase. In certain cases the viscosity practically

attainable is determined solely by the possibility of properly extracting the paraffin.

The value of slow regular cooling for the extraction of the first crop of paraffin or "hard scale" has for long been fully recognised, so far at least as natural or atmospheric cooling is concerned; but whenever refrigerator cooling has been used, the principle has been abandoned. Mr. A. C. Kirk tells me that at Mr. Young's Bathgate Works various schemes were proposed, and even partially worked out, for the cooling of paraffin oils in a state of repose, but these were put

erating machines, made it seem not unreasonable to consider the possibility of cooling paraffin oils in an artificial winter atmosphere. When ways and means came to be considered, it was evident that the employment of tray coolers, one to two feet deep, was quite out of the question, on account of the enormous ground area that would be occupied for a given quantity of oil, involving the erection and cooling of very large buildings. The quantity of oil to be cooled at Oakbank was 8000 gallons per day, and assuming that four days were necessary for cooling it, accommodation

FIG. 2.

aside in favour of the more rapid system of cooling by drums.

At Oakbank, about two years ago, it became necessary to devise means for cooling and crystallising certain very viscous oils. An experience of many years with this class of oils made it evident that proper crystallisation could only be ensured by cooling the oil slowly, and in considerable mass, to the desired temperature. The success of Mr. Coleman and others in maintaining a winter temperature in the meat safes of ships in the Tropics by means of refrig-

erating machines, made it seem not unreasonable to consider the possibility of cooling paraffin oils in an artificial winter atmosphere. When ways and means came to be considered, it was evident that the employment of tray coolers, one to two feet deep, was quite out of the question, on account of the enormous ground area that would be occupied for a given quantity of oil, involving the erection and cooling of very large buildings. The quantity of oil to be cooled at Oakbank was 8000 gallons per day, and assuming that four days were necessary for cooling it, accommodation

for four days' oil or 32,000 gallons would have to be provided. This quantity of oil spread out in tanks one foot deep would cover a ground area of 5120 square feet, equal to a rectangle of 160 feet by 32 feet. In the plans adopted and carried out at Oakbank, the coolers are turned edgewise, and are built in blocks with interspaces between the cells. It has been pointed out that the cooled and crystallised mass needs to be mashed or crushed before it can be filtered. In the flat tray coolers this has generally been done by manual labour, hand tools being forced through the

mass. In the coolers of this new arrangement such treatment was out of the question; it was, therefore, necessary to provide mechanical appliances for crushing the mass, and delivering it ready for the filter presses. After experimenting with various forms of crusher, the arrangement finally adopted was a screw laid along the bottom of each cell. The shaft of this screw passes out through a stuffing gland on the end of the cooler, and is fitted with worm gearing, by which it can be rotated when desired. The thread of the screw is right-handed, so that by rotating it backwards, or from right to left, the block or slab of cooled paraffin is bored out, the "borings" or crushed

In designing this plant it was necessary to know exactly the time that must be allowed for the effective cooling and crystallisation in cell coolers of a given size and thickness. Experiments were made in a temporarily fitted-up cold air chamber. A cooling cell one foot thick was filled with paraffin solution, at 95° F., and was subjected in this cold air chamber to a mean temperature of 21° F. for 96 hours. In the cooling cell were placed thermometers 1½ inches, 3 inches, and 6 inches from the outside. The temperature indicated by these, and by another thermometer hanging in the chamber, were observed and recorded every two hours. The results of these

FIG. 3.

paraffin being delivered through an opening at the opposite end from the driving shaft. As the screw occupies the whole length and breadth of the cell at the bottom, the whole base of the block of paraffin is sheared away by its rotation, and as the cooling cells are wedge-shaped—wider at the bottom than the top—the whole weight of the block rests on its base. As the base is sheared away the whole block settles down, and is gradually sheared and delivered by the screw.

The drawings (Figs. 1 and 2) show a block of cells in longitudinal and cross section. The interspaces between the oil cells are enclosed and provided with pipes for the circulation of cold brine.

observations were laid down on a diagram (Fig. 3). The great irregularity of the temperature of the chamber was due to the imperfect character of the cooling engine, and to the small size of the chamber, but fortunately the low conducting power of the oil and paraffin saves the mass from any great irregularity in cooling. The conclusions from these experiments were: That with a suitable cooling medium, oil and paraffin could be cooled sufficiently in 96 hours in cooling cells one foot in thickness; further, that with this rate of cooling the crystallisation of the paraffin was thoroughly satisfactory.

To aid in determining the needful dimensions and strength of the screw, gearing, etc., determinations

were made of the crushing and shearing strength of the cooled block of paraffin at 32° F. These of course must vary with the percentage of paraffin and the viscosity of the solvent oil; it is, therefore, hardly worth while to reproduce them here. With the particular oil experimented with, it requires a pressure of three tons exerted on the pitch line of a 12-inch worm wheel to start the screw in the midst of the mass of cooled paraffin. The screw revolving at 76 revolutions per minute throws 600 to 800 gallons of mashed paraffin per hour.

The cooling cells are arranged in four blocks of ten cells each. Each block contains one day's oil, or 8000 gallons. The blocks are carried on girders 10 feet above the floor level, the necessary filter presses being arranged on the floor below.

The house in which the cells are placed is built with double walls and a double roof, the interspaces being filled with non-conducting material.

Cold brine from an ammonia refrigerator is led through between the oil cells. A cold surface of about 1000 square feet is exposed to the air of the house, so that a considerable part of the effect of the refrigerator is devoted to keeping the air of the house cool. From experimental determinations of the conducting power of brick, it is estimated that the heat passing into the house through floor, walls, and roof, will amount during the heat of summer to the equivalent of six tons of ice melted per day.

#### DISCUSSION.

Mr. COLEMAN quite endorsed the author's views in respect of the advantages of slow cooling, compared with the old method of cooling rapidly by a revolving drum as detailed in the paper. He thought that the plan invented by Mr. Beilby of cooling in cells, and breaking up the mass by screw motion from below, was as ingenious as it seemed effective, and far less calculated to destroy the large crystals of paraffin. He stated that the reason why cold-air machines were used so extensively for meat preserving was that chemicals could not be employed for the purpose for hygienic and other reasons. But in the case of paraffin these objections were non-existent, and it then became a mere question of convenience and economy what method of refrigeration should be adopted. In conclusion, he considered that a debt of gratitude was due to the author for his very practical paper, and looked forward with interest to the results likely to accrue to the paraffin oil industry from the adoption of Mr. Beilby's process.

### ON DESTRUCTIVE DISTILLATION.

BY PROFESSOR MILLS, F.R.S.

IN the present paper I propose to deal with three topics—viz. (1) The definite character, (2) The limiting temperature, and (3) The course, of destructive distillation.

(1).—DEFINITE CHARACTER OF DESTRUCTIVE DISTILLATION.—It is universally recognised that when such bodies as calcic hydrate or carbonate, hydric salicylate or potassic acetate, are destructively distilled, the results are of a very definite nature, and it is the custom to express these by exact symbolic equalities. The destructive distillation, on the other hand, of coal, shale, bone, wool, cellulose and the like, has always been vaguely regarded; as if it were of an indefinite character, and open to a vast variety of modification at the hands of the chemical inventor. It appears to me that all kinds of destructive distillation are equally definite when the evidence with

regard to them is equally complete; and that they cannot be susceptible of indefinite variation, because the law of multiple proportions must apply, without exception, to every one of them. Some illustrations of this principle may be of interest to the section.

(a) *Coal*.—Most authorities are agreed that coal has been derived from more or less impure woody fibre or cellulose,  $nC_6H_{10}O_5$ , under the influence of heat, pressure, and time. The effect of heat is at first to dehydrate cellulose. By interpolation among Violette's well-known results on the heating of wood (*Ann. Ch. Phys.* [3], xxxii. 304), I find that  $nC_6H_{10}O_5$  corresponds to a temperature of about 185°, and  $nC_6H_8O_4$  to about 226° in the absence of pressure; in presence of pressure, the latter temperature corresponds to  $nC_6H_8O_2$ . At a point somewhat below 430°, and without pressure, the residue has the composition,  $nC_6H_2O$ . The final stage  $nC_6$  is probably not attained under ordinary experimental conditions.

According to these results, the composition and reactions of coal should turn upon the value of  $n$ , the losses of  $H_2O$ , and the collateral kinetic changes which, occurring in the course of these definite transactions, lead to the formation of isomeric (or even of polymeric) coals. The organic matter in coal or shale, if we agree to represent its composition by a formula, should correspond to an initial symbol  $nC_6$  or  $2nC_3$ .

In constructing equations to represent the transformations of coal and other complex bodies I shall, for the sake of convenience, frequently employ collocations of symbols to indicate mean composition; it will be understood that these collocations are not intended to suggest separate chemical compounds.

Prof. W. Foster (*Proc. Inst. C.E.*, April, 1884) has completely analysed, and distilled at a high temperature, two samples of Yorkshire and one of Durham coal. His mean results, apart from sulphur, nitrogen, pit-water and ash, correspond to the following relations:—

$2C_{24}H_{18}O$	$= 33C$	$+ C_2H_{2.0}$	$+ H_2O$ .
Organic matter in coal.	Fixed carbon.	Gas and tar.	Organic water.
(Calc.) 100	61.5	35.7	2.8
(Found) —	61.5	38.5	

Foster has also similarly examined a Scotch cannel. His data may in like manner be reduced as follows:—

$2C_{12}H_{12}O$	$= 12C$	$+ C_4H_{2.0}$	$+ H_2O$ .
(Calc.) —	41.9	52.9	5.2
(Found) —	41.3	58.7	

In my work on Destructive Distillation (2nd Ed., p. 28) I have shown that the organic matter in a good average Scotch shale has almost exactly the composition  $C_6H_{10}O$ . According to additional data (*loc. cit.* p. 26), reduced as before, the changes which this undergoes at a low temperature may be represented by the equality,

$7C_6H_{10}O$	$= 18C$	$+ C_2H_{2.0}$	$+ 4H_2O$
	Fixed carbon.	Gas and oil.	
(Calc.) 100	31.5	58.0	10.5
(Found) —	31.2	58.3	10.5

At a high temperature, we have the relation

$7C_6H_{10}O$	$= 6C$	$+ C_6H_{4.0}O_2$	$+ 4H_2O$ .
	Fixed carbon.	Gas and tar.	
(Calc.) 100	10.5	79.0	10.5
(Found) —	12.8	76.0	11.2

The Heywood Cannel Gas Coal, which may be taken as representing an average Scotch cannel, has (*loc. cit.* and special communication to the author)

been analysed and distilled. The reactions are—at a low temperature—

	Fixed carbon.	Gas and tar.	
(Calc.) 100 .....	59.6 .....	37.4 .....	3.3
(Found) .....	58.1 .....	38.3 .....	3.6

and at a high temperature—

	Fixed carbon.	Gas and tar.	
(Calc.) 100 .....	52.9 .....	43.8 .....	3.3
(Found) .....	52.5 .....	43.9 .....	3.6

The results for Boghead coal are as follows :—At a low temperature—

	Fixed carbon.	Gas and oil.	
(Calc.) 100 .....	33.3 .....	63.3 .....	3.3
(Found) .....	33.3 .....	64.1 .....	2.6

At a high temperature—

	Fixed carbon.	Gas and tar.	
(Calc.) 100 .....	13.3 .....	83.3 .....	3.3
(Found) .....	12.8 .....	84.6 .....	2.6

There is thus considerable evidence in favour of the definite character of the destructive distillation of coal and shale. It is probable that the organic matter in these minerals can be always represented with an  $\alpha C_3$  formula; and that a very simple relation exists between the C of the fixed carbon on the one hand, and the C of the [gas and tar (or oil)] on the other. It is clear also that  $C_3$  is the fundamental unit, or stable condition, in these effects; and that not less than this unit must be removed from, or left in, the "fixed carbon" during destructive distillation. Hence it is hopeless to expect that, for instance, more than fractional variations in the yield of oil from a shale can be effected by modifications in modern retorting.

It would have been a great gratification to me if I could have rendered this part of my subject more complete, by splitting up the symbolic collocations for "gas and tar (oil)" into two others, for gas and tar (oil) respectively. Unfortunately no data at present exist for this purpose.

The following reductions may, however, serve as a guide and assistance in future investigations.

P. Frankland (*Journal* iii. 273) has given the composition of fifteen samples of purified coal-gas (presumably bituminous). The mean percentage and variations are as follows :—

Ethylene and its equivalents.	Hydrogen.	Carbonic Oxide.	Marsh Gas.
6.69	47.39	4.05	38.83
1.45	3.74	0.69	1.37
Variation.	Variation.	Variation.	Variation.

These ratios correspond to

(=102 vols.; the last being added to fulfil the condition of unpurified gas). Summing the above formulae, we have the collocation  $C_{3.35}H_{14.0}O_6$ , which may otherwise be expressed as  $30CH_4 : 6H_2O : 4H_2$ . Having regard to variation, we shall be correct in regarding average unpurified coal-gas as consisting of redistributed marsh-gas and water. Here also the  $C_3$  unit recurs.

The same author (*loc. cit.*) gives the composition of three samples of gas from Scotch cannel. His figures tend to show that this gas tends to consist of redistributed methyl and water; but the data are too few, and their variation too great, to allow of any very exact inference.

The following complete analyses of London and average cannel gas-tar (Scotch) have been made in my laboratory :—

	London.	Scotch Cannel.
* Carbon .....	77.53 .....	85.33
* Hydrogen .....	6.33 .....	7.33
* Nitrogen .....	1.03 .....	8.5
Sulphur .....	.61 .....	.43
Oxygen .....	14.50 .....	6.06
	100.00	100.00

If we deduct nitrogen and sulphur, we shall obtain the following results :—

	London.	$C_3H_5O_3$ .	Scotch.	$C_3H_5O_3$ .
Carbon ...	78.82	...	86.44	...
Hydrogen ...	6.41	...	7.42	...
Oxygen ...	14.71	...	6.14	...
	100.00	100.00	100.00	100.00

The ubiquitous  $C_2$  unit again appears in the mean composition of the tars; it must therefore be common to both kinds of gas.

(*β*) *Cellulose*.—The material used for this experiment was well scoured handkerchief cloth. It contained 599 per cent. of water, and yielded .65 per cent. of ash. The still consisted of a glass flask holding 1130cc., whose neck sloped slightly downwards. By means of a piece of combustion tubing about 1.3m. long, this was connected with a two-necked receiver, on the outside of which cold water was constantly playing. The top of the still was covered with sheet asbestos. Heat was applied by means of a Fletcher burner. The distillation lasted six hours, during which a red heat was gradually attained. The following are the particulars of an experiment (substance taken, 100grm.) :—

	Grammes.
Water measured after drawing from receiver.....	42.6
„ in substance.....	6.0
Hydric acetate (sp. gr. 1.06) in water .....	36.5
Acetate : water : : $C_2H_4O_2$ : $2H_2O$ .....	2.4
Experimental drainage correction .....	34.5
Total water .....	35.7
= 39.4 per cent. on dry organic cotton.	1.1
Fixed carbon in retort .....	36.8
Ash correction .....	26.5
	7
	25.8

= 27.6 per cent. on dry organic cotton.

Tar (heavier than water), about 2.5cc.

Hydric acetate, 2.040grm.

= 2.20 per cent. on dry organic cotton.

The equation is

	Fixed carbon.	Gas and tar.	Organic water.
(Calc.) 100 ...	29.6 .....	29.6 .....	40.8
(Found) .....	27.6 .....	30.0 .....	39.4

In this case the weight of (gas and tar) is about equal to that of the fixed carbon. The  $C_2$  from the acetate, added to the tar, amounts to about 3.6 per cent. Hence the gas, saturated with moisture, must have amounted to about 26.0 per cent. [In this and similar experiments, all the acid in the distillate is reckoned acetic.]

(1) *Jute*.—The sample contained 10.65 per cent. of water, and yielded 1.29 per cent. of ash. It was distilled in exactly the same way as the cellulose. The results, reduced as before, are in accordance with the relation :

	Fixed carbon.	Gas and tar.	Organic water.
(Calc.) 100.....	27.5	43.1	29.4
(Found).....	27.5	41.3	31.2

The formula for jute is calculated from the analysis of Cross and Bevan (*Trans. Chem. Soc.* 1882, 100-101), who regard it as having the constitution of an aromatic cellulide. This may account for the unusual

Accordingly, only 25 grammes were distilled, the time taken being eleven hours. The corrected results were as follows :—

	Fixed carbon.	Gas and tar.	Organic water.
(Calc.) .....	31.6	15.8	52.6
(Found).....	31.5	17.7	50.8

Sugar furnishes 2.32 per cent. of acetate when thus distilled, and very little tar. The gas probably amounted to about  $17\frac{1}{2}$  per cent. The  $C_5$  unit now reappears.

(c) *Wool*.—The sample, which consisted of well-

relations between the coefficients of C on the right-hand side of the equation. Jute furnishes 3.0 per cent. of acetate when distilled as above described. The amount of tar from 100 grammes exceeded 1cc. (a little having been lost). The gas, as before, may have been 38.8 per cent.

(d) *Cumose*.—The sample contained .15 per cent. of moisture, and yielded .03 per cent. of ash. The same apparatus was used as before. The operation is extremely liable to fail, owing to intumescence.

scoured yarn, contained 14.93 per cent. of moisture, and yielded .84 per cent. of ash. 50grm. of it were distilled during six hours in the same manner as before; excepting that a suitable tower, containing standard acid, was placed to intercept any ammonia that might pass off with the gas. The first products observed in the course of the distillation were hydric sulphide and water; crystals of ammoniac carbonate were observed next; and these were succeeded by a pale yellow oil. The distillate smelled very strongly

of members of the pyridine series; and a very pungent body, probably acridine, occurred in the latest stages of the operation.

Analyses of wool by Märcker and Schulze, and Scherer, are given in Watts's *Gmelin*, xvii. 251 (an unfortunate exchange of H for N in this analytical statement led me some time since (*Trans. Chem. Soc.* 1883, 142) to an erroneous formula for wool). Their percentages agree fairly well with the expression adopted below.

	Märcker and Schulze. (Mean.)	Scherer.	$C_{26}H_{45}N_3SO_{13}$
Carbon.....	49.54	50.65	50.49
Hydrogen.....	7.29	7.03	7.01
Nitrogen.....	15.60	17.71	16.61
Sulphur.....	3.44	.....	3.45
Oxygen.....	24.13	.....	22.44
	100.00		100.00

The "fixed carbon" contained a considerable quantity of nitrogen. The following equation corresponds with the determinations so far as made:—

"Fixed carbon" Gas and tar,

	Percentages found.	Calc.
Water.....	5.4	5.8
Residual carbon.....	24.9	26.1
Nitrogen therewith.....	4.3	4.5
Ammonia.....	8.6	9.2

It must, however, be added that the sulphur was not entirely evolved, as I found 21 per cent. in the fixed nitrogenous carbon. Portions, also, of  $CO_2$  and HCN ought doubtless to be credited to the gas and tar; but it would have been a matter of extreme difficulty to determine the free cyanide and carbonate. The actual tar amounted to about 2.5cc. per 50grm. of wool; it was lighter than water.

We have thus seen that as regards coal, cellulose, cannose and wool, the process of destructive distillation has certain stable stages; which, when expressed in the common chemical symbols, correspond to  $C_3$  or a multiple of  $C_3$ . In the case of jute, also an apparently definite but partially aromatic compound, this relation either does not hold good or has become obscured. By adopting collocations of symbols to represent the average composition of the products of destructive distillation, we arrive at distinct and simple outlines of the complex results with which we had been previously familiar.

(2) LIMITING TEMPERATURES.—In a recent memoir [*Phil. Mag.* (5) xvii. 173] I have shown that the boiling points of all known normal paraffins having an even coefficient  $x$  of  $C$  are comprised in the equation

$$y = \frac{39.315(x-3.94)}{1 + .07053(x-3.94)}$$

Similarly, when the coefficient of  $C$  is uneven, the equation is

$$y = \frac{38.992(x-3.92)}{1 + .07056(x-3.92)}$$

When  $x$  is made exceedingly large in these equations,  $y$  (the boiling point) becomes 555.67 and 552.58 respectively. These values very nearly agree; and we may take their mean, 554°, as a working number. The normal paraffins have the highest boiling-points of any substances which it is the object of the shale-distilling industry to attain. Hence this number represents the highest temperatures required in the

interior of a shale retort during the evolution of paraffins.

(3) THE COURSE OF DESTRUCTIVE DISTILLATION.—The course of destructive distillation admits of quantitative admeasurement in various ways. The usual method is to determine gravities; but so far as I am aware, no chemical method is ever systematically followed at works.

The destructive distillation of resin furnishes an excellent illustration of the ineffectiveness of the physical, as compared with the chemical, examination. While the extreme range of gravities in the distillate is only from .90968 to 1.03038, the range of bromine absorptions is from 32.02 to 142.48. A distinguished firm of Glasgow distillers very kindly placed at my disposal a series of samples representing a complete distillation from one of their smaller stills. The samples were carefully sealed, and allowed to rest in a warm place for about eight months, at the end of which time the separation of the water was regarded as practically at an end. Two bromine absorptions (by the titration method) were then made for each sample, and the gravities determined at 9° C.

The resin used for distillation was American. It was blackish brown in colour. Specific gravity at 15° C. = 1.065; bromine absorption (determined colorimetrically) 101.66 per cent. [Pure resin absorbs nearly 112.96 per cent.]

The following table contains the whole of the results:—

No. of Sample.	Hours.	Sp. Gr.	Bromine Absorption.	Remarks.
			PER CENT.	
1	0.5	.90968	142.48	Spirit begins
2	1.0	.92308	131.56	
3	1.5	.92890	128.70	
4	2.0	.92342	119.24	
5	2.5	.93863	109.62	
6	3.25	.95100	107.18	( Spirit ends. Oil begins
7	4.0	.98400	85.31	( Not quite clear.
8	4.75	.98429	77.27	( More viscous
9	5.50	.99601	71.20	
10	6.25	.99792	63.37	
11	7.00	.99820	60.74	
12	7.75	.99621	63.50	
13	8.50	.99621	61.28	
14	9.25	.99621	61.62	Darker coloured
15	10.00	.99332	59.61	Still darker
16	10.75	.99241	57.28	" "
17	11.50	.99181	52.60	Less dark
18	12.25	.99920	43.46	( Dark layer at surface. Less viscous
19	13.00	.99880	50.76	Darkest of all
20	13.75	1.03038	38.83	Dark and turbid
21	11.50	1.01731	41.89	" "
22	15.25	.99122	32.30	Very dark
23	16.00	.96960	32.02	( Nearly as dark as 19

From these experiments some interesting inferences may be drawn. In the first place it is evident that neither the specific gravity nor bromine absorption follows a perfectly regular course; this is very possibly due to unavoidable errors in firing, and to some superheating at the sides of the still, which did not contain more than about 1000 gallons. On the whole, however, the bromine absorption quite evidently decreases as the specific gravity increases, and from sp. gr. .90968 to 1.03038 (the extreme range) 1 per cent. of bromine corresponds to about .00058563 sp. gr. There is some indication of a break in the series, where spirit ends and oil begins. The extremely heavy bodies formed towards the close of the distillation split up at last into lighter ones; but as shown by the bromine absorption, these are probably of nearly the same chemical order as the heavy ones. As the course of the distillation proceeds from a great to small bromine absorption, it involves the formation of more and more saturated bodies; in other words, an approximation is continually in progress towards the composition of the paraffin series.

In the accompanying drawing (page 327), I have plotted out the relation of bromine absorptions to time. Through the experimental points have been drawn two curves, whose equations are:

$$y = 158.5(86406)^{-t} \text{ and } \\ y = 62.4 - 2.2657(1.3689)^{-t}$$

$t$  being the number of hours, and  $y$  the bromine absorption. It will be observed that the first curve is in fair agreement with the actual work, and indicates that the bromine absorption could not exceed 158.5 per cent. This curve terminates at about the seventh hour, after which the absorption alters very little until the tenth hour, when it decidedly begins to fall. The exact position of the second curve is much more difficult to find, and lies less close to the experimental points. This indeed might have been reasonably expected from the diminished content of the still, the increasing effect of the heat, and the consequent magnifying of every irregularity that occurred. Better results could doubtless be attained with a still of greater capacity.

I wish to express my great indebtedness to Mr. Muter, and in particular to Mr. C. Ellis, F.C.S., for their practical assistance in connection with this paper.

#### DISCUSSION.

Mr. BEILEY, in proposing a vote of thanks to Professor Mills, said: It is unfortunate that Dr. Mills is not present to give us some further information as to the principles which have guided him to some of the deductions made in his paper. I am satisfied that the chemistry of destructive distillation can most profitably be studied if pure substances of known composition and constitution are operated on. Coal and shale are such complex substances, that even if their behaviour on distillation is carefully studied, the knowledge so gained can only contribute detached or partially connected facts, from which general laws cannot be deduced. I quite agree with Dr. Mills that the possible yield of paraffins from a given shale is quite definitely limited by the nature of the material, but are we further to understand him to say that these limits can be defined by a mathematical formula when nothing but the *ultimate composition* of the shale is known?

—♦♦♦♦♦—

#### A NEW PROCESS FOR THE ESTIMATION OF SULPHUR IN PYRITES.

BY JOHN CLARK, PH.D., ETC.

As pyrites in this country is usually sold on analysis, the correct estimation of the sulphur which it

contains is a matter of very great importance, both to buyer and seller. Chemists are practically unanimous in their opinion, that the best way of estimating the sulphur consists in oxidising it to sulphuric acid, and afterwards precipitating it as sulphate of barium. The oxidation of the sulphur can be effected either by a wet or dry process. The wet methods which consist in oxidising the sulphur with nitric acid, nitro-hydrochloric acid, or chlorate of potash and hydrochloric acid, require great attention to details to obtain even approximate results; but even when the greatest care is taken there are always two sources of error due, first, to the iron which is carried down by the sulphate of barium, and, secondly, to the solubility of the sulphate of barium in the acid perchloride of iron solution.

These errors, it is true, operate in different directions, but they do not counterbalance one another, the increase of weight due to iron being as a rule small, compared to the loss arising from the solubility of the sulphate of barium. The existence of these errors has been clearly proved by the experiments of Fresenius (*Zeitschrift*, xix. 53), and is admitted by Lunge (*Zeitschrift*, xix. 419); and it is to them that the difficulty of obtaining concordant results is frequently due. That considerable differences may be expected, is very well illustrated in the valuable paper of Fresenius to which I have just referred, and in which he points out that four assistants operating on the same sample, and strictly in accordance with the details laid down by Lunge in his work on sulphuric acid and alkali, found respectively:

42.14	Per cent. of sulphur.	{	Mean
42.46			
42.76			
43.10			42.61

or a difference of .96 per cent. of sulphur between the highest and the lowest estimation. I do not think however that these results represent the capabilities of the wet method, in the hands of experienced analysts, as by a slight modification of Lunge's method very concordant results can be obtained, provided the operator uses always the same quantity of acid and works under the same conditions. By this means the error becomes less apparent, but it does not cease to exist. To avoid the sources of error to which I have referred, Lunge proposes to separate the iron by means of ammonia, before precipitating the sulphuric acid with chloride of barium; but I think it will be generally admitted that the elimination of the iron can be effected more conveniently by a dry fusion process.

For this purpose Fresenius recommends the fusion of the pyrites with ten parts of a mixture of carbonate of soda and nitrate of potash, extraction with water, precipitation of any lead with carbonic acid, evaporation with HCl to expel nitric acid, and precipitation with chloride of barium in presence of a small quantity of free acid. By this means the whole of the sulphur of the pyrites is obtained. The same sample of pyrites to which I have referred, when treated in this way gave in the hands of Fresenius' assistants:—

43.82	Per cent. of sulphur	{	Mean
44.04			
43.74			43.87

or a difference of 1.26 per cent. between the means of the wet and the dry method.

The objections to this process are (1) The liability to loss by spurring from the violence of the action which takes place when the pyrites is fused with a mixture of carbonate of soda and nitrate of potash.

(2) The difficulty of operating upon more than half a gramme of the substance.

(3) The time occupied in evaporating to get rid of the nitric acid.

The new method of estimating the sulphur in pyrites, which I have to lay before you, avoids these objections, and at the same time secures the elimination of the iron.

C. Fahlberg and M. W. Iles discovered (*Ber. der Deut. Chem. Ges.* xi. 1187) that when sulphides are fused with caustic potash or caustic soda, the sulphur is completely converted into alkaline sulphite or a mixture of sulphite and sulphate, provided at least twenty-five parts of alkali are used for each part of sulphur, and they pointed out that under these conditions no sulphide or hyposulphite was produced.

In the course of my experiments, I found that when the alkali is intimately mixed with calcined magnesia, the sulphur under favourable conditions can be completely converted into sulphuric acid or alkaline sulphate with little more than the theoretical quantity of alkali, but it is always advisable to use a moderate excess. It is upon this action that the process for the estimation of sulphur in pyrites which I am about to describe is based.

*Process.*—The magnesia mixture which I employ is made by grinding together, in a porcelain mortar, pure sodium hydrate made direct from the metal, and pure freshly-calcined magnesia. The product is a light powder, which can be kept for any length of time in a properly stoppered bottle, without undergoing any appreciable change. A blank experiment must always be made with each lot of the mixture to test the purity of the materials, and any sulphur found is deducted.

In carrying out the process, from 1 to 1½ grm. of the dry pyrites, in a fine state of division, is introduced into a platinum crucible with four times its weight of the pulverised magnesia and sodium hydrate, and the whole is intimately mixed in the crucible itself, by stirring with a glass rod. The crucible is then placed in the mouth of a muffle furnace, and exposed to a low red heat for about three-quarters of an hour. Oxidation begins at once, and is practically complete in less than half-an-hour. The contents of the crucible do not fuse but simply contract in volume, and leave a space between the sides of the crucible and the contents, and there is practically no action on the platinum. After heating for three-quarters of an hour, the crucible is allowed to cool, then placed in a vessel containing water. In a few minutes the contents fall to powder, and the crucible is washed out. A stream of carbonic acid gas is then passed into the solution containing the insoluble, for about a minute, to precipitate any lead which may be present and carbonate the remaining alkali. The contents of the vessel are then boiled for a short time, and the solution passed through a filter. The insoluble is boiled three successive times with water, and about half a gramme of pure carbonate of soda, then thrown upon the filter and well washed with boiling water. The filtrate, which will now contain the whole of the sulphur as sulphate of sodium, and be perfectly free from iron and magnesia, is first neutralised with HCl, then acidified with about 3cc. of HCl, heated to the boiling point, and the sulphuric acid precipitated with a slight excess of chloride of barium. The precipitate is allowed to stand for several hours, then filtered, washed, dried, ignited, and weighed. The sulphate of barium thus obtained is perfectly pure. It is always advisable to dissolve the residue on the filter in HCl, and test for sulphuric acid. If any precipitate makes its appearance after standing for several hours, it must be filtered off and added to the result; but with proper care, this will be found to be merely a precautionary operation. I have made a great many

estimations of sulphur in different samples of pyrites by this process, and have invariably got results which agreed very closely with one another. I have found, however, that to get complete oxidation with the above proportions of soda and magnesia, it is necessary to use the muffle, or at least to heat the crucible in such a way that the products of combustion will not come in contact with the contents of the crucible. Apart from the danger of the result being vitiated by the sulphur in the gas, the process of oxidation is affected by the products of combustion, so that it requires a much larger proportion of the magnesia mixture to effect complete oxidation.

For the purpose of testing this process, and comparing the results with those obtained by experienced analysts by the ordinary wet method, Mr. Inglis, who is the head of the laboratory of the Tharsis Sulphur and Copper Company, very kindly furnished me with samples of pyrites, which had been carefully analysed under his supervision, and I may add that I was not aware of the results, by the wet method, till my tests were completed and in Mr. Inglis's hands.

The samples were marked A and B, and the following are the percentages of sulphur which were obtained by both processes:—

Clark's New Method.			Tharsis's Wet Method.		
Sulphur per cent.			Sulphur per cent.		
	A.	B.		A.	B.
1 Exp.	50.18	46.13	1 Exp.	49.46	45.68
2 "	50.00	46.17	2 "	49.58	45.50
3 "	50.01	46.16	3 "	49.58	45.41
4 "	50.08	46.18	4 "	49.62	45.48
5 "	50.07	46.16			
Mean 50.06		46.16	Mean 49.56		45.51

Another sample of pyrites which, in the hands of Mr. Tatlock, gave by the ordinary wet method 46.64 and 46.61 per cent. of sulphur, when analysed by my method yielded

47.24 per cent. of sulphur.
47.41 " "
47.20 " "
47.22 " "

or a mean of 47.26 per cent. of sulphur.

From these analyses, and a number of others which I could enumerate, if necessary, it would appear that the results obtained by this method are somewhat higher (about  $\frac{1}{2}$  per cent.) than by the wet method. This is what was to be expected when the sources of error to which I have referred are eliminated, and it corroborates the statements of Fresenius, although the difference is not so great as his experiments led me to expect.

The process which I have just described does not occupy more time than the ordinary wet method, and it avoids the sources of error—viz., nitrates, iron and excess of free acid—which so often lead to discrepancies.

#### DISCUSSION.

Mr. TATLOCK testified to the importance of the subject brought before them by Dr. Clark. He felt that had the reading of the paper been the first intimation to him of the new process referred to, he would have felt sceptical of any advantages to be derived from it, especially in view of the concordant, if indeed not absolutely correct, results of the wet process as shown by the table exhibited by the Tharsis Company. But having had an opportunity of examining the new process in detail, he felt convinced that it was destined to revolutionise the analysis of pyrites. At the same time he admitted the adoption of that process would inflict a certain hardship upon consumers, who, by a more complete estimation of sulphur in pyrites would have to

pay for more sulphur without obtaining any additional amount. At the same time he hardly thought that it would be sufficient ground for repudiation of contracts. Chemists, however, had nothing to do with these matters; their sole concern was to render methods of analysis as perfect as possible.

The CHAIRMAN, in concluding the discussion, thought that Dr. Clark had proved his case. There could be no doubt that the old process was open to objection on the grounds stated, slight though these grounds might be. He sympathised with Mr. Tatlock's early scepticism as to the process, but thought that it was practicable if only due care were taken to employ absolutely pure reagents.

## Nottingham Section.

Chairman: Professor Frank Clowes.

Vice-Chairman: Lewis T. Wright.

Treasurer: J. B. Coleman.

Committee:

L. Archbutt.	W. Jennings.
W. H. Carey.	H. J. Staples.
W. A. Curry.	E. B. Truman.
H. Doidge.	J. E. Warwick.
S. E. Field.	R. L. Whiteley.
R. Fitzgugh.	

Hon. Local Secretary:

J. R. Ashwell, Midanbury Lodge, Bentinck Road, Nottingham.

The first meeting of the Section will take place on June 5th, when a *Conversazione* will be held at University College, Nottingham, on which occasion the Chairman will deliver his inaugural address.

Notices of papers and communications for the meetings to be sent to the Local Secretary.

## Journal and Patent Literature.

### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

*Licitation Apparatus.* H. Parenty. *Revue Industrielle*, 1884, 353.

This apparatus, illustrated by Figs. 1 and 2, consists of four cylindrical vats, each capable of holding about 60

litres of water, and 60 kilos. of the material to be operated upon. The vats rest upon an oaken stand, and each is

connected with the next one by means of a metal tube *a* leading into an upright tube *b*, open above and below. Each upright tube is provided with a valve below the metal connecting tube, in order to permit the connection between two adjacent vats being cut. A tube *d* at the bottom of each vat, and just beneath the upright tube, serves to empty the vat; a perforated plate at *c* acts as a strainer. A cistern *A* for water stands upon the four

circular vats. It is fitted with a gauge and tube, also a U-tube, with graduations, to measure the duration of the flow of water. In the bottom are four openings corresponding in position with the vats. The apparatus is mainly an adaptation of the Buff Dunlop black ash vat system to smaller and more exact operations, or even for laboratory use.—W. D. B.

*Improvements in Filter-presses.* J. H. Porter and J. Porter, London. Eng. Pat. 6808, April 25, 1884.

THE object of the patentees is to dispense with the filter cloths or strainers used in ordinary filter-presses. The plates are formed with a series of ribs upon their surfaces, which may be rectangular or angular. The projecting portions in one plate are opposite the spaces in the next plate, so that the passage of any liquid through the machine is diverted from one side to the other in a zig-zag fashion. The flow of liquid into the filter is continuous throughout its length, so that it passes over the whole surfaces of the plates in succession, inlets being formed alternately at the top and bottom of the chambers. The patentees state that the continuous friction of the surfaces of the plates as formed, causes the solid matter to be retained on such surfaces, the fluid being clarified thereby. Sand or charcoal may further be placed between the plates, so as to obtain further clarification. The claims are (1) the construction of filter-presses, in which the use of cloths is substituted by the friction of the surfaces formed as described; (2) filter presses as described and shown.—C. C. H.

*An Improved Filtering Apparatus.* A. Domeier and B. Nickels, London. Eng. Pat. 7572, May 10, 1885.

THE improved apparatus is intended for use with liquids which contain a very small quantity of solid matter. It consists of a cylindrical tank, fitted with a cover and manhole at the upper part; the lower end is provided with a perforated bottom above a receiving outlet chamber, and a second manhole on a level therewith for the purpose of cleansing. The usual pressure gauge, inlet cocks, etc., are provided. The perforated plate is covered with cloth, over which is placed a second perforated plate; on the top of this is placed the filtering bed, consisting of any suitable substance, such as charcoal, sand, sawdust, lime, etc. The liquid is pumped into the cylinder, and then forced through by compressed air, the operation being repeated until the filtering bed is stopped, when it is removed through the lower manhole, a fresh bed formed, and the operation of filtering again started. The patentees claim under two heads the apparatus as described.—C. C. H.

*Improvements in Filter-presses.* H. H. Lake, London.  
From R. H. Smith, Carlisle, Pennsylvania, U.S.A.  
Eng. Pat. 13,580, October 14, 1884.

THIS patent is for an improved construction of plate used in filter-presses. A circular plate is built up of wrought-iron plates, a solid centre disc and two perforated discs, one on either side. The rim of the plate is formed of canvas or duck, several thicknesses being stitched together to form the recess for the deposition of the solid matter; this is secured to the plate by rivets. To strengthen the plate, pads or bosses are rivetted on its surface, of the same material and thickness as the rim; three or more of such pads are used, and bearing against each other when the plates are in the machine, they form a series of supports, thus preventing the plates from collapsing. The several details of construction are covered by seven distinct claims.—C. C. H.

## II.—FUEL, GAS, AND LIGHT.

*Calorimeter for Fuel.* Fr. Schwachhöfer. Zeits. Anal. Chem. 23, 453.

THE author has constructed a calorimeter for determining the calorific power of coal or other fuel. The calorimeters usually employed are only adapted for small quantities of substance (a fraction of a gram.), and produce smoke, indicating thereby incomplete combustion. The author claims that in his apparatus these disadvantages are entirely avoided. The construction is given in the accompanying diagram.\* A and A<sub>1</sub> are platinum combustion vessels, B a copper jacket, C the inner water vessel (the actual calorimeter) of nickled copper, D the inner non-conducting layer of eider-down, E a double-walled water vessel, F the exterior non-conducting layer of fine down, G a cylindrical wooden case, H the upper water vessel, J an annular cork board, K the lid, L the inner agitator, S and S<sub>1</sub> mirrors for observing the process of combustion, T<sub>1</sub> to T<sub>10</sub> thermometers. The most important part of the apparatus is the combustion vessel. It is of platinum, and divided into two parts; the lower A is for the sample of coal, the upper A<sub>1</sub> for sugar charcoal. The chambers have openings at a and b, for introducing the fuel, and also for removing the sieves c and d after each experiment. The sieves are of platinum foil, perforated specially for the apparatus. The perforations of the lower sieve c are so small that they are only visible by transmitted light. In the upper sieve the holes are somewhat larger. Each is provided with an upright rim, which fits tightly to the side, and keeps it in its place. Three tubes are connected with the chamber A. c conducts oxygen from beneath the coal. The tube f has a double use: (1) to bring oxygen above the coal in order to ensure complete combustion of the evolved gases; (2) to observe the process of combustion by reflection from the mirror S<sub>1</sub>. This is necessary, as the stream of oxygen requires to be carefully regulated, and the end of the combustion ascertained. The side tube g terminates under the sieve d. It is provided with a cross piece, and perforated on the upper side. It conducts oxygen to the upper chamber. All these tubes (c, f, g) are connected with well-fitting tubes, let into the lid of the case. After determining the actual thermal value of given volumes of water in the different vessels composing the calorimeter, it is next necessary to prepare and analyse quantitatively and calorimetrically the sugar charcoal to be used in the experiments. The calorimeter is then manipulated as follows: The vessel C is filled with 5200 cc. of water at the temperature of the air, and 5.6 gram. of the finely powdered sample of coal, and 2.4 gram. of the charcoal weighed out. The quantities should be so chosen that the rise of temperature in C may be about 10° C. The combustion lasts about an hour. The coal is introduced into A, the charcoal into A<sub>1</sub>, the two pieces then put

together, and the jacket B screwed down, the lid is lowered, the thermometers inserted, and the mirrors mounted. When the apparatus indicates a constant temperature the combustion is commenced. Oxygen is led through f, the cap S raised, a small glowing chip thrown in, and the cap refitted. The charcoal in A<sub>1</sub> is kindled, and the aspirator O is put in action. The bottle N is then closed, and after some minutes the smaller aspirator is set going. The flow of water from O and P is regulated so that about five-sixths of the gases collect in O, and one-sixth in P. When the charcoal is almost burnt, sparks fall through the sieve and kindle the coal beneath. A quicker stream of oxygen is then passed through f, and introduced through g; towards the end of the experiment the oxygen through g is stopped, and c is opened. The combustion proceeds regularly, and not a trace of smoke appears in N. The combustion of both charcoal and coal should be complete. When the combustion is finished the aspirators are disconnected, the water is agitated by the mixer until the thermometers T<sub>1</sub> and T<sub>2</sub> stand at the same temperature, and the other thermometers are then read off. The volume of gas collected in the aspirators is noted, and the gas in P analysed. From these data the author has made a number of calorimetric determinations, which agree well together, and are somewhat higher than the value calculated by Dulong's formula from the percentage composition.—J. B. C.

*An Improved Method of and Apparatus for Extracting Ammonia from Furnace Gases.* W. R. Lake, London.  
From the Société Anonyme Lorraine Industrielle de Hussigny. Eng. Pat. 5598, April 3, 1884.

THE inventor recommends the absorption of ammonia derived from furnace gases by calcium chloride. The mixture of calcium carbonate and ammonium chloride formed is either to be used as an ammoniacal manure, or by heating sesquicarbonate of ammonia can be obtained, which is to be employed in the ammonia soda process.—S. H.

*Improvements in Gas Producers and in Fuel-supplying Devices used in connection therewith.* J. G. Wilson, Manchester. From J. E. Bott, U.S.A. Eng. Pat. 6764, April 24, 1884.

THE novelty of this invention consists mainly in the manner of admitting the air necessary for ensuring complete combustion of the fuel undergoing destructive distillation in gas producers, continuous corrugated tuyeres injecting air, or air and steam, being employed, which supply the fuel with a continuous blast of steam. This by means of the variable vertical section of the waved tuyeres causes the blast to permeate a larger vertical, as well as horizontal mass of incandescent fuel, thus ensuring a uniform combustion taking place, and the distillation of the fuel into gas proceeding regularly, whilst the residue is left in a more friable form than is possible when blast is admitted in the form of concentrated jets through isolated tuyeres, for in the latter case combustion proceeds irregularly, and the tendency is to form clinkers in the immediate vicinity of the tuyeres whilst the gas is produced in flushes.—D. B.

*Improvements in the Purification of Coal Gas or of other Gases Containing Ammonia or Ammoniacal Compounds.* A. P. Price. Eng. Pat. 6983, April 29, 1884.

THE purification of the gas is effected by means of the hydrogen sulphates, sulphites or phosphates of potassium, sodium, or ammonium, either in a divided condition or in solution, whereby the ammonia existing in the ammoniacal products contained in the gas is absorbed, and may be subsequently recovered from the resulting compound.—D. B.

*Improvements in the Production of Combustible Gases from Finely-pulverised Coal, Peat, Wood-sawdust, or other Material.* F. J. Jones, Worcester. Eng. Pat. 915, January 22, 1885.

THIS invention relates to the production of heating or illuminating gas, and consists essentially in passing a regular supply of finely-pulverised coal, peat, etc., through an hermetically closed chamber of suitable construction provided with the necessary inlets and outlets, and heated to a temperature sufficient for evolving combustible gases from the materials introduced.—D. B.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

*Presence of High-boiling Phenols in Coal-tar.* K. E. Schulze. Ber. **18**, 150.

THE author has isolated  $\alpha$ - and  $\beta$ -naphthol from "green oil"—anthracene oil from which the crude anthracene has been extracted by filtration—and gives a detailed account of the process employed (*Ann.* 227, 143).—D. B.

*Constitution of Thiophen Compounds.* V. Meyer. Ber. **18**, 526-529.

THE essential points to be considered in proving the correctness of the formula

assigned to thiophen are (1) the number of isomeric substitution products of thiophen; (2) its property to form addition products; (3) the position of the sulphur atom; and (4) the behaviour of thiophen when subjected to oxidation. Referring to the position of the sulphur, which can be conceived to be combined in no other form than that of C-S or C-S-C or C-S-H, the author is of opinion that, taking into account the fact that thiophen is neither a thioketone, thioaldehyde, or mercaptan, there can no longer be any doubt as to the meaning expressed by its formula. The assumption that thiophen occupies the same position among its homologues as that held by benzene among the aromatic hydrocarbons requires, however, additional proof, which can be adduced only by taking into consideration the property which thiophen exhibits when subjected to oxidation. Although not yet finally decided, it is very probable that thiophen represents the first member of the homologous series, and little plausible as formulae, such as—

may appear at first sight, they have nevertheless not been hitherto confuted. As the homologues of thiophen are converted into thiophen carboxylic acid, when oxidised with potassium permanganate, it remained to be shown that when thiophen is similarly treated no acid is obtained which contains the same amount of carbon, or has the properties characterising a thiophen derivative. On oxidising pure thiophen with potassium permanganate, fatty acids and sulphuric acid were obtained. The substituting action of bromine and chlorine on thiophen is so energetic that the isolation of the resulting addition products is attended with great difficulties, and should the same be found to apply to

the iodine addition products, the best mode of procedure will probably be to prepare the mellitic acid of thiophen—tetra-carboxylic acid—and reduce it with sodium amalgam. Should the resulting acid take up four atoms of hydrogen, this circumstance would confirm the assumption of two double unions, seeing that mellitic acid takes up double the number of hydrogen atoms compared with the number of double unions it contains. It is therefore intended to prepare a tetrakylthiophen and convert it into the acid in question by treatment with potassium permanganate. Referring to the number of isomeric substitution products, the author is of opinion that should it be shown that the mono-derivatives are obtainable in two modifications only, this again would prove the correctness of the formula for thiophen. In the preparation of the sulphonic and carboxylic acids of thiophen and of methylthiophen, only two modifications have as yet been observed, a circumstance which should however be verified by further research. It is of especial importance to obtain means for ascertaining the position of the substituted group in the thiophen molecule. In a previous communication, the formation of the anhydride of a disulphonic acid, and the assumption that dibromothiophen is analogous in constitution to parabromobenzene, formed the basis of the author's speculations. He is continuing his researches in this direction. The three dicarboxylic acids of benzene being distinguished by characteristic properties, it was thought that by studying the behaviour of thiophen dicarboxylic acids it might be possible to observe an analogy between them and the three phthalic acids, and thus determine the position of the carboxyl groups. At the author's instigation, Jackel prepared a dicarboxylic acid from the disulphonic acid according to Merz's reaction. An acid was obtained which, although not yet fully examined, appeared to be the terephthalic acid of thiophen. In conclusion, the author suggests a mode by which the position of the sulphur in the thiophen group might be definitely determined. It has been shown that ethyl-sulphide is converted into thiophen at an elevated temperature according to the equation:

Should it be possible to apply the same reaction to propyl and isopropyl sulphide, two thioxenylenes should be obtained having the formulae—

*Nitrothiophens.* O. Stadler. Ber. **18**, 530-536.

IN a former communication it was shown that on distilling dinitrothiophen melting at 52°, by means of steam, a substance is obtained which melts at a higher temperature. The author has continued his researches in this direction, and finds that the substance has a constant melting point of 78°, and crystallises from water or alcohol in yellow needles. It is an isomeric dinitrothiophen  $\text{C}_4\text{SH}_2(\text{NO}_2)_2$ . By the action of bromine on dinitrothiophen at an elevated temperature, a substance is obtained which crystallises in white lustrous needles, melting at 112°. It is not a bromine derivative of dinitrothiophen, but represents tetrabromothiophen, the two nitro groups having been removed by the action of bromine at a high temperature. The author has studied the sensitiveness of the colour reaction which dinitrothiophen gives with alcohol and potash, and finds that it is distinctly discernible in a solution containing 0.000001 grm. of substance. Mononitrothiophen sulphonic acid,  $\text{NO}_2-\text{C}_4\text{SH}_2-\text{SO}_3$ , was prepared by treating three parts of mononitrothiophen with eight parts of fuming sulphuric acid. It gives white hygroscopic crystals, which are resolved into mononitrothiophen when heated. The potassium salt crystallises in grey shining needles, and the calcium salt forms a white crystalline mass.

The sulphonic chloride,  $\text{NO}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{SO}_2\text{Cl}$ , was prepared by heating the potassium salt with phosphorus pentachloride on a water bath. It was converted into the sulphonamide  $\text{NO}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{SO}_2\text{NH}_2$  by treatment with ammonium carbonate. The sulphonamide melts at 172-173.—D. B.

*On the Two Isomeric Thiotolens (Methylthiophens).*  
K. Egli. Ber. 18, 544

V. MEYER and H. Kreis in 1884 succeeded in separating a methylthiophen from coal-tar toluene, and later on in obtaining another one synthetically by means of thiophen-iodide, methyl-iodide, and sodium. The compounds produced in either way have the same boiling point, and the author investigated the question as to whether they are identical or isomeric. For this purpose the bromine derivatives of both thiotolens were compared with each other, when it was found that their fusing point invariably differed by 12 degrees. They must therefore have a different constitution. This result is quite in accordance with V. Meyer's view on thiophen and its derivatives. In one thiotolen the methyl group and sulphur have the  $\alpha$  position, in the second the  $\beta$  position to each other, thus:

In order to determine the position of the methyl group in both isomeric compounds, they were oxidised with an alkaline permanganate solution. Two different acids were obtained, thus:

Their bromine substitution product was also prepared. The final result of the investigation is as follows: Thiophen obtained from coal-tar toluene is isomeric, but not identical with that produced synthetically. In the former the methyl group is in the  $\alpha$  position, in the latter it is in the  $\beta$  position.—S. H.

*Isomeric Thiophen-sulphonic Acids.* J. Langer. Ber. 18, 553-563.

*Dibromothiophenmonosulphonic acid*  $\text{C}_6\text{H}_3\text{Br}_2\text{SO}_3\text{H}$ .—The lead-salt of this acid, formerly described, was converted into the sodium salt, and the latter dried at 120°, and treated with phosphorus pentachloride. The resulting chloride was converted into the amide by treatment with ammonium carbonate. It crystallises in fine needles melting at 146°-147°. To prepare the free  $\beta$ -thiophenmonosulphonic acid  $\text{C}_6\text{H}_4\text{SO}_3\text{H}$ , the sulphonic chloride described in a previous communication was decomposed by boiling with water, and the liberated hydrochloric acid precipitated with silver hydroxide. The solution was treated with sulphuretted hydrogen, filtered and the filtrate evaporated. A white crystalline mass of strongly acid reaction was obtained. It gave a deep blue coloration when heated with isatin and sulphuric acid. *Barium  $\beta$ -thiophenmonosulphonate*  $(\text{C}_6\text{H}_4\text{SO}_3)_2\text{Ba}$  was prepared by saturating the aqueous solution of the free acid with barium carbonate. *Debromination of dibromothiophen-sulphonic acid*.—By treating the sodium salt of this acid with sodium amalgam, and adding phosphorus pentachloride to the debrominated substance, the chloride of a new thiophen-sulphonic acid was obtained.  *$\beta$ -thiophen-sulphonic chloride*,  $(\text{C}_6\text{H}_4\text{SO}_2\text{Cl})_2$ , crystallises in small plates or laminae melting at 148-149°. It is readily soluble in ether, has the odour which characterises this class of bodies, and gives a bluish violet solution when heated with isatin and sulphuric acid.  *$\beta$ -thiophen-disulphonamide*  $\text{C}_6\text{H}_4(\text{SO}_2\text{NH}_2)_2$  was

prepared by the action of ammonium carbonate on the sulphonic chloride. It crystallises in white needles melting at about 280°. *Dibromothiophen-sulphonic chloride*  $\text{C}_6\text{H}_3\text{Br}_2(\text{SO}_2\text{Cl})_2$  was obtained by treating sodium dibromothiophen-sulphonate with phosphorus pentachloride. It crystallises from ether in white shining needles, which melt at 215°. *Dibromothiophen-sulphonamide*  $\text{C}_6\text{H}_3\text{Br}_2(\text{SO}_2\text{NH}_2)_2$  was prepared by intimately mixing and heating the sulphonic chloride with solid ammonium carbonate. It is sparingly soluble in hot water, and melts at about 270°. *Lead dibromothiophen-disulphonate*  $\text{C}_6\text{H}_3\text{Br}_2(\text{SO}_3)_2\text{Pb}$  was obtained by converting the anhydride of the acid into the barium salt, decomposing the latter with sulphuric acid, and adding a salt of lead to the filtrate. *Sodium dibromothiophen-disulphonate*  $\text{C}_6\text{H}_3\text{Br}_2(\text{SO}_3\text{Na})_2 \cdot 3\text{H}_2\text{O}$  was prepared by heating the anhydride of dibromothiophen-sulphonic acid with soda ley. It crystallises in silky needles which are readily soluble in water. *Ammonium dibromothiophen-disulphonate*  $\text{C}_6\text{H}_3\text{Br}_2(\text{SO}_3\text{NH}_4)_2 \cdot 11\text{H}_2\text{O}$  was obtained by boiling the anhydride with ammonia. To prepare the free *dibromothiophen-disulphonic acid*  $\text{C}_6\text{H}_3\text{Br}_2(\text{SO}_3\text{H})_2$  an aqueous solution of the lead salt described in the above was precipitated with sulphuretted hydrogen and filtered. On evaporating the filtrate the free acid was obtained in the form of a solid crystalline white mass readily soluble in water. *Sulphonation of monodibromothiophen*. The author has attempted to prepare a monodibromothiophen-sulphonic acid, but has not yet obtained successful results. He has, however, decolourised the disulphonic acid by treating its aqueous solution with sodium amalgam. The sulphonic acid was purified by conversion into its chloride, and as the latter contained traces of free iodine it was treated with ammonium carbonate to form the amide.  *$\beta$ -thiophen-disulphonamide*  $\text{C}_6\text{H}_4(\text{SO}_2\text{NH}_2)_2$  crystallises in laminae melting at 142°. It is sparingly soluble in water, and gives a deep blue solution when heated with isatin and concentrated sulphuric acid.  *$\beta$ -thiophenmonosulphonamide*  $\text{C}_6\text{H}_4\text{SO}_2\text{NH}_2$  was prepared by converting the barium monosulphonate  $(\text{C}_6\text{H}_4\text{SO}_3)_2\text{Ba}$  into the sodium salt, and treating the latter with ammonium carbonate. It crystallises from water in white laminae which melt at 147°.—D. B.

*Thioxen from Coal-tar.* J. Messenger. Ber. 18, 563-568.

SOME time ago V. Meyer proved the existence of a thiophen derivative in coal-tar xylene, and gave it the name "thioxen," and the formula  $\text{C}_8\text{H}_7(\text{CH}_3)_2$ . The author has isolated this substance, and investigated its properties. It was prepared from the acid used in the purification of xylene, which contains about 40 per cent. of pure thioxen. The product is a colourless liquid, boiling between 133° and 138°. *Dibromothioxen*  $\text{C}_8\text{H}_5\text{Br}_2(\text{CH}_3)_2$  was prepared by adding 50 grm. bromine to 50 grm. crude thioxen (2 mol. Br. to 1 mol. thioxen), washing the product with water, boiling it with an alcoholic solution of potash to decompose the bromine addition products formed, then pouring the mass into water, and separating the oil. The latter was distilled with steam, and the distillate fractionated. The first portion boiling between 135° and 165°, consisted mainly of xylene. The second fraction boiling between 205-215°, gave, on redistillation, a liquid boiling at 197-199°. It was composed of a mixture of equal parts of monobromothioxen and monobromothioxen, and could not be separated. The last fraction boiled between 240-250°, and gave a distillate which solidified in the receiver. It was crystallised from alcohol, and yielded long colourless needles, melting at 46°, and boiling between 246-247°, without decomposition. The substance was dibromothioxen. *Octobromothioxen*,  $\text{C}_8\text{HBr}_8(\text{CH}_3)_2$ , was obtained from dibromothioxen by treatment with bromine until the latter ceased to react. It crystallises from alcohol in yellow needles, which melt at 114°. *Thioxen*  $\text{C}_8\text{H}_7(\text{CH}_3)_2$ . For the isolation of pure thioxen, the method adopted by Meyer and Kreis for separating thiotolene from a mixture of toluene and thiotolene was employed. The pure product is a colourless, mobile liquid, of agreeable

odour, boiling at 136-137.5°. By the oxidation of thioxen with potassium permanganate, thiophendicarboxylic acid ( $C_{11}H_8O_4$ ) was obtained. The latter is sparingly soluble in water, but dissolves more readily in ether. Heated to 350°, it does not melt, but sublimes without decomposition. This acid, therefore, appears to be analogous in character to the isophthalic acid in the benzene group, but judging from the melting point of its dimethyl-ether (142°), it is more probably analogous to terephthalic acid. If this be the case, the formula for thioxen would have to be expressed thus—

—D. B.

*Fractional Distillation by means of Steam.* M. J. Lazarus. Ber. 18, 577.

THE object was to separate two mixed liquids, one of which was very volatile, whilst the other suffered decomposition at a comparatively low temperature. Naumann has shown that liquids, not miscible with water, when distilled with steam, boil below the temperature at which water boils. The author has, therefore, distilled a number of mixed liquids with steam to ascertain whether they could be fractionated in this manner. The distillation was effected with a moderately powerful pressure of steam, and the distillate collected in two or three fractions. Each fraction was then dried, and fractionated *per se* to ascertain its composition.

EXPERIMENT 1.—25cc. toluene and 25cc. nitrobenzene.

Fraction.	Temperature.	Volume.	Toluene.	Nitrobenzene.
1.....	90-95°	21cc.	19cc.	—
2.....	95-98°	6cc.	3.5cc.	—
3.....	98°	23cc.	—	23cc.

Recovered: 22.5cc. toluene and 23cc. nitrobenzene.

EXPERIMENT 2.—25cc. benzene and 25cc. nitrobenzene.

Fraction.	Temperature.	Volume.	Benzene.	Nitrobenzene.
1.....	96°	23.5cc.	22.00cc.	—
2.....	96-98°	4.9cc.	1.75cc.	—
3.....	98°	22.5cc.	—	22.5cc.

Recovered: 23.75cc. benzene and 23.5cc. nitrobenzene.

EXPERIMENT 3.—30cc. nitrobenzene and 5cc. toluene.

Fraction.	Temperature.	Volume.	Toluene.	Nitrobenzene.
1.....	95-98°	6cc.	4.25cc.	—
2.....	98°	29cc.	—	29cc.

Recovered: 4.25cc. toluene and 29cc. nitrobenzene.

EXPERIMENT 4.—25cc. toluene and 25cc. xylene.

Fraction.	Temperature.	Volume.	Toluene.	Xylene.
1.....	84-91°	22cc.	16.5cc.	2cc.
2.....	91-98°	28cc.	3.0cc.	18cc.

Recovered: 19.5cc. toluene and 20cc. xylene.

EXPERIMENT 5.—25cc. benzene and 25cc. carbon-disulphide.

Fraction.	Temperature.	Volume.	Carbon-disulphide.	Benzene.
1.....	64°	22	19cc.	—
2.....	64-67°	6	3cc.	—
3.....	67°	22	—	21.5cc.

Recovered: 22cc. carbon-disulphide and 21.5cc. benzene.

EXPERIMENT 6.—25cc. oil of turpentine and 25cc. nitrobenzene.

Fraction.	Temperature.	Volume.	Oil of Turpentine.	Nitrobenzene.
1.....	95-97°	21cc.	19cc.	—
2.....	97-98°	4cc.	2cc.	—
3.....	98°	25cc.	—	24cc.

EXPERIMENT 7.—25cc. aniline and 25cc. nitrobenzene.

The mixture distilled at 98°, and was collected in two fractions, each measuring 25cc. The first contained 15cc. aniline and 10cc. nitrobenzene, and the second 10cc. aniline and 15cc. nitrobenzene. Benzene and

toluene could not be separated perfectly, even when large quantities were operated on. The author has used this process with success for the separation of iodothiotolene and toluene and iodothioxen and xylene, an operation which has hitherto been attended with great difficulties and much loss, owing to the decomposition of the iodine compounds at comparatively low temperatures.

—D. B.

*Occurrence of Carboxylic Acids in Coal-tar.* K. E. Schulze. Ber. 18, 615.

HITHERTO bodies of the phenol group only have been shown to exist in the oxygenated constituents of coal-tar, of which phenol and  $\alpha$ - and  $\beta$ -naphthol have been isolated, whilst the presence of cresols, xylenols, etc., has been inferred from isolated derivatives of these compounds. In pursuing his investigations on the high-boiling phenols of coal-tar, the author discovered a carboxylic acid, which was found to be benzoic acid. It was isolated in the following manner:—In order to obtain cresols and xylenols, the residues from the distillation of phenol were subjected to fractional distillation. The last portions came over between 235° and 240°, and from this boiling point the author inferred the presence of pseudocumenols, of which there are three isomers. To separate the latter, the oil was treated with soda ley, and distilled with steam. The residue contained the sodium salt of the strongest acid present in the mixture. On adding sulphuric acid, a brown-coloured oil was liberated, which, on cooling, solidified in the form of needles, melting at 123°, and boiling at 249-2°. The silver salt was prepared, and its formula agreed closely with that of silver benzoate,  $C_6H_5O_2Ag$ . 100grm. of crude material gave 5grm. of recrystallised benzoic acid. As to the formation of this acid, the author states that it cannot be produced by any of the processes in vogue for preparing carboxylic acid; he is, moreover, of opinion that it is contained in the products of the distillation of coal-tar, and passes into the carboxylic acid during the treatment of the oil with soda ley.

—D. B.

*Thiophen from Erythrol.* C. Paul and J. Tafel. Ber. 18, 688.

IT has recently been demonstrated that the group  $CHOH-CHOH-CHOH-CHOH$ , which is contained in pyruvic acid, passes into the thiophen ring on treatment with sulphuretted hydrogen. The simplest body in which this complex of atoms is found is erythrol,  $CH_2OH-CHOH-CHOH-CH_2OH$ , which on heating with phosphorus pentasulphide gave thiophen.—D. B.

*Remarkable Formation of Anthracene.* H. Köhler. Ber. 18, 859.

IN a communication on high-boiling phenols contained in coal-tar, Schulze expressed the opinion that the phenols are the primary products of the destructive distillation of coal. By continuing the action of heat they are partly split up, water being liberated and high-boiling hydrocarbons formed, whilst another portion is reduced to low-boiling hydrocarbons, or is eventually converted into coal-gas through the complete disintegration of the molecules. A portion resists decomposition by heat at the point at which the various reactions reach an equilibrium. Schulze arrived at this theory by the observation that the phenols separated from anthracene oil when subjected to distillation yield liquid hydrocarbons with partial liberation of water. Some time ago the author made an observation which appears to confirm to some extent Schulze's view. In working up the high-boiling portions of crude carboxylic acid, a cast-iron still was charged with "carbolic residues," which distilled above 205°. They were free from hydrocarbons, and gave a clear solution with caustic soda. On distillation about two-thirds passed over in the ordinary way as a pale yellow-coloured oil, having the odour peculiar to phenol. After this the thermometer rose rapidly above 300°, and from the condenser dense white fumes issued, whilst the distillate in the receiver assumed a consistence like that of butter. On opening the still it was found to be half-

filled with a spongy mass of coke. The distillate was washed with alkali to remove the liquid constituents (phenols), and was tested for anthracene by Luck's method, which gave thirty-five per cent. of pure anthracene. The presence of methylanthracene, phenanthrene, etc., in the crude product was established by its properties. The author then made a number of distillations in the same boiler, but failed to obtain anthracene. He is of opinion that the decomposition was caused by local superheating in the still. The probability of this assumption is strengthened by the fact that the crude carboxylic acid in question had been obtained from light oil, which contains phenols of such complicated constitution that it would be difficult to conceive the formation of anthracene therefrom by the mere liberation of water; moreover, the whole course of the reaction—production of large quantities of non-condensable substances and separation of coke—points to a more complex decomposition. Be this as it may, the fact can no longer be doubted that under suitable conditions anthracene can be formed from phenolic bodies extracted from the light-boiling portions of coal-tar.

Many chemists are of opinion that the greater part of the anthracene obtainable from coal-tar is produced during the process of distillation, whilst it has been found that the yield of anthracene varies according as the fire is allowed to play round the whole or only part of the still. This view appears to be supported by the author's observations.—D. B.

#### Synthetic Lutidine. W. Epstein. Ber. 18, 883.

IN consequence of a recent communication made by Hanting concerning the production of a lutidine melting at 147-151° from derivatives of dehydroacetic acid, the author states that in investigating the derivatives of a body obtained by the aid of the condensation of acetoacetic ether with aldehyde ammonias, according to Hantzsch's method, he obtained a lutidine melting at 145-146°. It is different in properties to orthoparadi-methylpyridine (m.pt. 154-155°), first prepared by Hantzsch from lutidinetricarboxylic acid, and subsequently in larger quantities from pseudolutidostyryl. It differs also from Ladenburg and Roth's lutidine (m.pt. 142-143°), found in commercial picoline. The platino-chloride of the author's lutidine melts at 216°, the aurichloride at 119°, the picrate at 161°, the dichromate at 92°, and the mercurio-chloride at 155°.—D. B.

#### Caucasian Petroleum. P. Milkowsky. J. Russ. Phys. Chem. Soc. 1885 [2], 37.

THE author has subjected the portion of Bibi-Eibat and Balachany petroleum boiling between 85° and 105° to a succession of fractional distillations over sodium, and obtained the following products:—

	90-91°	93-91°	96-97°	100-101°
Sp. gr. at 0° ..	0.7176	0.7321	0.7650	0.7778
„ „ 17.5° ..	0.7320	0.7390	0.7515	0.7624
Vapour density	3.65	3.55	3.57	3.57

The fraction boiling between 100° and 101° was heptanaphthene,  $C_{14}H_{14}$ . By passing chlorine through this hydrocarbon at the ordinary temperature, 72.8 per cent. of chlorides lighter than water, and 27.2 per cent. of chlorides heavier than water, were produced, whilst at an elevated temperature 58 per cent. of heavy, and 42 per cent. of light, chlorinated derivatives were formed. Bromine acts readily on heptanaphthene, whilst iodine dissolves therein without further action.—D. B.

#### Examination of Caucasian Petroleum. W. Markownikow. J. Russ. Phys. Chem. Soc. 1884 [2], 294.

OCOTONAPHTHENE.—This hydrocarbon has already been isolated from Balachany petroleum, and the author has

recently extracted it from the petroleum which occurs at Bibi-Eibat. It boils at 119°, has a sp. gr. of 0.7649 at 0°, and 0.7503 at 18°, and is composed of 85.3 per cent. of carbon, and 14.7 per cent. of hydrogen. When chlorinated according to Schorlemmer's method, a number of isomeric chlorides are obtained. The chloride boiling at 174-176° was heated to 60° with dry calcium iodide, and the resulting iodide converted into the ether of the octonaphthenealcohol by treatment with silver acetate. The ether boils at 196-200°. The iodide prepared from the chloride boiling between 169-172° was converted into octonaphthylene,  $C_{14}H_{14}$ , by treatment with moist oxide of silver. It boils at 118-121°, and gives a liquid brominated derivative,  $C_{14}H_{14}Br_2$ . M. Putochin has obtained iso-octonaphthene from the intermediate products formed in the isolation of octonaphthene and nononaphthene by repeated fractionation over sodium, and treatment with fuming sulphuric acid. It boils at 122-124°, and has the formula  $C_{15}H_{16}$ . Its sp. gr. is 0.7768 and 0.7765 at 0°, and 0.7637 at 17.5°.

The chlorinated derivatives have higher boiling points than the corresponding derivatives of octonaphthene. In order to obtain iso-octonaphthylene boiling at 128-129°, the chlorinated derivative is treated with an alcoholic solution of potash.—D. B.

#### Anthracene in Tar from Water-gas. Arthur H. Elliott. Amer. Chem. J. 6, 248-252.

IN the fraction of water-gas tar boiling at 210-230° (product of the destructive distillation of light petroleum naphtha), 5.8 per cent. of anthracene was found, and 2.08 per cent. in the higher boiling fractions. The total yield from the original tar amounted to 2.6-2.9 per cent.—J. B. C.

#### Improved Apparatus for Carbonising Bones and Twigs, and for Coking and Distilling Brown Coal, Pit Coal, and other Carbonaceous Materials by means of Superheated Steam. B. J. B. Mills, London. From A. Zwilling, Vienna. Eng. Pat. 6995, April 29, 1884.

THE apparatus employed for carrying out this invention is principally composed of a furnace A (Figs. 1, 2 and 3), for superheated steam, several cast-iron retorts communicating with a common condenser, and of a gasometer of the usual form. The fireplace of the furnace is divided into two chambers, so that it is heated by two separate fires, and along both sides of the flue conduits are formed in the brickwork, communicating with the flue

fig 1.

at certain intervals by means of small apertures. The steam pipes  $e$  rest in two vertical walls, so that the elbow joints  $d$  are placed right and left in narrow channels  $f$ , which are in connection with the furnace proper by narrow flues  $g$ . The steam enters at  $g$ , and after traversing the heated pipes  $e$ , it passes through pipes  $h$  and branches  $h_1$ , which are provided with many small holes, into cast-iron cylinders G, containing the material to be treated. The fire-gases travel through a flue  $k$  into an annular space  $j$ , heating thus the steam pipes and the cylinders G, and escape at  $l$  into the chimney. The vapours and gases evolved in G are conveyed to a condenser H, and thence through  $n$  to coolers. The

admission of air to the fire-places can be carefully regulated by means of slides in the ash-pit doors *c*, and in order to prevent the destruction of the cast-iron pipes

their heat. Between the chambers of the retort a valve or slide is arranged, which can be operated from the outside of the apparatus to allow the contents of the

*e* and cylinders *G* by oxidation, they are covered with a fire-proof material, consisting of 120 parts fire-clay, 49 parts animal charcoal and 2 parts cow-hair.—S. II.

upper chamber to pass into the chamber below as required. The retort is provided with openings and pipes for the outlet of the volatile products of distillation at different levels.—D. B.

*Improvements in Apparatus for Distilling Shales and the Like.* R. Bell, Broxburn, Scotland. Eng. Pat. 9285, June 21, 1884.

THE inventor proposes to build a furnace, erect over the same the lower chamber of the retort, and mount over the latter the upper chamber. Surrounding these chambers is an outer wall, the intervening space being in communication with the furnace by suitable openings. In the lower part of the bottom chamber there is a shoot which passes in a downward direction at the side of the outer wall, and opens into the furnace beneath, and through it the contents of the bottom chamber of the retort are discharged into the furnace to further utilise

*Improvements in the Treatment of Oils and Tars obtained from Coke Ovens, for the Production of Valuable Hydrocarbons.* C. E. Bell, Durham. Eng. Pat. 9510, June 27, 1884.

AT the present time oils and tars are obtained from coke ovens which do not contain in their natural state any considerable proportion of benzene, naphthalene, anthracene, etc. By passing these oils in the state of vapour through retorts charged with coke heated to redness, the inventor claims to obtain large quantities of hydrocarbons of the above series.—D. B.

*Improvements in the Treatment of the Gases from Coke Ovens for the Recovery of Bye-products therefrom, and in Apparatus for that Purpose.* H. Simon, Manchester. From F. Carvès, St-Étienne, France. Eng. Pat. 15,920, December 3, 1884.

This invention relates to coke ovens, more particularly those known as the Simon-Carvès coke ovens, wherein the combustible gases generated in the coking chambers are first treated for the separation of tar and ammoniacal liquor, and are then used as gaseous fuel. According to the present invention, the gases before being burned are subjected to a further treatment, whereby the inventor separates from them the light hydrocarbons which are still retained in a gaseous form therein. For this purpose, the gases, after purification from ammoniacal and other easily condensable constituents, are subjected to the intimate action of heavy oils capable of absorbing the light hydrocarbons, the oils being then heated or otherwise acted on so as to separate from them the light hydrocarbons. The various parts of the apparatus for effecting the separation of the light hydrocarbons are described and illustrated in the original.—D. B.

*An Improved Process of Manufacturing Benzene and its Homologues by the Distillation of Coal, Wood, Turf, Oil and other similar Substances.* N. A. Hclouis, Paris. Eng. Pat. 6904, April 28, 1885.

This patent is similar in principle to a former invention, for which the author obtained provisional protection only. (See this Journal, vol. iii. p. 438).—D. B.

#### IV.—COLOURING MATTERS AND DYES.

*Process for the Production of Indigo.\** Dingl. Polytechn. J. 255, 356.

ACCORDING TO H. Müller (Ger. Pat. 30,329, June 12, 1883), benzaldehyde is chlorinated in presence of a dehydrating agent, and meta-chlorobenzaldehyde obtained as a colourless liquid of 1.246 relative density at 15°, and boiling at 206°. By the nitration of this compound, meta-chlor-orthonitrobenzaldehyde is formed and may be precipitated from the nitrating mixture with ice-cold water; crystallised repeatedly from alcohol, it forms yellowish needles, melting at 60°. By dissolving meta-chlor-orthonitrobenzaldehyde in acetone, and adding to this solution first a little water, then dilute soda-lyc, a formation and separation of chlorindigo takes place in a short time. The chlorindigo thus prepared closely resembles pure indigo; it is a deep blue crystalline powder with coppery lustre, without taste or smell, insoluble in water, alcohol, and ether, dilute acids, and alkalis, somewhat soluble in hot chloroform, aniline, and benzalchloride. When heated, chlorindigo sublimes with partial decomposition; distilled with sodium hydrate, it breaks up into carbonic acid and chloraniline. Treated with concentrated sulphuric acid, it forms a sulphonic acid soluble in water, which dyes wool blue. Treated with reducing agents, chlorindigo yields a vat which may be employed in the same manner as that from ordinary indigo. Chlorindigo exposed to the action of nascent hydrogen is converted into indigo.—W. D. B.

*Azo-dyes.* Soc. Anon. de Matières Colorantes de St-Denis. Dingl. Polytechn. J. 255, 404.

AZO-DYES which impart a pure yellow to vegetable fibres capable of resisting a soap bath of 60°, are obtained (Ger. Pat. 29,991, March 25, 1884) by the action of para- or meta-diazobenzoic acid on diphenylamine or monobenzylaniline. For example, 5 kilos. sodium para- or meta-amidobenzoate are dissolved in 200 litres of water, and 6.6 kilos. of a 33 per cent. solution of sodium nitrite are added. The mixture is acidified with 9.4 kilos. of sulphuric acid of 53° E. previously diluted with water; and care is taken, by the addition of ice, to keep the temperature below 20°. This mixture is then poured upon 5.3 kilos. diphenylamine or monobenzylaniline, which is suspended in 170 litres of

acidified water. After four to eight days the reaction is complete. The insoluble dye is filtered, washed and dried. The dye produced by the meta-compound is yellower than that produced by the para-compound; the latter approximates more to orange yellow. To apply this dye to cotton goods, the dye is thickened with starch or tragacanth, and then with the necessary quantity of alkali to convert the acid dye into a salt. On boiling, cooling and adding excess of acetic acid, the insoluble acid dye is again set free, but in a condition suitable for fixing on the goods. Chromium acetate serves best as mordant. After printing the goods are steamed. The dye retains its brightness in a soap bath heated to 60°. To obtain a bright yellow after simple washing with water, an aluminium salt is used as mordant. The yellow dye obtained with chromium mordant combines very well with artificial alizarin red.

—J. T.

*Nitropseudocumene, Pseudocumidine and Pseudocumino* (1, 3, 4, 5). E. Eder. Ber. 18, 629.

The derivatives of pseudocumene known up to the present have the symmetrical position 1, 3, 4, 6. The author prepared the isomeric compounds, whose constitutional formula may be represented by the nitropseudocumene, thus—

With this object in view, the common pseudocumidine was first converted into the acetyl and thence into the nitro compound. After separating the acetyl group and treating the resulting nitropseudocumidine with nitrous acid and alcohol, a nitropseudocumene was obtained. In order to determine its constitution, the nitroacetyl pseudocumidine

was reduced, whereby a base was produced whose hydrochloride had the following composition—

The author concludes that as it was found impossible to split off the acetyl group with alcoholic potassium hydrate, the nitro and amido group in nitropseudocumidine must be in the ortho position to each other. This conclusion proved correct, when by reducing nitropseudocumidine a base pseudocumylenediamine,

was obtained, which had all the characteristic properties of an ortho-diamine, as stated by Ladenburg (Ber. xi. 600 and 1650).—S. H.

*Preparation of Nitrosonaphthols.* R. Henriques and M. Ilinski. Ber. 18, 704.

*β-Naphthol:* 1 part commercial β-naphthol and 0.75 part zinc chloride are dissolved in 6 parts alcohol; 0.5 part sodium nitrite dissolved in little water is then added to the boiling alcoholic solution. The liquid turns red, and whilst the boiling is continued the red brown zinc salt separates out. On standing at rest over night, the salt is filtered and washed with alcohol. It is then suspended in 10 parts water and digested for a short time with 0.8-1 part caustic soda until it has been converted into the green crystallised sodium salt. The latter is filtered, washed with water and decomposed at the common temperature with hydrochloric acid. The nitrosonaphthol thus obtained, after filtering and washing, is almost chemically pure, and needs no further purification for the use as reagent. The yield is 110% to 115% of the β-naphthol used.

\* See also this Journal, iii. 411.

*a-naphthol*: A similar treatment of the *a*-naphthol for obtaining nitroso-*a*-naphthol is not advisable, the *a*-naphthol not being easily attacked by nitrites of metals. In order to produce the *a*-derivative in an almost pure state, a solution of 1 part commercial *a*-naphthol and 1 part zinc chloride in 6 parts alcohol is heated to the boil. A concentrated aqueous solution of 0.5 part sodium nitrite is added, and the boiling continued for two to three hours. After standing over night, the red zinc salt of  $\beta$ -nitroso-*a*-naphthol separates out, which is, however, permeated with fine yellow needles of *a*-nitroso-*a*-naphthol, whose zinc salt is decomposed by boiling with alcohol. The mass is filtered, washed with cold alcohol, and the two nitronaphthols are separated with an alcoholic potassium hydrate solution (Ber. xvii. 2390) without previously decomposing the zinc salt with hydrochloric acid. The alcoholic filtrate contains undecomposed *a*-naphthol and *a*-nitroso-*a*-naphthol. A large quantity of water is added, when only the nitroso compound separates out, whereas *a*-naphthol does not crystallise out but after some time. The precipitate is filtered immediately and washed with water. The nitronaphthol, thus precipitated, is nearly as pure as that previously prepared from the residual mixture. If it contains some impurities or traces of undecomposed *a*-naphthol it is washed with benzene. 100grm. naphthol yielded 50gr. yellow ( $\beta$ ) and 40gr. white (*a*) nitroso-naphthol.—S. II.

*Colouring Matters from Lepidine*. S. Hoogewerff and W. A. van Dorp. Rec. Trav. Chem. 3, 337-362.

THE present paper is a continuation of the authors' previous researches, and also the results of their investigations on cyanine and on a new colouring matter first obtained by Spätholz.

*Dimethylecyanine-chloride* is obtained from the corresponding iodide by the action of AgCl. Diethylecyanine-bromide can be prepared in the same manner as the iodide from diethylquinolinebromide and ethylepidine-bromide, and dissolves in alcohol with a pure blue colour, which is not fast to light or carbonic acid. By the action of potash upon the iodides of methyl-*p*-toluquinoline and methylquinoline, a resin is formed, soluble in alcohol with red colour. If a mixture of 2 parts of methyl-*p*-toluquinoline iodide with 1 part of methyl-epidine iodide, in aqueous solution, be heated with potash equivalent to one-half of the iodine present, dimethyldimethylecyanineiodide of the formula

is obtained, crystallising in blue needles. The authors find that the colouring matter of Spätholz has the formula  $C_{22}H_{25}N_2I$ , and not  $C_{24}H_{25}N_2I$ , the reaction taking place according to the equation

This substance, isomeric with diethylecyanine, is prepared from quinaldine-ethyl iodide with 1.9 part quinaldine-ethyl iodide in 25 parts of alcohol, and the calculated quantity of potash gradually added, the mixture being heated on the water-bath. On distilling off a portion of the alcohol, the new compound crystallises out. A crystalline body can also be prepared in a similar way from ethylquinaldine alone.

*Dimethylecyanine-iodide*.—The two representatives of the colouring matter known as cyanine have been shown by the authors to be mixtures, the composition of the pure compound being expressed by the formula  $C_{22}H_{25}N_2I$ , formed according to the equation

The best yield is obtained by digesting amyl iodide in alcoholic solution, with the corresponding bases—quinoline and lepidine—on the water-bath, the requisite amount of potash being added. On distilling off a portion of the alcohol, the colouring matter may be extracted from the residual resin by means of acetone. By heating amyl-epidine iodide with an alkali, a red substance is formed, soluble in alcohol; but it has not been crystallised.—J. B. C.

*Manufacture of Colouring Matter*. Charles Denton Abel, London. From the Farbwerke vormals Meister Lucius and Brining of Höchst-am-Main, Germany. Eng. Pat. 6311, April 12, 1884.

THE object of this invention is to prepare violet and blue colouring matters of the rosaniline series by the action of perchloromethyl-formate upon tertiary aromatic amines in the presence of condensing agents. As a typical example, the inventors give the following method of preparing hexamethyl-violet:—25lb. of dimethylaniline are mixed with 5½lb. of perchloromethyl-formate, and 12lb. of anhydrous zinc chloride gradually added to the mixture. The violet gradually forms as a crystalline mass, which is freed from excess of zinc chloride by washing with water, and then purified in the usual way.—R. M.

*A Process or Processes for Producing  $\beta$ -naphtholdisulphonic Acids, Separating the same and Obtaining Colouring Matters therefrom*. Jasper Wetter, London. From the Leipziger Anilinfabrik, Beyer and Kegel, of Lindenau-Leipzig, Saxony. Eng. Pat. 7097, May 1, 1884.

FOR 4 parts of sulphuric acid of 66° Bé. are heated to 125-135° C., and one part  $\beta$ -naphthol is then quickly introduced, the temperature mentioned being maintained for four to five hours. The product is dissolved in three times its weight of water, caustic soda equal to half the weight of the acid employed is added, and the solution is then saturated with common salt. On cooling, a portion of the acid salts of the sulpho acids crystallises out, and the remainder is left in the solution. The crystalline portion is filtered off and washed with brine, and both this and the soluble portion may be directly employed for the production of azo colours, the latter giving the more yellow shades. The inventors give a list of the diazotised bases employed, and the colours obtained respectively from the soluble and the crystalline modifications of the disulpho acids.—R. M.

*A Process or Processes for Separating the Different  $\beta$ -naphtholmonosulphonic Acids from a Mixture of the same, and for Obtaining Colouring Matters therefrom*. Jasper Wetter, London. From the Leipziger Anilinfabrik, Beyer and Kegel, of Lindenau-Leipzig, Saxony. Eng. Pat. 7098, May 1, 1884.

ACCORDING to this invention,  $\beta$ -naphthol when heated to 100° C. with the quantity of strong sulphuric acid, theoretically necessary to form a monosulphonic acid according to the process of H. E. Armstrong, gives rise to a mixture of two isomeric monosulphonic acids, which can be readily separated by treating the solution of the free acid or the sodium salt with common salt. Both the portion which separates out, and the soluble portion, can be directly employed for the preparation of azo colours.—R. M.

*Estimation of Orthotoluidine and Paratoluidine, if present together in Mixtures, by means of the Specific Gravity*. G. Lunge. Chem. Ind. 8, 74.

THE mixture of ortho- and paratoluidine forms a liquid at 15° C. as long as it does not contain more than 50 per cent. of paratoluidine. It is, therefore, easy to determine its specific gravity at 15° C. If it contains 60 per cent. of paratoluidine, the temperature at which the specific gravity is taken must be raised to 20° C. Beyond this percentage the author does not think his method available, owing to the different mixtures showing only very small differences in their specific gravities, and it being well-known that observations taken at temperatures artificially raised lose much in accuracy. For precise purposes the specific gravity must be found by means of a sensitive balance and pycnometer, but for practical purposes the use of an accurate hydrometer is admissible. Absolutely indispensable is an accurate observance of the temperature, 1° C. more or less causing a difference

of 7 per cent. Furthermore, the mixture must not contain water or aniline or xylidine, and if so the former must be removed by means of fused potassium hydrate and successive distillation. If the temperature of observation is not exactly 15° C., the specific gravity found, must be adjusted for each  $\pm 1^\circ \text{C}$ .; if it be more than 1.0008 it must be corrected by  $\mp 0.0008$ ; if it be less than 1.0008 by  $\mp 0.0007$ .

influence of the bleaching processes upon the strength of cotton fabrics is published in the *Mittheil. des Technologischen Gewerbe-Museums*, Section für Färberei, Vienna, 1884, p. 11. These experiments show that any tendering of a fabric cannot be ascribed to the action of chlorine or to any part of a properly conducted bleaching process. ## V.—TEXTILES: COTTON, WOOL, SILK, Etc.

*The Influence of Certain Processes in the Manufacture of Cotton Fabrics upon their Strength.* Dingl. Polyt. J. 255, 349.

SCHREUR (Bulletin de Mulhouse, 1883, p. 76) finds that water at a temperature of 150° has no marked tendering effect upon cotton, even when the action is continued for eight hours. At temperatures above 160° the tendering action of water is well-marked and considerable. Maintained in contact with air for one hour at a temperature of 170°, the fabric does not appear to suffer any diminution of strength. Grosseteste (*Ibid.* p. 65) contributes some experiments as to the temperatures to which fabrics attain during singeing. The fabric was saturated with a solution of an aniline salt, potassium ferriyanide and potassium chlorate, which at a temperature of 80° developed a green, at 100 a black, and between 120° and 130° a reddish-brown colour. With Tulpin's singeing machine the fabric became green; by passing three times through Blanchet's apparatus with three flames, a uniform black was developed.

An extended series of experiments by Haebler upon the

bleaching process, may be adduced in proof of the foregoing statement:—

Stage of Process.	Breaking Load. Kilos.
Unsize	4.656
Size	5.029
Singe	5.206
Boiled in lime, washed	4.634
Acidified with HCl, washed	4.664
Boiled in soda, washed	4.799
Treated with chlorine, washed	5.204
Acidified with H <sub>2</sub> SO <sub>4</sub> , washed	5.345
Dressed	6.423

A second series of experiments is devoted to the question of the tendering action of various mordants as follows:—

No. 1. Aluminium aceto-sulphate

with sodium phosphate.

No. 2. Sodium aluminate  $\text{Al}_2\text{Na}_2\text{O}_9$  with ammonium chloride.

No. 3. Aluminium sulphocyanide  $\text{Al}_2(\text{CNS})_6$  with sodium phosphate.

- No. 4. Pure acetate of alumina  $Al_2(C_2H_3O_2)_6$ .  
 No. 5. 140g.  $FeSO_4$ , 0.5l.  $H_2O$ , 55g. sodium acetate.  
 No. 6. Same as No. 5, but 110g. sodium acetate.  
 No. 7. Bistre: 100g. crystallised manganous chloride, 0.5l. of water, 55g. sodium acetate.  
 No. 8. Chromate of lead dye.  
 No. 9. Same as No. 8, but subsequently treated with lime water.

The breaking loads of portions of the same fabric treated with the above are here given:—

No. of Moriant.	Breaking Load. Kilos.
0	5.481
1	5.371
2	5.269
3	5.368
4	4.920
5	4.230
6	4.495
7	5.199
8	4.620
9	4.776

The conclusion to be drawn from the figures adduced is that cotton fabrics are weakened by the application of the mordants and compounds detailed above.—W. D. B.

## VL.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

### *Recent Progress in the Chemistry of Calico Printing.*

A Lecture delivered before the Verein z. Bef. der Gewerbeliebses, Berlin. O. N. Witt.

AFTER a general introduction, in which the author discusses the many-sided qualifications necessary to the discharge of the functions of a textile colourist, he proceeds to the treatment of the more important items in the recent progress of the art, viewed from the chemical standpoint. The processes of continuous steaming, and more particularly the apparatus invented by Mather & Platt, for instantaneous steaming, are exerting considerable influence upon the methods of development and fixation. The latter is of especial advantage in the development of aniline black, in the removal of the acetic acid present in the colour mixtures, as a preliminary to the longer exposure to steam in the ordinary apparatus, and in which the presence of the acid is objectionable, also in the fixation of many mordants, such as alkaline chrome. The author then refers to recent advances in the chemistry of cellulose, more especially to the researches of Witz and of Cross and Bevan, and the modifications of the fibre substance under oxidising influences, which they have brought to light (see this Journal, iii. 206 and 291). The power which cellulose has, of decomposing certain alkali-metal salts, and of appropriating the metallic oxide therefrom, is the basis of various novel mordanting processes, of which the application of a glycerine solution of the sodio-chromic oxide is the most important. The chrome mordant is most valuable for the fixation of carnelin, alizarin blue, gallein, gallocyanin; also of the newly-discovered Victoria blue (presumably a naphthyl-tetramethyrosaniline). Researches in connection with the application of this colouring matter have led to the discovery of the elegant method of chrome mordanting, which consists in padding with a mixture of an alkaline bichromate, sodium thiosulphate, and magnesium acetate. At ordinary temperatures these salts do not react, but on steaming decomposition sets in, and the chromic oxide is fixed in the fibre.

Manganese mordants are employed for the production of various fast shades, by a subsequent dyeing process, which consists in boiling the mordanted fabric in a solution of a salt of an aromatic amine. As a result of the oxidising action of the oxide and its combination with the product of oxidation, a series of extremely fast shades may be obtained. In this way a black may be obtained from aniline sulphate; a red brown from naphthylamine sulphate. The result is susceptible of numerous modifications in its mode of application, some of which are mentioned by the author. He then proceeds to review

the growth in the practice, which has now become general, of "preparing" cloth to be printed, by a treatment with Turkey-red oil. The efficacy of this mordant or prepare is entirely referable to the ricinoleic acid, which is its chief constituent. In connection with the subject of mordants, the author alludes to the experience of the dyer that one colouring matter may act as a mordant for another—e.g., Millar's canarin for almost all the aniline colours; alizarin red for safranin, alizarin violet for methyl violet. This has an important bearing on the practice of "topping" colours.

In his review of progress in the department of colouring matters, indigo is treated first. Mention is made of C. Koechlin's method of discharge by means of a neutral chromate, printed topically, and afterwards decomposed in a bath of sulphuric acid, containing in addition oxalic, the latter serving to arrest the action of the chromic acid. By incorporating with the chromate a suitable mixture of albumen and a pigment, the latter is fixed by coagulation of the albumen at the same time that the indigo is discharged. By employing aluminium chloride as a discharge, the fabric may be mordanted at the same time for alizarin, etc. Another process with the same object consists in padding with red prussiate and printing with sodium aluminate. The topical synthesis of indigo from nitrophenylpropionic acid, the outcome of Bayer's well-known researches, is a process that remains for the present very restricted in its application. The alkaline-glucose reduction method of Schlieper and Baum is favourably noticed. The observation that the alkaline mixture used in this process destroys the adhesion of an alizarin lake to the cotton, is the basis of an indigo blue print upon a Turkey-red ground. It is only necessary to pass through sulphuric acid of 7° B., to complete the topical removal of the alizarin. Mention is also made of the method of reserving alizarin red by means of tartaric acid; also of reserving aniline black by means of the sulphocyanides. In speaking of the colouring matters which have been proposed as substitutes for indigo, the author mentions (1) indophenol. This body, which resembles indigo in giving a colorless reduction product, labours under the disadvantage of being sensitive towards acids, by which it is coloured red, and, in fact, decomposed; hence it has received only a limited application. In the printing of woollen goods, however, it is of more value in consequence of its peculiar property of acting, in the reduced state, as a discharge, upon the azo ponceaux. This is the basis of a method of producing very pretty effects in indophenol blue upon red grounds, and one which the author believes to be destined to a wide application. (2) The colouring matter, as yet uninvestigated, produced by the action of potassium bichromate upon logwood extract, in presence of the bisulphites. It gives, with acetate of chrome mordants, blue shades resembling indigo, but greyer in tone. They are, however, not very fast. In violet colouring matters the only recent introduction of importance is gallocyanine, a body of both basic and acid properties, produced by the action of nitrosodimethylaniline upon gallic acid. It can only be fixed by means of chrome mordants. It is extremely fast. In combination with berry liquor it gives indigo shades.

Cornelin and gallein, colouring matters discovered by Bayer, which remained for long unnoticed, are now being extensively used. The former is the basis of the new olive greens, which are extremely fast, and easy of production. The mordant is a mixture of acetate of chrome and sodium bisulphite. The indulins are now commonly used for the production of grey shades; they require a tannin mordant.

In red colouring matters, alizarin continues to be almost exclusively used. Great hopes are, however, entertained of the use of the new product azarin, the bisulphite compound of an azo colouring matter resulting from the action of  $\beta$ -naphthol upon didiazodioxysulphobenzide. A new feature, in this compound, is the presence of the  $SO_2H$  group, and the consequent absence of the tendency to sublimation. It is easily fixed by means of alumina mordants, and gives fast shades.

The author then mentions a group of colouring matters which appear to unite directly with cellulose,

and are, therefore, fixed without the intervention of a mordant; these are flavophenin, canarin, a product of oxidation of hydrosulphocyanic acid, and the so-called Congo red.

Lastly, of new yellows, the author mentions anramine, an ammonia derivative of tetramethyldiamidobenzophenone; and flavaniline, a base belonging to the quinoline series; and also a pigment yellow produced by steaming a mixture of cadmium nitrate and sodium thio-sulphate.

—C. F. C.

*Process for Bleaching Worsted Fabrics.* J. B. Thompson and J. P. Rückman (D. R. P., Cl. 8, No. 26,839, March 6, 1883). Dingl. Polyt. J. **252**, 392.

LINEN yarns and fabrics are first boiled for three hours in a dilute solution of potassium cyanide, washed, and again boiled in the cyanide. Cotton does not need this treatment unless it is more or less greasy, and even then the solution of cyanide must only be half as strong as for the linen, and only two hours' boiling is necessary. For the remainder of the bleaching process, the reader is referred to this Journal, vol. ii. 411, and vol. iii. 291.

—E. G. C.

*On the Discharge of Indigo-blue and Turkey-red by Electrolysis.* F. Goppels-roeder. Dingl. Polyt. J. **253**, 431.

It had been found by Scheurer that indigo-blue was attacked even by moist chlorine gas far too slowly for the discharge process described by Persoz to be a practical success; it, however, the fabric dyed with indigo-blue or Turkey-red were printed with a thickened alkali solution, Scheurer found that the colour of the parts so printed was discharged immediately the fabric was exposed to the action of chlorine gas. In the author's earlier experiments (*Ibid.*, 253, pages 245 and 381, 1884) the discharge of these colours was effected by employing as electrolytes solutions of nitrates or chlorides, together or singly, and either neutral or acidified with sulphuric acid. On passing the electric current through a dyed

fabric printed or saturated with such solutions, the colour was discharged at the positive electrode, and in the case of neutral solutions being employed caustic potash or soda was set free at the negative electrode. The author was then led by Scheurer's discovery to employ as electrolyte a solution of sodium chloride rendered alkaline with either sodium or potassium hydrate, and found that the evolution of chlorine at the positive electrode was more vigorous than when the electrolyte was neutral or acid. If a fabric dyed indigo-blue or Turkey-red, saturated with a solution of sodium chloride or potassium nitrate, and caustic potash, be laid upon a platinum plate forming the negative electrode, and a platinum wire or plate forming the positive electrode, brought in contact with the upper surface, either colour is immediately discharged. In his experiments the author had recourse to the simple arrangement here figured. Upon the caoutchouc plate A the platinum plate B forming the negative electrode is laid, and upon this, the red or blue fabric C previously saturated with the electrolyte. Between B and C from eight to sixteen folds of similarly saturated white cloth may be interposed if desired. Upon the dyed fabric C the platinum plate D forming the positive electrode is placed, and glass plates E serve to protect the portion of the cloth not covered by D from the action of the gases evolved at the positive pole. This process may also be found of value for the development of various colours.—W. D. B.

*H. Kochlin's Chrome Mordant with Colouring Matters.* Dingl. Polyt. J. **255**, 447.

THE cloth is twice taken through a mordant consisting of one volume of chrome acetate 16°, three parts water, two parts NaOH solution 38° and  $\frac{1}{2}$  part glycerine. The cloth is left several hours after mordanting and then thoroughly washed. The dyeing was made with the addition of different substances by way of comparative tests, such as alum, alum and chrome alum, and chrome alum alone, tin crystals, and glue. One part of the sample was steamed and the half of each soaped at 60°. The following results were obtained:—

1. The best effect produced by the addition of an equal weight of chrome alum. Bismarck brown, Couper's grey, Victoria blue (this requires twenty times the weight of chrome alum), cochineal, eosin B, alkali blue.

2. The best effect produced by the addition of 25 per cent. of tin crystals. Ponceau 3 R., Bordeaux 3, rose Bengal, rocceline, eosin, orange II., indigo-carmine, cochineal and Persian berries.

The colours in all cases are brightened by steaming. Those which under these conditions resist soaping are Bismarck brown, malachite green, Victoria blue, gallo-cyanine, cochineal, logwood, alizarin, nitro-alizarin, Persian berries, quercitron, caruceline, eosin and rose Bengal. The following three colours give a negative result: Auramine, saffranine, alizarin blue. Ponceau 3 R. dyed with an equal weight of chrome alum on wool after steaming resists soaping at 75°.—J. B. C.

*A New Red Discharge on Vat Blue.* A. Schenrer. Dingl. Polyt. J. **255**, 452.

A MIXTURE of aluminium chloride and bichromate of potash thickened with starch is printed on the indigo-dyed cloth and then steamed for a minute in a Mather & Platt machine. It is washed, dyed in alizarin, and soaped. The red is somewhat dull, due probably to the products of decomposition of indigotine, which become fixed with the alizarin lake. This method resembles that of G. Saget, who proposed a mixture of aluminium chloride and finely-powdered manganese dioxide.

—J. B. C.

*Printing Blue Grounds upon Woolen Fabrics.* O. Breuer. Dingl. Polyt. J. **255**, 534.

To obtain, by printing, a uniform blue ground upon woollen fabrics, the author advises the addition to the colour of fifteen per cent. of ammonia. When Blue 5 B. is employed, the best results are obtained by decomposing this colouring matter in aqueous solution, with an acid, and redissolving the blue precipitate obtained, with ammonia. The printing colour is composed of two kilos. of precipitated blue dissolved in 350 grammes of ammonia, together with 500 grammes of glycerol, and 1100 grammes of dry gum senegal. The employment of ammonia is chiefly to be recommended when working with aniline colours; it exerts, however, a beneficial influence in conjunction with nearly all the artificial dyestuffs, even those—the ponceaus, for instance—upon which it has little specific action.—W. D. B.

*The Fixing of Various Artificial Dyestuffs by Means of Ferro- or Ferri-cyanides.* Dingl. Polyt. J. **256**, 42.

CERTAIN artificial dyestuffs being precipitated by prussiates, C. Reber (*Bulletin de Rouen*, 1884, 768) makes use of this property for fixing colours on vegetable fibres. For instance, if a solution of aniline violet be added to a solution of a yellow or red prussiate, a complete precipitation of the dyestuff takes place, probably as the ferro- or ferri-cyanide of methylrosaniline. The same is the case with fuchsine, methylene blue, etc. To carry out this process, the tissue is mordanted with a solution of prussiate. After drying, the dyestuff is printed on it, allowed to hang for 24 hours, steamed, washed, and soaped. Methylene blue and violet produce the darkest and fastest shades with red prussiate, whereas fuchsine yields the most beautiful colours with the yellow salt.

In order to employ the mordanting power of ferro- or ferricyanides for dyeing tissues previously printed upon, the author precipitated zinc ferro- and ferricyanide on the fibre, which compound, indeed, attracts the dyestuff forming permanent lakes. Thus prussiates may in certain cases take the place of tannin, a very desirable matter from an economical point of view.—S. H.

*Manufacture of Antimonial Compounds suitable as Mordants in Dyeing and Printing.* Wetter. Eng. Pat. 5887, April 3, 1884.

If alkalis, carbonates of the alkalis, or alkaline earths are allowed to act on sugar, gum, dextrin, or other carbohydrates, the products thus obtained give, with antimony, compounds which are soluble in water without decomposition. For instance, a solution of grape sugar is treated with a strongly alkaline substance until no further diminution of the free base takes place. The mass is then acidulated with a strong acid, and digested with antimonious oxide or any antimonial compound adapted to introduce into the liquid simultaneously with the necessary antimony a certain quantity of strong acid; such compounds are the trichloride, the sulphate, etc. In any case, however, that degree of acidity should be imparted to the liquid which causes the absorption of a maximum of antimony. The salts formed from the acid introduced into the liquid, and from the base contained in the same, are removed by filtration or crystallisation. The antimonial liquids resulting from these operations may be directly used in dyeing and printing textile materials, or they may be concentrated by cautious evaporation, or converted into a dry state.

—S. H.

*Process of Bleaching Webs or Yarns of Vegetable Textile Materials.* William Mather, Manchester. Eng. Pat. 471, January 13, 1885.

THIS invention consists in applying the operations referred to in the inventor's specification (2641, May 28, 1883), Thompson's specification (593, February 3, 1883),

and Cross's specification (4984, Nov. 30, 1880), in combination, and as successive steps of one process.

What is claimed is "in bleaching, by a continuous process, webs or yarns of vegetable textile material, the combination of the operations of saturating with alkaline or equivalent solutions (*i.e.*, sulphite of soda, etc.), steaming, saturating with bleaching liquor, and exposing to the action of carbonic acid gas."—H. A. R.

## VII.—ACIDS, ALKALIS, AND SALTS.

*The Decomposition of Ammonium Sulphate by Sodium Sulphate under the Influence of Heat.* G. Blattner. Dingl. Polyt. J. 255, 253.

CAREY and Hurter have patented a process for the preparation of ammonia from ammonium sulphate, which consists in the decomposition of that salt by means of sodium sulphate at a high temperature, the products of the reaction being free ammonia and acid sulphate of soda, which latter, mixed with common salt and heated, will give hydrochloric acid and neutral sodium sulphate. The author now records experiments he has made with the object of determining the degree of accuracy with which the reaction expressed thus:

takes place. In the experiments recorded the substances in different proportions were heated to various temperatures in a retort connected with two conical flasks, containing dilute sulphuric acid, for the absorption of ammonia evolved, a stream of air being passed through at the end of each operation. The ammonia which remained in the body of the retort, and also as a sublimate of bisulphite upon the neck, was driven off by soda ley, and estimated. The amount of ammonia lost, probably due to decomposition and liberation of nitrogen, was determined by subtracting the total amount found from that employed in each experiment.

No.	EXPERIMENTAL DETAILS.	Ammonia obtained, Parts per 100 of that taken.		
		Evolved as $\text{NH}_3$	Remaining in the body of the retort and on the neck of the flask.	Lost.
1	10g. $(\text{NH}_4)_2\text{SO}_4$ in solution + 15g. $\text{Na}_2\text{SO}_4$ .....	58.5	27.1	14.4
2	10g. " " 13g. " .....	69.4	14.2	16.4
3	10g. " " 13g. " .....	67.8	17.0	15.2
4	40g. " " 60g. " .....	65.7	20.6	13.7
5	20g. " " 50g. " .....	50.0	37.0	13.0
6	20g. " " 25g. " gradually heated till fused...	56.3	25.5	18.2
7	20g. $(\text{NH}_4)_2\text{SO}_4$ ground up with 25g. $\text{Na}_2\text{SO}_4$ , rapidly heated.....	66.6	16.4	17.0
8	Same as 7, but temperature not allowed to rise above $400^\circ$ .....	15.4	60.6	24.0
9	20g. $(\text{NH}_4)_2\text{SO}_4$ , 35g. $\text{Na}_2\text{SO}_4$ , moistened with water and rapidly heated	58.5	23.0	18.5
10 {	20g. $(\text{NH}_4)_2\text{SO}_4$ in solution + 23g. $\text{Na}_2\text{SO}_4$ , practically equivalent quantities.....	68.2	15.1	16.7
11	20g. $(\text{NH}_4)_2\text{SO}_4$ , heated by itself .....	23.1	65.7	11.2
12 {	20g. $(\text{NH}_4)_2\text{SO}_4$ in solution + 25g. $\text{Na}_2\text{SO}_4$ , temperature not allowed to exceed $400^\circ$ .....	28.0	57.8	14.2

These figures show that the best results are obtained by employing approximately equivalent amounts of the substances, but that even then only between 65 and 70 per cent. of the ammonia present is obtained, the remaining 30 to 35 per cent. being partly retained, partly sublimed as bisulphite, and partly lost by decomposition. It may be found possible to prevent or at least lessen the loss of ammonia, by conducting the heating in presence of a current of water vapour.—W. D. B.

*Apparatus for the Manufacture of Liquid Carbonic Acid.* Dingl. Polyt. J. 256, 36.

H. & J. F. BEINS, Groningen (Germ. Pat. 30,192, 1884), have patented the manufacture of liquid carbonic acid by heating sodium bicarbonate in an apparatus in which the carbonic acid evolved is liquefied by its own pressure. The cylindrical retort A (Fig. 1) is covered with a strong lid F, containing the outlet pipe for the carbonic acid. Its bottom is formed by a pipe B, closed at the top, and open at the lower end, thus exposing a large surface of the retort to the heat of the fire-gases, by compelling them to travel in the direction of the arrows in the diagram. A cooling arrangement protects the packing of the lid from getting destroyed. The carbonic acid

*On the Solution of Magnesium Carbonate by Carbonic Acid.* R. Engler. Compt. Rend. 100, 444.

By estimating the solubility of magnesium carbonate in water at 12° C., charged with carbonic acid at various pressures, the author has obtained numbers from which he calculates the general equation  $X^{.333} = ky$  (where  $y$  = quantity dissolved,  $X$  = pressure of  $\text{CO}_2$  and  $k$  = a constant = .03814);

$$\text{Hence } X = k^3 y^3 \text{ or } y = \sqrt[3]{X/k^3}$$

that is to say, the quantity dissolved at any fixed temperature is proportional to the cube root of the carbonic acid pressure.—A. G. G.

*A Crystallised Hydrate of Phosphoric Acid.* A. Joly. Compt. Rend. 100, 447.

By cooling the mother-liquor from the trihydrate, prismatic plates of a tetrahydrate ( $\text{P}_2\text{O}_5 + 4\text{H}_2\text{O}$ ) crystallise out. This melts at 27° C., its heat of liquefaction being 3.64 cal. It dissolves in less than 100pts. of water with absorption of heat, in more water with evolution of heat.—A. G. G.

given off travels through a cooling vessel J, where the steam is condensed and collects in the cylinder L. Thence it proceeds through two coke-towers, which serve to retain any organic matter, and lastly into the cylinder S, surrounded by cold water or ice. This cylinder is fastened to the beam of a scale for the purpose of filling it with any definite weight desired. The coke-towers stand in a vessel which can be filled with warm water in order to prevent the carbonic acid from being condensed in this part of the apparatus.—S. H.

*On the Law of Solution.* H. le Chatelier. Compt. Rend. 100, 50 and 441.

IN the first of these communications, the author deduces from the principles of thermodynamics a relation between the solubility of salts, their heat of solution and the temperature. From this equation it is shown that the solubility of a salt which dissolves with absorption of heat, will increase with the temperature and inversely; whilst the solubility of a salt which dissolves with evolution of heat, will diminish with rise of temperature.—A. G. G.

*Nitre-earth from Turkistan.* N. Ljubawin. J. Russ. Chem. Ges. 617, 1884.

AN area of about four square kilometres, south-west of Fort Nukus, on the left bank of the Amu-Darjoo, in the Khanate of Khiva, is covered with a layer of nitrate earth of the following composition:—Constituents soluble in water=27.89; Ditto soluble in  $\text{HCl}$ =17.14;  $\text{CO}_2$ =5.73; insoluble=48.42. Total 99.18. The part soluble in water contains—

$\text{KNO}_3$ .....	5.52	} 10.61 total nitrate.
$\text{NaNO}_3$ .....	4.05	
$\text{Mg}(\text{NO}_3)_2$ .....	1.04	
$\text{NaCl}$ .....	12.90	
$\text{CaSO}_4$ .....	3.25	}
$\text{MgSO}_4$ .....	0.66

*Improved Method of Producing Oxide of Strontium or of Barium.* E. F. Trachsel, Middlesex. Eng. Pat. 6022, April 5, 1884.

SULPHATE of strontium or barium is reduced to sulphide by heating with carbonaceous substances. The sulphide

is then heated with oxide of iron or iron in a muffle in presence of air, and hydrate of strontium or barium is obtained from the product by extraction with water.

—G. H. B.

*Improvements in the Method of Generating Carbonic Acid Gas, and in Apparatus therefor.* J. Magnall and R. S. Lloyd, Middlesex. Eng. Pat. 6179, April 9, 1884.

CARBONIC acid is obtained by the action of dilute sulphuric acid on whiting, the reaction being maintained by agitation.—G. H. B.

*Improvements in the Manufacture of Alumina.* G. Rosenthal, London. Eng. Pat. 6290, April 12, 1884.

SULPHATE of alumina is heated with its equivalent of magnesium chloride, the reaction being assisted in the later stage by the application of superheated steam. Hydrochloric acid is evolved, and the residue, consisting of alumina, oxide of iron and magnesium sulphate, is lixiviated with water, and the oxide of iron is removed "by magnets."—G. H. B.

*Improvements in the Manufacture of Carbonate of Soda.* C. Wigg. Eng. Pat. 7525, May 10, 1884.

THIS invention is a combination of the Le-blanc and the ammonia soda process, in order to obtain hydrochloric acid as well as carbonate of soda. The process can be resolved into the following stages: 1. Common salt is converted into sodium sulphate, the hydrochloric acid given off being condensed in the usual manner. 2. Sodium sulphate is mixed with a strong solution of ammonia or ammonium carbonate, and the temperature raised to that point at which the maximum of sodium sulphate enters into solution. The operation is performed under pressure in a closed vessel, provided with hollow rotating beaters. 3. The solution is allowed to cool while impurities settle out which can be removed. 4. Carbonic acid is passed into the solution under a pressure of from 15 to 40 lb., until all carbonate of ammonia is converted into bicarbonate. Sodium bicarbonate is thereby precipitated and ammonium sulphate enters into solution. 5. Sodium bicarbonate is separated from ammonium sulphate by filtration, first through cloth and afterwards through gypsum, so as to ensure that the ammonium carbonate which has not entered into reaction with sodium sulphate shall be decomposed into ammonium sulphate. 6. The filtrate is evaporated to obtain ammonium sulphate for sale, or the solution is treated with brine and boiled down. By this means anhydrous sodium sulphate, free from iron, is precipitated and a solution of ammonium chloride is obtained, from which the ammonia can be liberated for re-use. 7. The sodium bicarbonate is roasted to convert it into carbonate of soda, carbonic acid being recovered at the same time.

—S. H.

*Improvements in Apparatus for Disintegrating and Removing Impurities from Lump Salt.* T. Higgin, Liverpool. Eng. Pat. 8266, May 27, 1884.

THE object of this invention is to remove without pulverising the "pan scale" and "sand scale," which the lumps contain, and which are harder than the salt. These can then be removed by sieving. The lump salt is disintegrated by hacking or tearing, as distinguished from crushing or pulverising. The specification contains a large number of drawings, giving the details of the machinery employed.—S. H.

*Manufacture of Sulphate of Ammonia and Bye-products resulting from the Process.* Kelly and Weigel. Eng. Pat. 8680, June 6, 1884.

KIESERITE solution is mixed with common salt and the mixture subjected to a low temperature, when a double decomposition takes place producing sodium sulphate, which crystallises out, and magnesium chloride, which remains in solution. Ammonia is then passed along with carbonic acid through the solution of sulphate of

soda, thus producing sodium bicarbonate and ammonium sulphate. During this reaction the vessels are kept cool. The bicarbonate is allowed to settle and removed in the solid condition, whereas the solution of ammonium sulphate, which also contains small quantities of sodium bicarbonate, sodium sulphate, ammonium hydrate and carbonate, is subjected to distillation, in order to drive off the volatile ammonium compounds. At the same time, the small quantity of sodium bicarbonate is converted into sulphate of soda, which can be removed by crystallisation. Ammonium sulphate is then obtained from the residual solution by evaporation.—S. H.

*Improvements in Purifying Sulphuric and Sulphurous Acids and their Salts.* J. Meikle. Eng. Pat. 11,866, September 2, 1884.

THIS invention consists in passing sulphuretted hydrogen through the acid or a solution of their salts. The effect is to form a precipitate of sulphides of arsenic or other metals, and this precipitate, which is separated by filtration, may be utilised by burning so as to yield sulphurous acid. Sulphuric acid derived from pyrites and purified by this process is well suited for making sulphate of ammonia of good quality.—S. H.

*Improvements in the Manufacture of Chlorine.* Ernest Solvay, Brussels. Eng. Pat. 7258, January 15, 1884.

THESE improvements relate to the process referred to in Patent No. 77, January 8, 1877; No. 838, January 25, 1880; and No. 839, January 25, 1880. 1. To prevent the introduction of carbonic acid into the chlorine, the silicious or aluminous substances used are treated with an acid to decompose carbonates, and ignited (with nitrate of soda, if necessary) to remove organic carbon. 2. When the mixture to be decomposed contains chloride of calcium corresponding with the required theoretical quantity of silica and alumina, the matter agglomerates and the apparatus works with difficulty. The addition of more silica or alumina gives the required infusibility, but the material is no longer suitable for the manufacture of cement. This difficulty is obviated by the introduction of a sufficient quantity of the residuum of a previous operation. 3. The air used is purified from carbonic acid and moisture by passing through a series of suitable absorbing vessels.

—A. R. D.

*Improvements in the Manufacture of Chlorine and Chloride of Lime.* Ernest Solvay, Brussels. Eng. Pat. 7259, January 16, 1885.

THESE improvements relate to the same process as the preceding. To enable the apparatus to resist the action of chlorine the iron or cast-iron is covered with preservative coatings of certain mixtures of soda, clay, and vitrifiable products. To this enamel is sometimes added a fireproof coating which adheres to the metal through the intermediary of the vitrified enamel. The absorption by lime is effected by placing the lime in a layer of suitable thickness on beds of porous mineral matters, such as pebbles, or mineral fabrics, such as asbestos cloth, and causing the diluted chlorine to pass downwards through the same. If the gases pass upwards, channels are soon formed and irregularity ensues.—A. R. D.

*Improvements in the Manufacture of Hydrochloric Acid.* Ernest Solvay, Brussels. Eng. Pat. 7260, January 16, 1885.

THIS invention relates to the process of decomposing calcium chloride with aqueous vapour in the presence of silica or silicious substances. When this mixture is made in the theoretical proportions the matter agglomerates and the apparatus works with difficulty. The addition of more silica and alumina, while promoting the infusibility of the mixture, renders it unsuitable for the manufacture of cement. The difficulty is obviated, however, by introducing a sufficient quantity of the residuum of a previous operation. Silicious clays, infusorial silica, fossil flour, etc., as well as precipitated silica, are much to be preferred to sand in the above operation.—A. R. D.

*Improvements in obtaining Solid Caustic Soda from Fused Caustic Soda.* W. Weldon. From A. R. Pechiney et Cie, Salindres. Eng. Pat. 2478, February 24, 1885. This invention consists in a method of obtaining caustic soda in films or sheets, capable of being readily converted

into powdered caustic soda. Fused caustic soda is brought into contact with the exterior surface of a revolving hollow cylinder, the heat being carried off by water passed through the interior of the cylinder. In Figs. 1 and 2, A is a hollow cylinder turning on hollow

FIG. 1.

FIG. 2.

FIG. 3.

axles CC. Water is admitted into A, passing out near the top by the pipe K. Below the cylinder is a small trough B, into which fused caustic soda is fed. As the cylinder A revolves, it dips a little below the surface of the caustic soda and emerges coated with a film of solid

exact and certain correspondence; this was not the case in the original machine. The slide S, which carries the upper mould, is actuated by the cam J. The moulds are of plaster of Paris, and are fixed in iron boxes in the usual manner. With 1 horse-power, 55 or 60 revolutions

FIG. 4.

caustic soda, which on reaching the scraper E is detached from the cylinder and falls into a conduit, from which it falls between the toothed rollers G and H, which crush it into small fragments. Figs. 3 and 4 represent another disposition of apparatus for the same purpose. There are two hollow cylinders A and B turning in opposite directions. At each extremity of the cylinder A is a flange which overlaps the corresponding extremity of the cylinder B. C is a hopper into which the fused caustic soda is charged. It is provided with a slit at the bottom and a contrivance to regulate the feed at will. The two cylinders are kept cooled by water continually passing through them. E and F are scrapers which detach the solid caustic soda and deliver it between the two toothed rollers.—S. H.

*The Protection of Nitrate of Ammonia from Deliquescence.*  
W. R. Lake, London. Eng. Pat. 1868, Feb. 10, 1885.

NITRATE of ammonia, used in the manufacture of explosive compounds, is protected from deliquescence by mixing it in a granulated condition with bye-products from the petroleum distillation. It then resembles moist brown sugar, and is not liable to become lumpy or solid.—S. H.

## VIII.—GLASS, POTTERY, AND EARTHENWARE.

*Recent Improvements in the Manufacture of Earthenware.* Dingl. Polyt. J. 255, 365.

IMPROVEMENTS in Schmerber's press for the manufacture of fluted tiles have been made by Boulet, Lacroix & Company. In Figs. 1 and 2 are shown the arrangements now adopted. The prism B, upon the five sides of which the lower moulds are fixed, revolves upon the axis C, motion being transmitted from P by S, G, G, E and D, the two latter being pulley wheels in connection. The revolution of B is regulated by the ratchet wheel L, and catch M. When M is lifted up by means of the cam X upon the spindle F, the prism is free to revolve, but the catch soon falls again, and when the next notch of L is brought beneath M, the prism is brought to rest. By this means the moulds upon B and S are brought to

of the driving wheel P, and two men serving, 500 fluted tiles can be turned out per hour by this machine.

In Vincent's fluted tile press, shown in Figs. 3, 4 and 5, the mechanism for working the upper mould-carrier P<sup>1</sup> is placed below the revolving five-sided prism, P carrying

the lower moulds. By the introduction of steam into the interior of M, and P the moulds are heated that the tiles may have less tendency to adhere. The flat plates of clay to be fluted are carried on to the lower mould by the endless band G; when the pressing is accomplished a frame A is laid upon the tile and there held by catches C, until by the revolution of P the tile attains a horizon-

tal position; on releasing the catches the tile falls off. This arrangement for retaining the tile upon the mould forms the subject of the patent (Ger. Pat. 29,514, May 29, 1884). Magowan and Bassett (Ger. Pat. 28,527, December 19, 1883) adopt the plan of warming the moulds for dishes and such ware, in order to facilitate

fig 2

the removal of the moulded clay, interposing thin sheets of metal or caoutchouc between the mould and the clay. Thus in moulding plates, the lower mould is covered with a thin sheet of metal, by means of which the moulded clay is easily removed from the mould; between the clay and the upper mould is a thin sheet of caoutchouc which can be readily detached from the clay plate after pressing. The Brothers Netzsch (Ger. Pat. 28,651, February 5, 1884) have devised the following process for placing clay sheets with rapidity and accuracy upon the mould or wheel for further manipulation. The sheet of clay is first prepared upon a wheel covered with leather, the edge of which is turned down, as shown in Fig. 6, and held firmly between two rings *b*. The inner ring firmly embraces the circumference of the wheel. The clay which projects beyond the edge of *a* is cut off with wire, and the disc lifted from off the wheel by its rings.

fig 3

fig 4

A second workman, who has to carry the work a further stage, has, near his wheel, the apparatus shown in Fig. 7. A rod *S*, movable vertically in two guides shown, carries at its lower end an arm *E* with disc *G* attached,

The counterpoise *M* is adjusted to maintain *S* in its highest position until it is required to depress *G*, which

fig 5

FIG. 6.

fig 7.

is effected by the cord *N* and a foot lever. The ring of the leather disc described above is now passed over *C*,

which is fixed in such position in respect to *E* that by turning the latter round upon *S* until *E* is in contact with *H*, the centres of *G* and the wheel are in vertical line. *G* is now brought down to the wheel, upon which,

on rising, it leaves the clay sheet and disc. The wheel being set in motion, the leather is loosened by a spatula, removed, and the clay manipulated as usual. By means of the machine patented by Gregg (Ger. Pat. 29,693, May 30, 1884) it is intended not only to measure off accurately the requisite quantity of clay for each tile, but also to distribute coloured clay or glazing flux over the two opposite surfaces of each tile.—W. D. B.

*Solubility of Glass.* E. Bohliger. Zeits. Anal. Chem. **23**, 518.

THE author found that a number of new flasks ordered for laboratory use gave up to 100cc. of boiling water sufficient alkali, in the form of silicate of soda, to neutralise 1 c.c. of oxalic acid every two seconds. The solubility in this particular case appears to be quite exceptional.—J. B. C.

*Improvements in the Manufacture of White Opaque, Opalescent or Semi-transparent Glass and Enamel.* John Henry Johnson. From Adolf Zeddesco, Mügeln, Saxony. Eng. Pat. 6899, April 28, 1884.

THE inventor substitutes for phosphate of lime, cryolite-felspar or fluor-spar, or the double fluoride of aluminium and alkali in conjunction with the usual ingredients for producing opacity in glass—an alkaline fluoride either with or without the conjoint use of a substance containing alumina. He regards as an important point the advantage of this mixture as a substance of easy production, either by adding to fluorine acid the requisite quantity of an alkali or its carbonate, taking care to have an excess of alkali. Or by treating the aluminate of an alkali with fluorine acid till all the alkali is fixed so that hydrate of alumina is precipitated, and after calcination a mixture of alkaline fluoride and alumina will result. Although mentioning the use of alumina and alkaline fluoride for the production of opalescence in glass or enamel, the inventor claims only the use of the fluoride of an alkali in conjunction with materials employed for producing such result.—T.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, CEMENTS.

*Adulteration of Portland Cement.* R. and W. Fresenius. Zeits. Anal. Chem. **24**, 66-71.

THE name Portland cement should be confined to the product obtained by heating together lime and clay in definite proportions and then finely powdered. When this product is mixed with more than 2 per cent. of foreign matters, such as gypsum, the authors contend that the name "Portland cement," if applied to the mixture, is fraudulent. Whether a cheap substance, without any influence on the durability, etc., of the cement is used as an adulterant or a substance added to improve the quality, the name "Portland cement" cannot rightly be employed for the mixture. The authors consider that the nomenclature needs revision and seek the co-operation of cement manufacturers for this purpose. Their tests furnish a ready means of distinguishing the pure article and substitutes or mixtures (Zeit. Anal. Chem. **23**, 175).—S. R.

*An Improved Process and Apparatus for Treating Wood, chiefly Designed for the Preservation of Railway Sleepers.* W. R. Lake, London. From E. L. Collings and C. F. Pike, U.S.A. Eng. Pat. 533, Jan. 20, 1885.

THIS invention consists in the treatment of wood by first steaming it, then drying it by radiated heat and subjecting it to the action of an antiseptic material vaporised by radiated heat. The apparatus and the mode of procedure are described in detail in the specification.

—D. B.

## X.—METALLURGY, MINING, Etc.

*Process for the Extraction of Cobalt and Manganese.* Herrenschildt and Constable. Dingl. Polyt. J. **252**, 392.

ORES containing cobalt or manganese are pulverised and boiled for half-an-hour with water and sufficient ferrous sulphate to convert the oxides present into cobaltous and manganous sulphates, which go into solution; this is decanted from the residue, the proto-salts being afterwards oxidised into per-salts.—E. G. C.

*On the Preparation of Aluminium.* Dingl. Polyt. J. **253**, 426.

H. D. GADSDEN, London (Ger. Pat. 27,572, August 8, 1883), mixes corundum, bauxite, and the like with about 10 per cent. of sodium or potassium fluoride and the same amount of calcium fluoride. The whole is calcined, ground to a powder, mixed with 10 per cent. of wood-charcoal or carbonaceous matter, balled and transferred to a retort or muffle, in which it is burnt. The spongy mass obtained is removed to a second retort, and exposed to the action of a stream of chlorine gas; the aluminium chloride which is formed, is distilled into a receiver, having been, if necessary, previously freed from iron by leading the vapour through a tube filled with iron turnings. To effect the reduction to aluminium of the chloride so obtained, the latter is transferred to a fire-clay retort, connected by a leading tube with a second similar retort, in which a mixture of 20 parts of sodium carbonate and 16 parts of charcoal, or an equivalent amount of other carbonaceous matter, and 5 parts of lime or chalk, is heated to such a temperature that sodium vapour distils over into the aluminium chloride, reducing the latter to the metallic state. The aluminium collects at the bottom of the retort, and may be drawn off and cast into bars.—W. D. B.

*Progress in Metallurgy.* Dingl. Polyt. J. **255**, 375.

*Siemens-Martin Process.*—J. Riley read an important paper on the arrangement of plant, at the Chester meeting of the Iron and Steel Institute (see *Journal, Iron and Steel Inst.* ii, 1884, pp. 443-452). With a modern 12-ton Siemens furnace, "good work" requires that 140-150 tons of ingots shall be made weekly per furnace. In 1880 experiments were made with a basic lining, but great difficulty was caused by fluxing at the lines of division of the basic and acid material, and the experiments were stopped. At Blochairn a row of twelve 15-ton furnaces was erected, and the arrangement finally adopted for casting was as follows:—The furnaces were marked A to M, the last one being capable of holding 25 tons, the others being 15-ton furnaces. On a railway in front of, and parallel to, the furnaces runs a small locomotive which moves a special carriage conveying a ladle for the steel, and a mould for the slag. A 20-ton hydraulic lift is erected between furnaces E and F, and over the railway. In front of this is a 20-ton casting crane which does not lift, but turns on its axis, and has a ram for turning over the casting ladle after each cast. This crane is placed in the centre of a semi-circular casting pit, 40ft. in diameter and 3 feet deep. Around the casting pit are three ingot cranes, and between the cranes are two sets of soaking pits, each with six cells of differing capacity for ingots of 30 or 60cwt. each. The two outer cranes set the moulds in the pit, strip the ingots and deposit them in the soaking pits. The centre crane lifts the ingots from the soaking pit and places them vertically on the tipping carriage at the end of the feed rollers of the cogging-mill. A hydraulic ram tips the ingot easily and without shock on to the feed-rollers of the mill. When a furnace is ready for tapping, the contents are run into the ladle on the carriage, the whole of the steel and slag being run into it, while the latter overflows into the slag mould. Being brought under the lift the ladle is raised and tipped automatically, so that the steel flows into the casting ladle. The charge is now transferred to the moulds in

the usual manner. The time occupied in tapping the furnace, transferring and casting is fourteen to fifteen minutes. After standing twenty minutes the ingots are stripped and placed in the soaking pits, where they remain about fifty-five minutes; altogether the slab is finished in about ninety-five minutes, five minutes going to cogging and shearing.

to bind it. The furnace so prepared was charged with freshly burnt lime, then with pig iron, and lastly with iron and steel scrap. The amount of lime was  $\frac{1}{10}$  to  $\frac{1}{5}$  of the pig charged. In three to four hours the pig is melted, and a liquid slag can be run off. In three hours more the scrap is melted and more slag is run off. If necessary the slag may be thickened by the addition of

*Basic Process in Siemens-Martin Furnace.*—T. Gillot read a paper before the American Institute of Civil Engineers. The hearth was formed of lime 58 parts, magnesia 24, silica eight, alumina and iron oxide 10 parts. This material was burnt at a strong white heat, pulverised, and mixed with hot tar. The mass is at once stamped in position with red-hot stamps. Between the basic mass and the acid wall is inserted a layer of magnesia and bauxite. After 72 hours' firing, a layer of freshly burnt dolomite was spread over the hearth. About 10 per cent. of refractory stone is mixed with the dolomite

lime or iron ore, according as the proportion of pig to scrap is large or small. After the boiling period, a test is taken, and if the result is satisfactory the whole of the slag is run off. Five per cent. of hematite pig is now added, and a violent boiling results for 15 minutes; after 15-30 minutes more the charge is tapped off. The hearth is repaired, and in one to four hours is ready for another charge.

*Bessemer Converters.*—P. Lamberty (Ger. Pat. 29,571, April 30, 1884) proposes to make the bearing ring hollow, to serve as air chest, and from it the air is

passed obliquely downwards through the side of the vessel.

W. Hupfeld, discussing the same subject, remarks that for rolled articles which do not require to be further treated, such as rail, a moderate amount of silicon up to 0.5 per cent. is not injurious in presence of an equal amount of manganese; but for articles richer in carbon, or which have to bear reheating, the silicon should be reduced as much as possible. Although a metal can be produced in large vessels with 0.12-0.20 per cent. carbon, 0.03-0.06 silicon, 0.25-0.4 manganese, 0.035-0.05 phosphorus, and 0.01-0.03 sulphur with the greatest certainty, still a method of further reducing the silicon in Bessemer metal is desirable. According to F. Müller the metallic bath only reduces silicon from a rich silicious slag at a high temperature. Hence, according to Hupfeld's view the lower temperature of a small Bessemer apparatus offers a partial solution of the problem. Successful results have been obtained at Právali as was previously the case at Avesta. *P. v. Tunnér* writes on the subject, but concludes that large blows must prove most economical.—J. T.

*Combination of Carbon with Iron.* Walther Hempel. Ber. 18, 998.

It has been shown that iron can take up carbon from its gaseous compounds, such as carbonic oxide, cyanogen, and hydrocarbons, at temperatures only moderately high.

The author describes experiments which prove that a much higher temperature is required for absorption of solid carbon by iron if oxygen is excluded. This temperature varies with the modification of carbon used, and is lowest for diamond. The lowest temperature at which a plate of wrought iron absorbs carbon when covered with powdered diamond and heated in a stream of nitrogen is 1160° C., with pure charcoal this temperature is between 1385° and 1420° C. If iron is fused in the electric arc in an atmosphere of nitrogen it is converted into white iron.—A. G. G.

*Improvements in the Manufacture of Metallic Compounds or Alloys.* John Radford, Shipley, Yorksire. Eng. Pat. 3233, February 13, 1884.

The improvement consists in the addition of chromium, either as such or as chrome iron or chrome steel, to bronze, brass, gun metal, white metals, or similar alloys. Nickel and cobalt are sometimes employed in addition to the chromium.—W. G. M.

*Improvements in the Collection and Treatment of Flue-dust.* H. Barelay and R. Simpson, Cumberland. Eng. Pat. 3498, February 18, 1884.

The deposition of the flue-dust from furnace gases is assisted by means of trays placed in the flues, and also by washing the gases with water. Alkaline salts are obtained from this dust by extraction with water and evaporation of the solution, and the residue may be used as a raw material for iron smelting.—G. H. B.

*Improvements in Electro-plating Chromium Alloys.* Thomas Slater, Bayswater. Eng. Pat. 5245, March 21, 1884.

The anodes of chromium alloy may be prepared by heating chromium compounds with charcoal in a closed crucible, and pouring upon the reduced mass 2½ parts of fused copper, and, subsequently, 1 to 1½ parts of molten tin; and then granulating, re-fusing, and casting in moulds of the desired shape. These are next used as anodes in a solution, preferably made by dissolving 1 lb. of potassium cyanide and a like quantity of ammonium

carbonate in a gallon of water, heated to 150° F., until a good deposit of alloy is formed upon the cathode, when the bath is ready for use. To finish the plated articles, they are coloured with a bath of chloride of tin (6 to 8 parts), chloride of copper (20 to 25 parts), bichromate of ammonia (10 to 15 parts), chloride of platinum (6 to 12 parts), cyanide of potassium (25 to 30 parts), and water (101 to 110 parts). A very moderate current only is necessary.—W. G. M.

*Improvements in Extracting Gold and other Metals by Amalgamation, and Apparatus therefor.* Ewald Fischer, Silesia, and Max William Weber, London. Eng. Pat. 5834, April 2, 1884.

According to this invention, ground or crushed ore mixed with water is stirred with mercury for a sufficient time to effect the amalgamation with it of the precious metals. The ore is then discharged, leaving part of the metal in the mercury, but carrying away with it a considerable amount of the mercury and amalgam in a finely divided condition. These tailings are then subjected to the action of an electric current at the same time that they are stirred or agitated, which effects a complete condensation of the metallic and amalgam particles. Suitable apparatus is described in the specification, and four drawings.—B.

*Improvements in the Purification of Iron Ores and of Iron by the Basic Process.* Wm. Ph. Thompson, Liverpool. From R. Solliwa, Dortmund, Germany. Eng. Pat. 7401, May 8, 1884.

The invention refers to a method of eliminating sulphur and silicon from iron ores and iron whilst under treatment by the Thomas and Gilchrist process.

The bottom of a converter lined with magnesite and lime is covered with a mixture consisting of two parts of pulverised anhydrous carbonate of soda, and one part of pulverised carbonate of lime. When the blow has begun a sufficient quantity of the mixture is added to make the total weight of the mixture present to be in the proportion of one part of carbonate of soda and one-half part of carbonate of lime to two parts of the silicon present in the whole charge.

After formation of the silicates, the fluid slag is carefully removed, and for every three parts of sulphur in the crude iron, ten parts of carbonate of soda (without lime) are added to the molten metal, the blowing being continued until desulphurisation has been effected. The slag now formed is again carefully removed, and another ten parts of carbonate of soda (without lime) are added for every three parts of phosphorus contained in the crude metal, and the blow finished. The slag resulting from this final blow is added to that first obtained, and is afterwards treated as phosphatic slag containing phosphoric acid soluble in water.—B.

*Improvements in the Manufacture of Spongy Iron, and in Apparatus employed therefor.* Gustav Bischof, London. Eng. Pat. 8093, May 22, 1884.

The inventor treats iron ores or products containing iron in an oxidised state with hydrogen and carbonic oxide and anhydride in such a way as to heat and deoxidise them at one operation.

For this purpose steam is decomposed over incandescent coke, the resulting gases consisting essentially of hydrogen, carbonic oxide, and carbonic anhydride, and some free steam. The latter having been removed by cooling and condensation, the remaining gases are strongly heated and passed into the lower part of an inclined retort into the upper end of which the ore is fed, and allowed gradually to descend to the lower part. Here it comes in contact with the mixed gases, and is reduced to the metallic state by the hydrogen contained in them. The spongy iron so obtained is discharged into a receptacle and cooled before exposure to the air.

The remaining gases which pass upwards through the inclined retort, deprived of the greater part of their hydrogen, but still combustible, are met by a current of air, and burned inside the retort. In this way they heat the oxide of iron preliminarily to its contact with hydrogen, and make any external heating in most cases unnecessary. The process is carried on at a low red heat.—B.

*Improvements in the treatment of the Oxides of Iron obtained either from Iron Pyrites or from other sources, so as to render them more suitable for employment in the Blast or other Furnace.* James Mason. Eng. Pat. 8679, June 6, 1884.

THE inventor proposes to remedy the difficulty hitherto found in the use, for blast and other furnaces, of iron oxide in a state of dust or minute particles. He mixes such oxides with a considerable amount of water, and places the wet mass, whether in lumps or moulded, upon a bed of fuel in a kiln, filling in the interstices and covering up with fuel. After the firing has commenced further layers of the mass and fuel are gradually added, and the process continued until the kiln is filled, when the burning is completed, and the mass allowed to cool. The small particles will then be found to have been strongly agglutinated by the heat, and the mass be fit for use as required. The specification is accompanied by a sheet of drawings, showing a kiln arranged for the purposes of the patent.—B.

*An Improved Method of Amalgamating or Separating Metals from their Ores.* Jonathan Aldous Mays, London. Eng. Pat. 8295, May 27, 1884.

IN this process the mixture of ore and water is fed in thin streams beneath the surface of flowing mercury, by means of a series of nozzles, themselves stationary or moving in a direction opposite to that of the mercury. This is effected by confining the mercury in a circular metallic pan, in which it rotates, either through the rotation of the pan itself or by the action of internally revolving arms. The nozzles are fed through an annular chamber, connected with a supply tube of sufficient height to allow of the contained mixture of ore and water overcoming the pressure of the column of mercury in the pan.—W. G. M.

*An Improved Process of Preparing or Treating Copper.* Alex. Melville Clark, Middlesex. From Wunibald Braun, Frankfort-on-the-Maine, per Wirth & Co. Eng. Pat. 8355, May 28, 1884.

A CURRENT of hydrochloric acid gas is passed through the melted copper, and thus all metallic oxides (including that of copper), and all metals, which are capable of decomposing the gas, are removed as volatile chlorides. A very pure metal of low electrical resistance is obtained, and may be cast free from blowholes in moulds filled with any neutral gas, such as hydrochloric or carbonic acid, or lighting gas. The process of poling copper may be partially or entirely superseded by this process.—W. G. M.

*Process for the Reduction of Iron Ores and Production of Iron and Steel.* Fredk. Siemens, Westminster, and Joseph G. Gordon. Eng. Pat. 8490, May 31, 1884.

FINELY pulverised iron ore, intimately mixed with carbonaceous and fluxing materials, is introduced (in the form of bricks or enclosed in iron vessels) into an open hearth regenerative furnace of the Fredk. Siemens type (Eng. Pat. 5677, 1883). There it is reduced, and the metal and slag fused as fast as they are formed, solely by the radiant heat of, and not by direct contact with, the flame. The fluid metal and slag separate by gravity.—W. G. M.

*Improvements in Processes for obtaining Copper, Silver, and Gold from Copper Matte or Regulus.* Wm. Aristides Vèrel and Peter Stewart, Tharsis Sulphur and Copper Co., Glasgow. Eng. Pat. 8562, June 4, 1884.

THIS patent is intended to render the ordinary wet process available for the treatment of regulus. The matte is crushed fine and mixed with its own weight of sodium chloride, and then, to the extent of 5 or 6 per cent., with the usual mixture of burnt pyrites and salt; the whole mass is then calcined, and subsequently treated as in the usual wet process.—W. G. M.

*Improvements in obtaining Gold and Silver from Auriferous and Argentiferous Sulphide of Antimony Ores.* Jas. Simpson and Edward Wm. Parnell, Liverpool. Eng. Pat. 13,074, October 2, 1884.

IN the treatment of sulphide of antimony ores with solution of the sulphide in alkali or alkaline sulphide as by Patents 11,827 and 11,828, 1884, the whole of the silver, and the greater part of the gold, remain in the residue, a small portion only of the gold passing into the solution as sulphide. To obtain the precious metals from the residue, the sulphur is to be removed by roasting, or by any wet method; and the desulphurised mass treated by amalgamation, chlorination, or any other suitable process. The gold is recovered from the sulphide solution by precipitating a small quantity (2½%) of the antimony sulphide by acid or other means, which quantity will carry with it the whole of the gold; the latter may then be removed by any known process.—W. G. M.

*Depositing Magnesium and its Alloys.* F. W. Gerhard, Wolverhampton, and Jas. Smith, Stoke-upon-Trent. Eng. Pat. 16,651, December 19, 1884.

AMMONIA sulphate of magnesia, prepared by crystallising together 228 parts magnesium sulphate and 132 parts ammonium sulphate, and dissolving in 35,000 parts water, is best used at from 150° to 212° F. For white metal, a nickel anode; for magnesium bronze, a copper anode is used; in the latter case the bath consists of magnesium ammonium sulphate 360, potassium cyanide 550, ammonium carbonate 550, water 35,000.—W. G. M.

*Improvements in the Treatment of Sulphide of Antimony to obtain Chlorides, Oxychlorides, and Metallic Antimony.* John Hargreaves, Widnes, and Thomas Robinson, Widnes. Eng. Pat. 7206, February 4, 1885.

THE bulk of the free acid contained in the solution of chloride of antimony, prepared by dissolving ores containing sulphide of antimony in hot hydrochloric acid, is either removed by evaporation or neutralised with lime or magnesia, and the concentrated solution of chloride of antimony is slowly mixed with water in a wooden or stone vessel provided with stirring apparatus. The precipitated oxychloride of antimony is allowed to settle, the supernatant liquor decanted, and then sufficient milk of lime added to convert the oxychloride into oxide, the mixture meanwhile being kept at about boiling heat. The oxide of antimony is thoroughly washed from calcium chloride, dried, mixed with alkali and free carbon, and reduced to metal in any convenient way.—A. R. D.

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

*The Extraction and Treatment of Fats.* Dingl. Polyt. J. 253, 415, 1884.

FOR the extraction of oil from sesame seeds, maize and the like, Bang and Sanguinetti have recourse to mineral

oil, boiling between 40 and 70°, purified by repeated agitation, first with sulphuric acid of 66° B., then with two or three per cent. of fuming sulphuric acid. The naphtha thus purified leaves no odoriferous matter, either in the oil or in the seeds. The form of apparatus patented (Austro-Hungarian Patent of July 5, 1883) is shown in Fig. 1. The ground seeds are contained in the metal basket *c*, which is inserted in the boiler *R*, the cover *u*

Fig. 1.

being then placed on *c*, and the lid *c* tightly fitted on *R*. The purified naphtha is run in through *t*, displaced air escaping at *s*. After about fifteen minutes' digestion, the second boiler is connected at *r*, with an exhaust arrangement, and the naphtha from the first boiler drawn over, allowed to remain in contact with the contents of *R* (II.) for fifteen minutes, drawn over into a third apparatus, and thence so on through several more vessels *R*, until by the process of repeated diffusion a mixture of oil and naphtha is obtained, containing very little of the latter.

Fig. 2.

Fig. 3.

Successive quantities of fresh naphtha are passed through the apparatus, and when the contents of the first of the series of vessels *R* are found to be free from fat, connection is made at *r* with a condenser, and superheated naphtha vapour passed in at *s*, until by the temperature of the mass in *R*, it is evident that all the naphtha retained by the seeds has been vaporised. The stream of superheated vapour is now shut off, and the basket *c* taken from *R*, the contents being in a completely dry state. If it be desired to remove every trace of naphtha from the seeds, this can be effected by the application of dry steam.

According to O. Korschelt (Ger. Pat. 27,321, September 4, 1883), the saponification of fats by superheated steam

is effected advantageously only between the narrow limits of 310° and 315°, the glycerine being decomposed at higher, and the reaction being incomplete at lower, temperatures. If the fatty matter be finely subdivided, however, the limits of temperature may be somewhat wider. For the purpose of subjecting finely divided fatty matters to the action of superheated steam, and at an efficiently regulated temperature, the apparatus shown in Figs. 2 and 3 has been patented. The fat is heated in *A* to about 100°, and passes thence into the winding tube *a* lying in the bath *B*, filled with an alloy of 100 lead with 6 or 4 tin, kept as nearly as possible at its melting point 290°. The oil attains to a temperature of about 300°, this being observed by interposing between *B* and the tower *C* a vessel *h*, through which the oil flows, fitted with tubes open above, but closed below, containing lead melting at 334°, and the above lead-tin alloy melting at 289°. The pipe *a* enters the tower *C* near the bottom, and passes up to within a small distance from the top, where it is bent over and fitted with a circular spreader, of diameter slightly less than that of the tower. The oil rises to this height either by reason of the elevated position of *A*, or by the aid of a force pump interposed between *A* and *B*. The tower *C* is constructed of sheet iron, or of cast-iron plates, surrounded with masonry, and is filled with earthenware balls. Superheated steam is passed in at the bottom by *c*, its temperature being observed by aid of *g*, an arrangement similar to *h*, described above. The products of the decomposition of the glycerides are carried away by the current of steam through *d* at the top of the tower, and are condensed. The temperature within the tower may vary from 250° to 400°: it is not advisable, however, to allow it to sink below 280°. Any undecomposed fat is run off from the bottom of the tower by the pipe *i*.—W. D. B.

#### The Production of Grape-stone Oil. J. v. Jobst. Dingl. Polyt. J. 255, 450.

As a fatty oil is said to be extracted from grape stones in Italy, the author attempted, although unsuccessfully, to express the oil. By extracting with carbon bisulphide or petroleum ether, about 10 per cent. of a thick green oil was obtained, which is nearly decolorised by filtering through charcoal. It possesses an unpleasant smell and taste, and solidifies at 11°. On standing in the air it becomes rancid and thick. These properties exclude its use for culinary purposes, and also as a lubricating oil. It may be employed for lighting; but better for the manufacture of soap. The production of the oil in small

quantities is unprofitable, and is confined to certain districts, where it is chiefly employed for lighting purposes.—J. B. C.

*Preparation of Cured Soap.* F. Eichbaum. Dingl. Polyt. J. **255**, 539.

A good curd soap with silvery fracture may be prepared by boiling 700kg. tallow, with soda lye of 15°, to a clear jelly, introducing 450kg. of palm-nut, and 100kg. of cocoa-nut oil, with the requisite amount of caustic lye of 25°, and boiling the whole until a clear jelly, free from froth, is obtained. After about two hours any scum upon the surface is removed, and the soap salted out or precipitated respectively with salt solution of 20°, or caustic soda lye of 40°.—W. D. B.

## XII.—PAINTS, VARNISHES, AND RESINS.

*On the Manufacture of White Lead.* Dingl. Polyt. J. **252**, 372.

ACCORDING to an American Patent (292,119, January 15, 1884), M. Roth and G. Sylvester pass an electric current through a solution of sodium acetate, using leaden plates as the poles. Acetate of lead is formed at the positive pole, and caustic soda at the negative pole. By the mutual reaction of these compounds, lead hydrate is produced, which is afterwards converted into white lead by the action of carbonic acid gas. E. V. Gardner (D. R. P., Cl. 22, No. 25,239, August 19, 1882) heats lead with graphite, carbon, platinum, or some other substance electro-negative to lead, in a solution containing 1 part acetate of lead, or 1 part nitric acid, in 40 parts of water, or acetic acid in 24 parts of water. Basic lead salts, or lead oxide, or lead suboxide, will in this way be formed. After one or two hours, the lead is taken out, and the fluid rendered capable of being used again by the addition of acetic or nitric acid. If the operation be performed in chambers, the lead is so placed as to be in contact with the carbon or platinum. Ozonised air should be conducted into the chamber, or generated therein by electric discharges. The apparatus employed is shown in the figure.—E. G. C.

*Analysis of Vulcanised Caoutchouc, including the estimation of the Sulphur.* B. Unger. Zeits. Anal. Chem. **24**, 167-174.

THE method adopted for estimating the sulphur in caoutchouc by heating the sample with copper oxide and sodium carbonate, and then, after dissolving in aqua regia, precipitating the sulphate formed with barium chloride, is untrustworthy. Antimony sulphide and sulphur only give a sulphate, when soda is present as well. The presence of alkalis does not retard the reaction, but prevents the dissociation of the sulphuric acid at the high temperature necessary for the complete combustion. The antimony sulphide used in the English manufacture contains free sulphur (6.30 per cent.) and gypsum (9.62 per cent.). The sulphur of the gypsum present is not available for vulcanisation, so that the determination of the amount of sulphur in the caoutchouc should be accompanied with the percentage of calcium as well as that of the antimony present. The author recommends the following processes:—

1. *Sulphur.*—About 5grm. of the sample is cut into fragments and heated with 12grm. copper oxide and 2grm. soda, in which the amount of sulphate present has been previously determined. The copper oxide is prepared by heating well-washed copper carbonate. The caoutchouc is added to the crucible in small quantities at a time—the progress of the reaction and the amount of heat can be regulated by observing the smell emitted which should be pleasant and aromatic (not unlike kiesel). The product is dissolved in aqua regia and evaporated over a water bath to dryness to render the antimonious acid insoluble, and to obtain a solution which can be easily filtered. After treating with water, filtering and washing, the filtrate is diluted to 600cc. The sulphate is then precipitated with barium chloride in the usual way.

2. *Antimony.*—About 1.5grm. of the substance is cut up into fragments and heated with 10grm. of crystallised sodium sulphide. The product is triturated with water and filtered, and then the filtrate is heated with hydrochloric acid. The mixture of antimonious sulphide and sulphur is weighed on a tared filter paper, and the result checked by heating a known portion with excess of sulphur and reweighing.

3. *Calcium.*—About 2.5grm. are incinerated in a porcelain dish, and the temperature gradually raised to redness. The ash is heated with strong hydrochloric acid and allowed to stand for 24 hours. The solution is diluted with water to precipitate the antimony as oxide, and ammonia is added in excess to complete the precipitation. To the filtrate ammonium oxalate is added, and the calcium is then weighed as carbonate in the ordinary manner. The results are calculated out to give the percentage of—Sb<sub>2</sub>S<sub>3</sub>, CaSO<sub>4</sub>.2H<sub>2</sub>O, and free S in the caoutchouc. The amount of rubber present is given by difference.

Another mixture used in England to give a black vulcanised indiarubber contains—

66.55 Talc (with FeO; Al<sub>2</sub>O<sub>3</sub>; H<sub>2</sub>O).  
21.10 Litharge.  
4.30 Zinc Oxide.  
8.05 Sulphur.

100.00

With lead present as in this last case, when the sample is heated with copper oxide and soda, the sulphate formed is chiefly lead sulphate, which can be dissolved out from the residue with ammonium acetate. Part of the lead sulphate and the zinc are estimated in the copper solution, and a second sample is heated first in the air and then with soda to find the percentage of talc present.—S. R.

*Improvements in, and in Apparatus for, the Manufacture of Lead Salts for making White Lead.* W. V. Wilson, Middlesex. Eng. Pat. 6464, April 17, 1884.

THE apparatus described has for its object the formation of solutions of basic lead salts by causing finely divided metallic lead to be exposed alternately to the action of air and steam, and then of a solution of neutral acetate or nitrate of lead. It consists of a revolving drum provided internally with shelves, on which the lead is raised and allowed to fall on a perforated cylinder also provided with shelves, and revolving in the centre of the drum. Air and steam or hot air is sent through the drum at the central bearings, which are made hollow, and the drum is kept half-full of solution of acetate or nitrate of lead. The treatment of the basic lead solution takes place in another vessel.—G. H. B.

*Improved Means and Apparatus for Facilitating the Dissolution of Metallic Lead, or of Oxide of Lead in the Manufacture of White Lead.* A. W. Anderson, London. Eng. Pat. 5166, December 18, 1884.

A HOLLOW wooden drum rotating slowly on a hollow axis has a number of radial shelves projecting more or less towards the centre, and on the axis of the said drum are secured other radial shelves projecting towards the circumference. The hollow axis is perforated and provided with a partition so that a hot blast of air may be admitted to the drum on the one side of this partition, and escape through the perforations on the other side. Finely-divided lead is placed in the drum, which is then partially filled with suitable solvent liquid, and caused to rotate. By this means the lead, being alternately exposed to the action of the solvent liquid and the blast of hot air, is rapidly dissolved. When the liquor is sufficiently concentrated it may be drawn off for the precipitation of the lead with carbonic acid gas, or this precipitation may be effected in the drum itself.—A. R. D.

## XIV.—AGRICULTURE, MANURES, Etc.

*Improved Process and Apparatus for the Utilisation of Human Excreta, Drainage from Stables, and the like.* W. P. Thompson. From J. R. Bryden, Georgetown, British Guiana. Eng. Pat. 6441, April 17, 1884.

This invention is based on the fact that if sewage matter be received in reservoirs, in which it can be kept out of contact with outside air and in contact with soil, a natural chemical process ensues resulting in the transformation of the excrements into a liquid manure containing nearly all the valuable nitrogenous matter of the sewage. By natural filtration through the soil, animal and vegetable remains become disintegrated, the decomposing matter being finally converted into nitrates. A series of underground closed reservoirs with earth bottoms receive the sewage which is afterwards utilised for manurial purposes.—E. G. C.

*Improvements in the Manufacture of Phosphates.* F. W. Harbord, Wolverhampton. Eng. Pat. 7562, May 10, 1884.

THE object of this invention is to obtain phosphates practically free from iron from the slags resulting from the Thomas-Gilchrist process, or from other phosphatic materials containing iron. The phosphate is finely ground and freed as far as possible from metallic iron. It is then treated with very dilute acid, care being taken to dissolve as much phosphoric acid as possible. The solution is separated from the residue and steam, and air blown through it, in order to peroxidise the iron. A solution of a ferrocyanide is then added in just sufficient quantity to precipitate all iron in form of Prussian blue, which is separated and treated to recover the ferrocyanide. The phosphatic solution may be worked up for free phosphoric acid or precipitated with chalk or lime, if precipitated phosphate be required.—S. H.

*Improvements in Treating Phosphates of Calcium or Lime.* P. M. Justice. Eng. Pat. 7963, May 20, 1884.

THIS invention relates to the treatment of phosphates of lime which may be in a dry or humid state, and consists in first calcining and decarbonating them, and subsequently subjecting them to the action of cold or hot water or steam, and as soon as they are cold subjecting them to a high temperature. By this means the material is more thoroughly decarbonated, and a more perfect division or disintegration obtained, the material being left in a condition to permit of the easy elimination of the lime by any of the ordinary means.—S. H.

## XV.—SUGAR, GUMS, STARCHES, Etc.

*Extraction of Sugar from Molasses.* Dingl. Polytech. J. 253, 421.

IN the extraction of sugar from molasses by his stromtia process, Scheibler now avoids the formation of bistrontium saccharate by adding to the mother liquors and washings separated by filtration from the monostromtia saccharate prepared as originally described, further amounts of molasses and strontium hydrate in the proportion requisite for the production of monostromtia saccharate. The mother and wash liquors are thus worked up repeatedly until they contain so much non-saccharine matter as to prevent further advantageous treatment. After 6 or 8 successive operations, the sugar remaining in the liquors need not amount to more than 4 or 3 per cent. of that originally present in the molasses treated. The ammonium chloride osmose process as carried on at the sugar refinery at Haussay is described by Dureau in *Journal des Fab. de Sucre*, 1883, No. 46. The syrup separated from product 1 is mixed with 1 per cent. of ammonium chloride, heated to 100° and subjected to osmose with 10-12 parts of water at 75°. After this treatment the syrup has a density of 11° B. (hot), the proportion of sugar to mineral matter being 12 or 14 to 1, whilst the original proportion was 5 or 6 to 1. The osmosed

symp is added to fresh juice. In the *Zeit. deut. Ver. Rübenzucker-Ind.* 1884, p. 85, details are given of the working of Stutzer's precipitation process, depending upon the precipitation of calcium saccharate from an alcoholic solution of the molasses. It has been shown by experiment, that the precipitation of the calcium saccharate takes place most readily if the lime has previously been slaked in spirit, whilst the precipitation is effected both slowly and incompletely if the lime be introduced as powder. From this it appears that the lime when hydrated combines more readily with sugar than when in the form of oxide, especially in a saccharine solution containing alkali. The hydroxides of barium and strontium behave similarly.—W. D. B.

*Sugar-Beet Culture.* Dingl. Polytech. J. 255, 354.

FOR the valuation of sugar-beet seed, Semptowski (*Deutsche Zucker-Industrie*, 1884, pp. 272 and 1280) allows 5 grammes to germinate at 20° in a wooden box filled with sifted garden soil. From 1 gramme of very good seed 81 to 112 sprouts may be expected, of good from 55 to 80 sprouts; a sample of seed giving less than 40 sprouts per gramme is to be regarded as bad. The best results in cultivation trials, made in Saxony in the year 1883 by Maereker (*Neue Zeit. für Rübenzucker*, 1884, 12, pp. 142 and 257), were obtained with Dippe's improved "Little Wanzlebener Beet." The best nitrogenous manure for the potato and sugar-beet is, according to Wagner, not ammonium sulphate but Chili saltpetre. That the former has under certain conditions—such as moist, warm weather, or on soils rich in lime and humus and especially rapid nitrification—given as good results as the latter is not denied. On the other hand there is no undoubted case on record where manuring with Chili saltpetre was followed by a worse crop than that with ammonium sulphate. P. Delherain (*Compt. Rend.* 1884, 99, p. 920) found that the "Vilmorin" variety, unmanured, yielded a juice of which 100 parts contained 19 parts of sugar, and that, with favourable weather, a plot manured yielded beets equally rich in sugar. The advantage gained by the application of manure was the increase in total crop: 1 hectare, unmanured, gave 29,700 kilos.; manured with stable dung, 35,000 kilos.; with stable dung and Chili saltpetre, 43,000 kilos. of beet. From experiments conducted at the experimental station at Gembloux as to the best method of applying artificial manures, it appears that upon sandy-clay soils a surface dressing after harrowing is not sufficient, since the absorptive powers of such soils are so great as to prevent, even in wet years, the plant food from finding its way to the tap-root. The manures are most advantageously dug in for some depth in the spring-time. The results of Corenwinder's experiments as to whether the sugar beet derives the carbon of its sugar contents mainly from the atmosphere, are instructive. The plants were cultivated partly in pure sand containing the necessary salts, partly in a manured soil, partly in the open. The following results were obtained:

	Total Weight of		Composition of Root.		
	Leaves.	Root.	Water.	Sugar.	Ash.
Sand .....	270g.	490g.	80.8	12.26	0.98
Manured Soil 2560g.	1145g.		83.8	10.60	1.16
Open Field ...	.....	.....	83.2	9.00	0.91

The beet grown in pure sand thus produced 61 grammes of sugar, for the formation of which 31cc. of carbonic acid must have been assimilated on an average per diem.

—W. D. B.

*Analysis of Honey.* E. Sieben. Dingl. Polytech. J. 255, 441.

THE amount of cane-sugar in the samples was determined by Meissl's method by difference before and after inverting with dilute hydrochloric acid. The method of Sachsse for estimating dextrin compounds present by boiling with hydrochloric acid, and thus converting them into grape-sugar is unreliable. A method for estimating the grape-sugar in honey is to boil with an excess of six-fold normal hydrochloric acid, which destroys the

levulose. After neutralising with caustic soda the grape-sugar is determined according to Allihn. The difference in the amount of grape-sugar given by this method and that of Saccharose-Fehling varied between  $-2.44$  and  $+2.29$ . The analyses show that in the majority of cases grape-sugar and levulose are present in nearly equal quantities. In most samples cane sugar is absent, the highest percentage found being about eight. The amount of water varied between 16 and 25 per cent., and the amount of non-sugars, including wax, between 1 and 9 per cent. The author gives a useful review of the methods for detecting starch-sugar syrup used in the adulteration of honey. The sulphuric acid reaction is condemned, as pure honey also contains larger or smaller quantities of this acid. Precipitation with alcohol cannot be employed as not only is the dextrin of the starch-sugar thrown down, but also albumen and other substances present in the unadulterated article. The method proposed, which will detect the smallest trace of this adulteration, is based upon the following facts. Solutions of honey, in which the cane-sugar present has been inverted, when heated with a slight excess of Fehling's solution contains no longer any substance which on further heating with hydrochloric acid forms sugar. Starch-sugar syrup, on the other hand, by a similar treatment yields for every 100grm. syrup nearly 40grm. grape-sugar. 14grm. honey are dissolved in 450cc. water and heated with 20cc. of half normal hydrochloric acid for half an hour on the water bath, by which the cane sugar is inverted. It is neutralised, made up to 500cc. so that a 2 per cent. invert sugar solution is obtained. 100cc. Fehling's solution is titrated with this solution. It is filtered through asbestos, washed with hot water, neutralised with concentrated HCl, and 1 volume of concentrated HCl added, and then heated for one hour on the water bath. The solution is nearly neutralised with concentrated NaOH solution and made up to 200cc., 150cc. of the filtered solution is heated with 120cc. Fehling's solution and 20cc. water, and the grape-sugar estimated according to Allihn from the weighed copper.

—J. B. C.

*Apparatus for the Manufacture of Starch.* Dingl. Polyt. J. 256, 35.

FOR the manufacture of rice-starch H. Mack, Ulm (Ger. Pat. 30,256, 1884), proposes treating rice with

assumes the appearance of a boiling liquid. For this purpose air enters through many small tubes  $t$  (Fig. 1) into a tank B provided with a false bottom  $p$ , on which finely ground rice is spread, whereas the tank is filled with a very dilute solution of caustic soda. After finishing the operation the caustic liquid is run off at  $h$ , and the rice-starch formed allowed to drain on the perforated bottom. The inventor states that by the aid of large volumes of air the rice softens quicker, and yields from 6 to 8 per cent. more of the finished product, thus saving time, plant, and chemicals.

L. Fehrmann, Paderm (Ger. Pat. 29,600, 1884), uses for drying starch a drum revolving round a shaft  $a$  (Figs. 2 and 3). Discs  $d$  are screwed to the journals  $c$ , and serve as a support for the ends of a great number of iron rods. From the centre of each disc also issue the distributing rods  $b$ , which meet in the middle, where they are fastened to a wheel  $e$ . Starch enters the apparatus at  $g$ , and being seized by the outside row of rods it is carried to the highest point of the drum, falls to the bottom only to make the same way over again. The drum inclines towards the outlet, and the revolution thus causes the mass to proceed gradually to the outlet  $z$ . When it arrives here it is dry, and in a finely divided state. The warm air necessary for drying travels in a channel along the whole length of the drum, and escapes at the top, deprived of its heat, into an air-filter, which retains the powder mechanically carried away.—S. H.

*The So-called Plus-Sugar.* E. von Lippmann. Zeits. dent. Zucker Ind. 1885.

THE author has found needle-shaped crystals of a sugar, so-called plus-sugar, in molasses, which appear to be identical with the substance examined by Tollens (Ber. 18 (1), 26). Being readily soluble in dilute alcohol and water the crystals were separated from the molasses by means of absolute alcohol. Analysis gave numbers corresponding to the formula  $C_{12}H_{22}O_{11} + 3H_2O$ , which agrees with Tollens's formula. A 10 per cent. solution shows a specific rotation  $[\alpha]_D = 105$  at  $19^\circ$ . The sugar is insoluble in absolute alcohol and ether, is not precipitated by lead acetate except in an ammoniacal solution, and is not acted on by solutions of alkalis or alkaline earths.

Fig. 1.

Fig. 2.

Fig. 3.

caustic soda, and blowing air under pressure at the same time through the liquid in such quantities that the latter

It does not reduce Fehling's solution, but after treatment with acid becomes strongly reducing. The presence

of this sugar is the cause of the occurrence of needle-shaped crystals in raw sugar extracted from molasses, and of the high rotation of such sugars.—D. B.

*Improvements in the Extraction of Sugar from Molasses and other Saccharine Products, and in the Quality of Alkaline Salts resulting therefrom.* Victor Daix and Antoine Louis Pozsoz, Paris. Eng. Pat. 7255, May 5, 1884.

This process consists in osmosing molasses or other saccharine products, and then precipitating the sugar from the exosmose waters, molasses, and other residues, as surcrates of lime, strontia, or baryta. The mother waters which have been exhausted of sugar are concentrated, and nitrate of soda is then added in sufficient proportion to transform the chlorides and other potassic salts into nitrate of potash, which can be more easily obtained from the liquors than the original potash salts.—A. W.

*A New or Improved Process for obtaining Sugar from Saccharine Substances.* C. D. Abel. From Dr. Ludwig Harperath, Cologne. Eng. Pat. 7982, May 20, 1884.

This process consists in treating molasses, diffusion juices, or other saccharine solutions with burnt natural dolomite or a calcined mixture of magnesia and lime, so as to produce a magnesium lime saccharate, which is more permanent than the lime saccharate, and is not so subject to retrogressive action. As little or no development of heat takes place on the admixture of the dolomite with the saccharine solution, no special cooling appliances are required. The magnesium lime saccharate, in contradistinction to the poly-basic lime saccharates, always forms without cooling, and even at temperatures above 50° C., but not between 30° and 50° C. Cooling is only required when the atmospheric temperature reaches or exceeds 30° C., as the reaction will not commence above that temperature. The purification and decomposition of the saccharate is effected by known methods.—A. W.

*Improved Apparatus for Osmose Treatment of Saccharine Liquors.* J. Imray, London. From H. Leplay, Paris. Eng. Pat. 8502, May 31, 1884.

This apparatus is a modification of the well-known "osmogene" of Dubrunfaut. In conducting the process of osmosis in Dubrunfaut's apparatus, the molasses or other liquor under treatment becomes gradually more dilute as the process goes on, and this increased dilution is accompanied by a corresponding decrease in useful effect—in other words, as the liquor becomes more dilute, the proportion of salts eliminated from the molasses becomes smaller, and the loss of sugar into the osmose water greater. In order to avoid this difficulty the author adopts a novel arrangement which he designates "evaporative osmogene with strong osmose." The upper parts of each of the 100 constituent frames of the osmogene are so arranged as to form a reservoir of liquid above all the frames, and this reservoir communicates directly with the molasses cells of the osmogene, and is supplied with a coil of closed steam pipes. By this means evaporation is maintained in the liquor undergoing osmosis, and the dilution which would otherwise ensue is counterbalanced. Full description with diagrams is given.—A. J. K.

*Improvements in Osmose Apparatus.* C. D. Abel, London. From H. Leplay, Paris. Eng. Pat. 9243, June 20, 1884.

This invention relates to an improved construction of apparatus for the osmose treatment of saccharine and other liquors, which is termed "steam osmogene with triple action," and which produces simultaneously the three following results: (1.) The separation of the salts contained in the liquors treated. (2.) The evaporation of the liquids of exosmose. (3.) The evaporation of the osmose liquids. The simplest form of this apparatus is as follows:—A metal tank is divided by a horizontal

perforated metal partition, on which is placed the parchment paper, into an upper and lower compartment; the latter serves to evaporate the liquid of exosmose, and to furnish the steam required for the osmose action. The upper compartment receives the liquid to be subjected to the osmose treatment. The lower compartment is supplied with a steam coil, supply and discharge pipes, cocks, etc. The action of the apparatus is as follows:—The lower compartment is in the first instance charged with water to sufficient depth to cover the steam coil, whilst into the upper compartment is introduced a layer of molasses or other liquor to be osmosed. The apparatus can be worked either continuously or intermittently; in the latter case the water in the lower compartment is heated to boiling point by the steam coil; the steam produced is condensed against the underside of the parchment paper diaphragm, and is partly absorbed by the current of endosmosis passing to the molasses through the diaphragm, while the other portion mixes with the salts of the exosmose current, and falls back into the lower compartment. The molasses become heated, and increase in volume and decrease in density in consequence of the absorption of the water by the current, and rapidly reach 30° B. Arrived at this point, a kind of equilibrium ensues. About the same quantity of water which the molasses receive is separated by evaporation from the surface. As the operation proceeds, a large quantity of the salts passes from the molasses into the exosmose water in the lower chamber; when the required purity is obtained, the osmosed molasses is run off, and a fresh charge put in, whilst the same water in the lower compartment can be used over again until it is thoroughly charged with salts. When operating continuously, a small continuous stream of molasses is admitted into one end of the upper compartment, and escapes at the other end. As the condensation of the steam in the lower compartment will not be effected if the temperature of the osmosed molasses rises too high, such temperature may be reduced by means of air currents on the surface, or by a zigzag coil of cold water-pipes through the molasses. The osmose apparatus above-described requires to be placed horizontally, necessitating a large amount of surface in the factories, which is often inconvenient. In addition to this, there is often considerable loss of heat, and waste of fuel by the evaporation taking place from the surface of the molasses. To obviate these disadvantages, a second osmose compartment may be placed above the first, and a third again above that, so that the liquor in each cell acts as exosmose to the one above it, and the steam from the lower is in each case condensed on the surface of the diaphragm above it. Another arrangement for still further economising space is as follows:—The exosmose compartment at the bottom is formed, as before, of a horizontal tank heated by steam coil or otherwise. Above this, however, instead of the horizontal perforated plate and diaphragm, there is arranged a series of vertical wedge-shaped pockets (apex down), whose sides are made of wire gauze, lined with parchment paper. At the top, these pockets unite to form one large shallow vessel, which, as before, contains the molasses or other liquor to be osmosed. By this means much larger surface is obtained, but otherwise the process is conducted as described in connection with the more simply-constructed apparatus.—A. J. K.

*Improvements in Means and Apparatus for Bleaching Sugar.* C. H. Day, High Holborn. From C. O. Foster, Brookline, U.S.A. Eng. Pat. 1972, February 12, 1885.

The invention consists of a special apparatus for the treatment of crystalline or granular sugar by sulphurous acid gas. The sugar is made to pass slowly through a rotating drum, provided with shelves inside for regulating the motion of the sugar. The sulphurous acid gas is generated by burning sulphur in a small furnace, and after being cooled by suitable means, is forced into the cylinder with the sugar by means of a jet of dry steam or of air. At the other end of the cylinder the sugar is delivered into a hopper, and the gas escapes up a flue.

—A. J. K.

*Improvements relating to the Preparation of Food for Animals from the Refuse of Breweries, or of Starch and Glucose Factories, and Apparatus therefor.* W. R. Lake, London. From F. W. Weisbrock, New York, U.S.A. Eng. Pat. 2208, February 17, 1885.

BREWERS' grain, as well as the refuse from starch and glucose factories, are well known to be wholesome food for cattle, provided they can be used in a fresh state. These bodies contain carbohydrates and albuminates, and on keeping for any length of time, are liable to undergo fermentation, with formation of lactic and other acids. The author states that the various processes which have been devised for drying brewers' grain and similar materials have failed to produce a sweet and wholesome food, owing to the fact that the air used for drying has not been freed from active fermentation germs. As a result the article contains a large proportion of dry lactic acid, which is no more desirable than the same material in the moist state. It is claimed that by the invention herein described this objection is overcome. The brewers' grain or refuse is first mixed with salt or salt water in proportion of 5lb. salt to 1 ton of the grains, with the object of keeping the latter sweet during transit from the place of its production to the drying apparatus. The wet grains thus salted are next subjected to the action of dry air, from which all active germs have been previously removed by exposure to a temperature of over 400° F. By this means, when thoroughly dried, a sweet and wholesome food is obtained. Special apparatus, suitable for carrying on the necessary operations, is fully described.—A. J. K.

*Improvements in Apparatus or Devices for the Treatment of Sugar Cane.* H. J. Chapin, New York, U.S.A. Eng. Pat. 2553, February 25, 1885.

THE inventions described under this specification "consist of a cane shredder of improved construction and mode of arrangement, of improved devices for conveying the shredded cane and juice from the shredder to the juice extractor, and of the more convenient arrangement—relatively to each other—of the mechanical elements or members of the combination therein described." Full description, with copious reference to diagrams, is given of the construction and arrangement of machinery above mentioned.—A. J. K.

## XVI.—BREWING, WINES, SPIRITS, Etc.

*Apparatus for Spirit Distilleries.* Dingl. Polyt. J. 255, 345.

A DISINTEGRATOR, patented by Gaul and Hofmann (Ger. Pat. 27,351, September 19, 1883), to be connected

with the delivery pipe of a Henze steaming apparatus, is shown in Figs. 1, 2, 3. The disintegrator is clamped

by *h* to the delivery pipe. The steamed grain as it leaves the disintegrator falls upon the wheel *g*, which gives a rotary motion to the graters fixed upon the spindle *d*.

The disintegrator patented by Hall (Ger. Pat. 27,807, November 22, 1883), illustrated by Figs. 4 and 5, is intended to be attached at *A* to the delivery pipe of the

steaming apparatus. Supported by *d*, there is a double grating, of which the under half *D* is stationary, but the upper half *E* movable in a direction at right angles to the bars by the screw at the end of *FG*. The slits of the grating can thus be closed entirely, or their width adjusted at will. The side *H* can be easily removed for

the purpose of cleaning the gratings. Upon opening the valve *C*, the contents of the steamer enter *B*, and by the steam pressure are forced through the slits of the gratings in a very finely divided condition, stones and large or hard particles being caught by *E*.

Wösl's disintegrator (Ger. Pat. 28,278, December 21, 1883) is shown in Figs. 6 and 7. It is attached at *a* to the delivery tube of Henze's steamer. Stones and similar substances are caught by the rake *c*. Accumulated stones are removed at the manhole *e*. The ribbed cone

*u*, forming the grinding apparatus, is rotated by the wheel *h*, which the rapid flow of material from the steamer sets in revolution. The tap *o* serves for the introduction of water.

The washing and cooling apparatus patented by Hampel (Ger. Pat. Addition 28,891, February 5, 1882)

is shown in Figs. 8, 9, 10. The cooling water enters at K, and takes the course indicated by the arrows. The steamed grain or other material is forced by steam pressure through the tube *u* into the vessel *a*.

—W. D. B.

**Liquorice Root in Beer-Brewing.** R. Kayser. Dingl. Polyt. J. 255, 538.

It has been found by experiment that 1 part of liquorice root imparts to water the same degree of sweetness as 8.5 parts of sugar-candy. Thus in sweetening efficiency one part of glycyrrhizin is approximately equal to 140 parts of sugar-candy. Since glycyrrhizin is not affected by fermentation like sugar, the addition of 1 kilo. of liquorice root to 500 litres of wort will give a sweeter beer than if 5.5 kilos. of sugar had been used.

—W. D. B.

**Analysis of Pure Wine.** W. Klinkenberg. Zeits. Anal. Chem. 23, 514.

SAMPLES of wine from Saar were analysed by the following method:—100cc. were distilled with milk of lime to fix any CO<sub>2</sub> present, and the alcohol estimated from the specific gravity of the distillate. The amount of extract was estimated by evaporating 50cc. to a syrup on the water bath, and drying in a steam oven. The acid present, after freeing from CO<sub>2</sub> by boiling, was determined by titration with baryta solution. For the mineral constituents 100cc. were taken in each case. CaO and MgO were determined directly in the wine, the sulphuric acid after decomposing organic matter with KClO<sub>3</sub> and HCl, chlorine, phosphoric acid, and the alkalis in the ash. Wild's instrument was employed for polarisation.—J. B. C.

**Estimation of Wine Extract.** C. Weigelt Rufach. Zeits. Anal. Chem. 24, 26-30.

WINE extract is defined as the sum of the non-volatile substances. The author discusses the relation existing between the sp. gr. of the solution and the weight of the extract, and a tabular statement is appended showing

that the indirect method for estimating the amount of extract is comparable with the direct method in wines of very various qualities and specific gravities. The percentage of extract can also be calculated by finding the sp. gr. from Balling's saccharimetric tables, and the numbers so obtained agree satisfactorily with those obtained by the other two methods.—S. R.

**New Apparatus for the Treatment of Hops.** Dingl. Polyt. J. 255, 165.

A BOILER, devised by A. Steinecker, is shown in Figs. 1 and 2. It is furnished with a double bottom; while the bottom, sides and lid of the hop-basket are made of perforated tin or wire-netting, as in the boilers A and B, or if it is, instead, only an enclosed sieve, as in the boiler C. In the centre of the boiler is a tube *l*, provided with a head-piece, which scatters the boiling water around, and by means of which the hops are kept continually soaked during the boiling. The vessel being filled with fresh hops, the cock *c* is opened to admit steam from the pipe *D*, while the cock *f* is also open to allow of the exit of the steam and volatile oil of hop, which pass by the pipe *g* beneath the surface of the wort. After the steaming, hot water is injected through the cock *o* and the rose *u*. This water, together with dissolved volatile oil and condensation water from the steam, passes into the wort by the cock *c* and tube *g*, the cocks *c* and *o* now being shut. If the steam and scalded hops are to be heated in the next boil, the steam-cock *a* is opened, water having been already admitted the day before and left to stand. This water is soon raised to the boiling point. While the lid *m* is still closed, the cock *f* remains open, so that the steam produced can reach the wort through the tube *g*. The steam-cock *a* is closed

after each boil, *f* remains open, *c* is opened and the aqueous extract is drained off into the wort-pan. The boiling with water having been repeated from two to four times, the lid is removed, and the hops are transferred to the wort. According to A. Kempe, of Moscow, 55kilos. of hops are sufficient for one boil, in place of

through the pipe *F*, the fluid penetrating also into the spaces *B* and *C*, through the sieves *JJ*. When all the valves are closed, steam is allowed to enter by the cock *K* in the casing *A<sub>1</sub>*. The hops and fluid in *A* are hereby brought to the boiling temperature, or even higher, the amount of pressure being indicated by the manometer

the 70kilos. generally used by brewers. At the beginning of a boil, 33kilos. of hops are thrown into the wort: this is boiled for three to three and a half hours, and then transferred to the cooler in the usual manner. Twenty-two kilos. of hops are placed in the inner iron or tinned copper boiler *A* (Fig. 3), provided with a stirrer *D*, and either wort or water is now added

*M*. In order to quicken the exhaustion of the hops, the valve *a* is opened, so that the fluid passes through the depositing vessel *V* and the tube *r* into a cooler placed above the boiler, flows through the spirals present therein, then through the gauge-glass *S*, and the valve *O*, into the chamber *B*, and finally, through the sieve *J*, back into the chamber *A*. Should sufficient

cold water for the cooling not be at hand, so that this circulation cannot be effected, the pump *W* is employed. Hünnerkopf & Son and F. Rutschmann, of Nuremberg, do not at once add the entire hops to the hot wort, but

dry them at a temperature of not more than  $35^{\circ}$  in the drying apparatus shown in Fig. 5, until they become greatly disintegrated and fall asunder into powder under the action of a rake. The drying chamber is con-

structed so that the temperature can be regulated with the greatest nicety. In order to effect the removal of moisture from the hops as quickly as possible, passages

Fig. 6.

(ii) are constructed beneath the chamber for the admission of cold air. The chamber is further provided with two thermometers *ff* (Fig. 7), and with sliding doors *e* and *e'*, which latter serve to screen off the fire *b* when necessary. The box *g* is made of fine perforated

tin, and is filled with hops from the trap-door *h*. When the drying is completed, the slide *m* is pulled up, and the hops are allowed to fall from *g* on to the cylindrical

rake *n*, and to pass from thence, in a finely divided condition, into sacks ready to receive them.—E. G. C.

*Contributions to our Knowledge of Caramel.* C. Anthor. *Zeits. Anal. Chem.* 24, 30-33.

PARALDEHYDE destroys the colour of an alcoholic solution of caramel, and forms at the same time a brown precipitate. This reaction is made use of by the author for determining the amount of caramel added to wines and spirits. A standard solution of caramel is prepared by caramelising 10 grm. of pure cane sugar and dissolving the product in water. Any undecomposed sugar is then destroyed by fermentation, and the solution is diluted to 100cc. A solution of paraldehyde in absolute alcohol completely destroyed the colour of this solution after twenty-four hours. With pure white wine, natural wine, and extract of raisins, paraldehyde gives a white precipitate; the caramel precipitate can be further identified by its reaction with phenyl-hydrazine. A solution containing two parts of phenyl-hydrazine hydrochlorate with three of sodium acetate dissolved in twenty of water, gives with solutions of caramel a brown precipitate soluble in warm ammonia, or weak caustic soda to a red liquid, and is reprecipitated from this alkaline solution by the addition of hydrochloric acid. The precipitate is soluble in concentrated hydrochloric acid or nitric acid, but is reprecipitated on diluting with water. Alcohol similarly dissolves it, and water reprecipitates it after some time. The method adopted in testing for caramel in white wines or spirits is as follows:—10cc. of the liquid (if a wine 10-15cc. of alcohol are first added) are placed in a tall glass cylinder, and 30-50cc. of paraldehyde solution added, together with sufficient absolute alcohol to make the two liquids mix. After twenty-four hours the precipitate is collected, washed with alcohol, and dissolved in warm water. The clear filtered solution is then evaporated to lcc.—the intensity of the colour is a measure of the amount of added caramel. With very small quantities it is best to evaporate the solution over sulphuric acid in the receiver of an air-pump. The solution must not be warmed, or a caramel-like precipitate is obtained even with the purest wines. The concentrated solution of the paraldehyde precipitate can then be treated with phenyl-hydrazine solution, when the caramel phenyl-hydrazine precipitate is thrown down. If the solution is weak it first only becomes cloudy, but the precipitation is complete after standing for a day. Any resinous bodies present can be dissolved out by ether, which has no action on the precipitate. Phenyl-hydrazine, unlike

paraldehyde, gives no precipitate with natural wines. Wines containing a large percentage of sugar should be diluted before trying the above reactions.—S. R.

*The Sugar and Acids in Must.* E. Schmidt. Zeits. Anal. Chem. **24**, 33.

THE following table shows the percentage of sugar and acid in the must from Montreux and Villeneuve during the last five years:—

Montreux.	Sugar %	Acid %	Villeneuve.	Sugar	Acid %
1880	15.2	0.9	.....	.....	.....
1881	17.8	1.1025	.....	.....	.....
"	17.5	1.0867	1881	18.525	1.1025
1882	16.6	1.085	1882	16.726	0.9075
1883	16.9	1.085	1883	17.64	1.1025
1884	15.7	0.915	1884	15.23	1.005
"	16.8	0.924	"	15	1.0935

Last year's must from Villeneuve is exceptionally low in sugar, since owing to a hailstorm a great part of the grapes had to be plucked before they were quite ripe. —S. R.

*Improvements connected with Preserving, Storing, and Aerating Lager and other like Beers.* W. Aubert, jun., Balham. Eng. Pat. 5747, March 31, 1884.

THE beer is stored in iron drums having a pipe reaching to the bottom, through which carbonic acid under pressure is forced in, so as to charge the contents. The pipe also serves as an outlet when the contents of the drums are discharged. A modification of the apparatus is also described and shown, in which a spherical vessel is placed in the interior of the drum, charged with carbonic acid gas or air under pressure; a two-way cock is so arranged that the gas is used for forcing the liquor from the drum when the outlet cock is opened. The claims are two, for the apparatus as described.—C. C. H.

*Making Fudler from Distillers' Wash.* Jasper Wetter, London. Eng. Pat. 6768, April 24, 1884.

THE wash is submitted to the action of a spray of glue or gelatine solution, which carries down most of the nutritious matter. The precipitate is allowed to settle, the supernatant liquid run off, carbonate of lime is added to the residue nearly to neutralisation, which is completed by sodium bicarbonate, and the neutralised mass is raised by an elevator and caused to flow down over the surface of heated rollers, and then over an endless drying band until sufficiently dry to be ground by crushing rollers. The roller drying apparatus, and the means of heating it, are claimed as well as the process.—J. M. H. M.

*Utilisation of Hops in the Manufacture of Intoxicating Beverages otherwise than Beer.* Max Hedicke, London. Eng. Pat. 7478, May 9, 1884.

THE object of this patent is the preparation of a hop-liquor. The extract may be made by maceration, digestion, distillation, or a combination of any such processes without materially affecting the result. The patentee prefers to proceed as follows:—7lb. of hops are macerated in 60 quarts of spirit 7° over proof, and after twelve hours the extract is removed; the partially spent hops are then distilled with 40 quarts of spirit, and the distillate mixed with the extract first obtained. Brandy or whisky, etc., and sugar and water, are then added according to taste. The process of manufacture as described is claimed.—C. C. H.

*A Novel Non-alcoholic Drink.* T. F. Wilkins, Chiswick. Eng. Pat. 83, January 2, 1885.

THIS specification describes the preparation of three different liquors for consumption as beverages composed of infusions or decoctions of kola nut roasted, maté, coca leaves, and hops. Different proportions of the various ingredients are used according to the circumstances of the intended consumption. The claims are: (1) For a beverage composed of the decoctions described, with the addition of a small quantity of salicylic acid; (2) a similar beverage, but with the omission of the decoction of hops.—C. C. H.

## XVII.—PRESERVING FOOD, MEATS, Etc.

*Arresting or Preventing Fermentation.* F. S. Barff, Middlesex. Eng. Pat. 5096, March 18, 1884.

FRUIT or vegetables are heated with or without water to a temperature somewhat under the boiling point, and from 2 to 4 per cent. of boroglyceride is added. Two per cent. of boroglyceride added to weak wines prevents the second fermentation, and enables them to bear transportation as well as the stronger wines.—J. M. H. M.

## XVIII.—SANITARY CHEMISTRY, DISINFECTANTS.

*Apparatus for Use in the Process of Softening and Purifying Water.* W. Wyatt. Eng. Pat. 6213, April 10, 1884.

THE apparatus is to be employed for the purpose of mixing lime-water or other liquid or liquids for use in the said process, or for mixing such liquids with lime or other solid matters. A hollow standard, capable of revolution on its axis, and provided near its bottom with a hollow perforated arm standing out at right angles, is placed in a tank, preferably near the floor, so that the apparatus may be immersed in the materials to be acted upon. At the top of the standard is an arrangement by means of which a stream of water can be injected under pressure, together with a quantity of air drawn in through apertures. The air and water pass down the hollow standard and along the arm until they reach the perforations, through which they escape, causing a more or less violent agitation of the liquid by which the arm may be surrounded. The apparatus may be placed in the centre of a tank, or two or more of them may be placed in one tank, motion being given to them by suitable contrivances. In place of a stream of water under pressure, air may be forced from a pipe through the hollow standard.

—E. G. C.

*Improvements in Apparatus for Use in the Treatment of Sewage and in other Operations in which Solid Matter is required to be Added to or Mixed with Fluid Matter in Certain Relative Proportions.* S. K. Page, C. E. Robinson, and W. Stevens. Eng. Pat. 7198, May 3, 1884.

ACCORDING to this invention, the flow of the sewage or other fluid, to which the solid matter is to be added, or with which it is mixed, is caused to actuate apparatus by which the latter is supplied or by which its supply is controlled. The mixture of the solid and liquid matters is thus effected automatically. A vessel of the required form and size is mounted on pivots or trunnions, in such a position relatively to the mouth of a pipe from which the fluid issues, that the fluid so issuing will pass into the vessel. The latter is counterbalanced in such a manner that, when it has received a certain quantity of fluid, it turns on its pivots or trunnions and discharges the fluid received; it then returns to its original position and is ready to receive another charge of the fluid. Above the vessel is mounted a hopper containing the solid matter to be mixed with the fluid, and provided in its lower part with slides or valves, one above the other, and at such a distance apart that the space enclosed between them will hold the quantity of solid matter required for each charge of the sewage or other fluid. These slides or valves have openings in them to permit of the passage of the matter from the hopper when the openings are brought within the mouth of the latter, and they are so connected with the vessel already described that, when it turns on its pivots to discharge its contents, they slide in one direction, the lower valve closing the mouth of the hopper and the opening in the upper valve being brought within the hopper. On the vessel returning to its original position, the upper valve is closed and the opening in the lower one is brought within the mouth of the hopper. The matter previously enclosed between the two valves thus falls into the mounted vessel. The capacity of the lower part of the hopper between the two slides or valves can be increased or diminished as may be required.—E. G. C.

*Preventing the Emission of Metallic Vapours, Compounds of Metals, Sulphur Dioxide, or other Vapours from the Chimneys and Fluxes of Chemical, Metallurgical, or other Works.* E. H. Cook. Eng. Pat. 7731, May 13, 1884.

THIS invention consists in the use of sulphuretted hydrogen, alkaline sulphides, and mixtures of these for preventing the vapours given off from furnaces leaving the stacks, and thus getting into the atmosphere. The sulphur compounds are produced from alkali waste, and the modes of treating the waste are as follows: 1st, The substance is moistened with water, and air or steam blown through the mass. The gases escaping at the outlet are thus charged with sulphur compounds, and being brought into contact with the gases or vapours given off from furnaces, chemical changes occur, resulting in the deposition of the metals present as sulphides, and also in the decomposition of the sulphur dioxide, sulphur being deposited. 2nd, The waste having been mixed with water, cloths are steeped in it, and these are suspended in the flues, etc., when similar changes will occur as before. 3rd, The waste is mixed with water, and the gases and vapours from furnaces are made to come into contact with the mass.—S. H.

*An Improved Preparation of Carbon, Adapted Especially for Electrical and Filtering Purposes.* S. J. Coxeter and H. Nehmer. Eng. Pat. May 22, 1884.

CARBON and peroxide of manganese, or any other substance capable of giving off oxygen, is mixed with silicate of potash or soda, so that the compound forms a pasty mass. After drying, it is immersed in a solution of an ammonium salt, or chloride of metals, or in any acid that will have the effect of decomposing the alkaline silicate, so that the silica be precipitated intimately amongst the particles of the carbon, and the other substances employed. The mass is then boiled in water, which dissolves out everything but carbon, peroxide of manganese, and silica. After this it is dried and fit for use, especially for elements in electrical batteries. The inventors term their finished product "Silico-carbon."—S. H.

*Improvements in the Purification of Water.* W. Anderson. Eng. Pat. 5496, November 23, 1883 (Amended Specification dated May 23, 1884).

THIS invention relates to the treatment of water by means of spongy iron. According to the method at present adopted, the purifying material is arranged in layers, as in an ordinary filter bed, the disadvantages of this system being that the spongy iron, when used with bad water, becomes covered with slime and caked into lumps, that it has to be disturbed and cleaned from time to time, and that, "the process of purification by percolation being very slow, large areas of filters are required, and a heavy capital expenditure in the purifying material." The inventor proposes to place the spongy iron in a revolving vessel, mounted upon hollow trunnions, which serve as the inlet and outlet for the water. The vessel referred to is not nearly filled with the spongy iron, the particles of which must be free to be carried up on to shelves or ledges within the vessel, and to fall again through the water, fresh surfaces being in this way constantly exposed. The water operated upon flows continuously through the revolving vessel.

—E. G. C.

*Apparatus for Disinfecting Rags and other Fibrous Materials.* S. W. Parker and H. Blackman, New York. Eng. Pat. 16,539, December 16, 1884.

ACCORDING to this invention, rags and other fibrous materials may be disinfected while in the bale or package, and liquid or gaseous disinfectants can be caused to penetrate and permeate the mass of the bale in every direction. The disinfecting chamber in which the operation is to be carried out, is furnished with a series of five or more rotary, tubular, perforated screws, which, by means of suitable gearing connected with them, and also with a car

upon which each bale in succession is brought into the chamber for treatment, are caused to penetrate the bale to the distance of their full lengths. The hollow interiors of these perforated screws are connected with a separate chamber or receptacle, into which is forced in any desired way a disinfectant, either in the form of gas or liquid. The disinfectant employed passes through the hollow screws and perforations therein, and permeates the whole mass of the bale of rags, etc. When the bale has been subjected for a sufficiently long time to the action of the disinfectant, a stream of pure air can be forced through the screws to drive all noxious gases from the interior of the bale and surrounding chamber. Immediately above the disinfecting chamber is a tank containing a disinfecting liquid, through which all gases and vapours must pass before escaping into the air. Each bale, after having undergone the purifying process, can be withdrawn from the chamber by shifting the driving belts, and so reversing the direction of the rotation of the driving gear connected with the tubular screws and car already referred to.—E. G. C.

## XIX.—PAPER, PASTEBOARD, Etc.

*Improvements in Bleaching Paper Pulp.* J. H. Johnson, Middlesex. From Jean Baptiste Fessy, France. Eng. Pat. 7511, May 9, 1884.

LITHIETO the bleaching of materials for paper-making, and the bleaching of other materials, has been effected by immersion in baths of different kinds, whereby there results a considerable loss of the bleaching agents, owing to the large quantities required for immersing the materials. This invention has for its object to effect economy in the cost of bleaching by reason of the small quantities of bleaching agent required, and also to save time, "owing to the rapidity with which the process can be performed by applying the decolorising or bleaching agents in a nascent condition."

The bleaching is to be effected by acting on the materials to be bleached with the solution of the bleaching agent in the form of spray, which may be produced by the action of steam or compressed air. It is proposed to employ for this purpose an apparatus similar to "Körting's Pulveriser," but constructed as described in the drawings accompanying the specification, which should be consulted for details.

"This system of bleaching can be readily applied by utilising the apparatus ordinarily employed in paper-mills, and requires no special skill or training on the part of the workmen. The effect produced on the materials is permanent; and paper pulp, usually very difficult to bleach, can be bleached with rapidity, the operation lasting from a few minutes to a few hours, according to the nature of the materials. Pulp which, owing to the chemical nature of the colour or the mechanical condition of the materials (e.g., wood pulp), hitherto could not be bleached in a practically available manner, can be successfully treated by means of this process; and facility is also given for obtaining an absolutely regular and uniform bleaching, to any desired tint or degree, as the chemical and mechanical action can be arrested at any desired stage." Inventor may use as a means of pulverising any other chemical or mechanical agent; and any bleaching agent may be employed. A saving of 60% in bleaching powder is claimed by the patentee.

—H. A. R.

*Improvements in the Manufacture and Subsequent Treatment of Sensitive Paper for Copying Drawings, Documents written on one Side, and the like, by Photography.* H. J. Shawcross. Eng. Pat. 8771, 1884.

THIS invention has for its object the obtaining of exact copies of line drawings or photographs on sufficiently translucent paper in black lines, or in some cases of coloured lines, on a white surface, and consists in spreading on the surface of the paper two chemicals, one of them very sensitive to light, and both capable, when combined, of colouring the paper. The inventor uses, for the sensitive solution, a mixture of per-chloride of iron,

gelatine, ferric sulphate, sodium chloride and tartaric acid; for the developing material, powdered tannic acid. The surface of the paper is first covered with the sensitive solution, thoroughly dried, and the developing material is then rubbed or pressed in. In using paper prepared in this way, the tracing must be laid over the sensitive surface and exposed to light in a glass frame. After some time the paper is taken out, laid on the surface of water, wetted on both sides, well washed and dried, when it will contain an exact copy of the original tracing. If a deep blue be required, ferrocyanide of potash can be used instead of tannic acid; if a deep red be required potassium thiocyanate may take its place; catechu will give a green.—S. H.

*Improvements in Treating Vegetable Substances in order to obtain Fibrous Materials for Textile Purposes, and Pulp for Making Paper, and for other Useful Applications.* Thomas Graham Young and John Pettigrew, jun. Eng. Pat. 14,735, November 8, 1884.

THE process consists in treating wood or other vegetable substances with a 20 per cent. solution of nitrous acid, preferably at a boiling temperature. The disintegrated wood is then washed and treated with a solution of caustic soda or other alkali or alkaline earth, with or without pressure. The pulp, after washing, can then be bleached in the ordinary way. The oxides of nitrogen produced in the first part of the process can be recovered by leading them into a tower, where they are acted upon by air and steam.—E. J. B.

*Improvements in Treating Vegetable Substances in order to obtain Pulp for Making Paper, and for other Useful Applications.* Thomas Graham Young and John Pettigrew, jun. Eng. Pat. 14,988, November 14, 1884.

THIS process is similar to the above, nitric acid or nitric acid containing nitrous acid being substituted for the nitrous acid.—E. J. B.

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

*On Derivates of  $\psi$ -cumylquinizine.* S. Haller, Ber. 18, 706.

THE derivatives of cumylquinizine can be prepared in the same manner as Knorr's quinizines (Ber. xvi. 2597, and xvii. 546 and 2032), with which they also agree as regards reactions and properties. The constitution of the compounds belonging to this group can be represented, thus:—

The most characteristic compound is  $\psi$ -cumyldimethyl-Oxyquinizine ( $\psi$ -cumylantipyrene) obtained by heating in a sealed tube  $\psi$ -cumylmethoxyquinizine with methyl iodide and methyl alcohol, from four to five hours, at 100° C. Its reactions are very peculiar. Its aqueous solution is coloured red with iron perchloride. Nitrous acid produces a bluish green colouration, owing to the formation of isonitroso- $\psi$ -cumylantipyrene. It dissolves with a deep red colour, in cold concentrated nitric acid, which contains no nitrous acid. On adding water the nitro-derivative is separated as a pink crystalline mass.—S. H.

*Brucine.* O. de Coninck. Compt. Rend. 99, 107.

ON fractionating the distillate obtained by heating cinchonine or brucine with potash, tetrahydroquinoline is formed. It is an oil of high refractive power, and possesses the smell of quinoline and indol. Tetrahydro-

quinoline is, therefore, present in the molecule, both of cinchonine and brucine.—J. B. C.

*Improvements in the Manufacture of Salicylic Acid.* W. Lloyd Wise. From Chemische Fabrik vormals. Hofmann and Schoetensack, Ludwigshafen. Eng. Pat. 3723, November 19, 1884.

CHLORO-CARBONIC acid (carbonyl chloride or phosgene gas) is passed into a dry-heated powdered mixture of 30gs. phenol and 40gs. caustic soda, which is agitated mechanically, and heated gradually from 140° C. to 200° C. The operation is continued till 90 per cent. of the phenol has been converted. The residue is dissolved in water, heated with acid, the phenol driven off by steam, and the salicylic acid precipitated from the sodium salicylate in the usual way. The claim is for causing chloro-carbonic acid (carbonyl chloride) to act as above stated upon dry powdered heated mixture of phenol and an alkali.

## XXI.—EXPLOSIVES, MATCHES, Etc.

*The Removal of Erections by means of Dynamite.* Dingl. Polyt. J. 254, 456.

THE plan adopted and found successful at Aszod for the removal of a chimney shaft by means of dynamite is described in *Mittheilungen über Gegenstände des*

*Artillerie- und Geniewesens*, 1884, p. 215. In Fig. 1 the details of construction of the shaft are shown; the height was 59.6m. At a height of 6m. above the ground a wedge-shaped hole, 1m. high at its widest end, 0.20m. at

its small end, was blasted out, and the chimney fell towards the side in which this cavity was made. In Figs. 2 and 3 the position of the bore-holes is shown, and the following table gives the amount of dynamite No. 2

used in each hole. The charges were exploded in series, I., II., III., IV. :—

I.	No. 1.	0.20m. deep ...	0.04k. charge.
	2.	0.25 " " " "	0.07 " "
	3.	0.30 " " " "	0.11 " "
II.	4.	0.25 " " " "	0.06 " "
	5.	0.30 " " " "	0.11 " "
	6.	0.50 " " " "	0.50 " "
III.	7.	0.40 " " " "	0.25 " "
	8.	0.30 " " " "	0.11 " "
	9.	0.25 " " " "	0.06 " "
IV.	10.	0.55 " " " "	0.50 " "
	11.	0.55 " " " "	0.40 " "
	12.	0.50 " " " "	0.50 " "
IV.	13.	0.60 " " " "	0.80 " "
	14.	0.50 " " " "	0.50 " "
	15.	0.53 " " " "	0.60 " "

The charges in the holes 6, 10, 11 were made sufficiently heavy to cut through the brickwork; the shots of group IV. effected the final displacement, being fired simultaneously. The work occupied in all three days, and

required 4.61k. of dynamite, 15 detonators, 10.2m. of Bickford and 8m. lead fuse. The total cost was 70 marks. Of the 250,000 bricks in the shaft, 150,000 were quite serviceable, and other 20,000 still useful.—W. D. B.

#### Improvements in Match-making Machinery. Dingl. Poly. J. 255, 239.

A MACHINE to obviate the necessity for hand labour in the dipping or heading of matches has been patented by

Holmström (Ger. Pat. No. 25,788, June 30, 1883). To obtain good heads it is not sufficient simply to dip the ends of the splints into the melted composition, but the

splints require to be moved about. In the machine patented the arrangement is such that the splints, in the usual carrying frame suspended on an endless band, are led over and pressed by means of a spring upon three or more drums or cylinders dipping into the composition, which, by the revolution of the cylinders, is brought to

the ends of the splints. The heads are obtained round and uniform by placing the cylinders at an angle with the line of motion of the carrying frame; the composition is thus pressed against two adjacent sides of the quadratic splint by every drum. A machine for filling flat splints into carrying frames for dipping has been patented by Sebold (Ger. Pat. No. 26,937, July 11, 1883), and is a

modification of that devised by the same for the purpose of filling the frames with oval, round, and quadratic splints. The box K (Figs. 5 and 6) is divided into a number of compartments, and rests upon the tube-box K1, upon the top O of which the splints rest. This top O has perforations corresponding in position with the tubes of

K1, and shaped as shown in Fig. 3, the third form being found most advantageous. The greater diameter of these openings is parallel to the laths L. The tubes of K1 are filled by shaking the box K, the perforated slide S is brought into such position that the splints from K1 fall through the perforations, then through the grid R with the

narrow openings parallel with *L*, pass through a second grid *R*, the openings of which are at right angles with those of *R*, and by this guiding arrangement can be easily and correctly placed between the laths of the carrier, their ends resting in the grooves of *P*. If the boxes *K* and *K*, together with the slide *S* and the grid *R*, be lifted up, the carrying frame may be tightened up in the usual manner and removed from the machine. The surface of the carrier has the appearance shown in Fig. 4. To facilitate the opening and closing of *K* and *K*, and

the shaking of *K*, there are two levers (Figs. 1 and 2) on either side of the machine, turning around a fixed axis *O*, provided with counterweights *G* and connected at the other end by *M*. The boxes also turn round *O*, and resting upon *M*, are moved by the levers. By means of a bolt *D* fixed in position by the bent lever *W*, the cross-bar *M* can be held down, and the boxes *K* and *K*, being rendered independent of the weights *G*, can then be readily shaken.—*W. D. B.*

#### Improvements in the Manufacture and Application of Explosive Substances. *Dingl. Polyt. J.* 255, 518.

A DETAILED description, with illustrations, is here given of Lauer's improvements in his apparatus for sub-

marine blasting with unconfined charges (*Ger. Pat.* 30,242, May 6, 1884; see also *Journ. Soc. Chem. Ind.* iii. [3], 193).

Ballabene prepares a plastic dynamite named lignite by absorbing from 80 to 85 parts of nitroglycerin with from 20 to 15 parts of a nitrocellulose obtained by the nitration of wood-flour. The apparatus shown in the figure is employed for the nitration of the wood. The vessel *A* is lined with lead, and has a false bottom consisting of two perforated plates, *c* and *b*, between which there is a layer of gun-cotton. The nitration acids, consisting of 62 parts of nitric and 142 parts of sulphuric acid, are introduced into *A*, *d* being closed, the wood-flour immersed therein, the lid *a* screwed down by *g* to form by aid of the washer an air-tight covering, and after a short space of time *d* opened and about 50 per cent. of the mixed acids expelled by the introduction of air at 2 atmospheres' pressure at *f*. After a short digestion the acids are squeezed out as far as possible by the press *g* *h*, and the nitrated pulp washed with water. It is to be noted that no arrangement for cooling is applied.

The Société Anonyme des Poudres et Dynamites proceed according to Lanfrey and Renard's patent in the manufacture of a dynamite with active absorbent, named *Palcine*. Five qualities, *A* to *E*, are issued, of which *A* contains 40 to 50 per cent. of nitroglycerine, and 60 to 50 per cent. of nitrated straw. *A* is said to be about  $\frac{1}{3}$ , *B* about  $\frac{1}{2}$ , and *C* slightly more powerful than ordinary 75 per cent. Kieselguhr dynamite.

Dolliak contributes his observations upon the properties of straw nitrocellulose (nitrated straw). Rye straw boiled 15 hours in a 1-2 per cent. solution of soda was nitrated and washed. The product matted together, possessed a brownish yellow colour, contained 11.07 per cent. of nitrogen, and when gradually heated flashed at a temperature of 177°. Exposed to a current of dry air at 60°, signs of decomposition were evident in three minutes.

Guttmann contributes a report upon the explosives manufactured in the Austro-Hungarian Empire. The following is a list of all the blasting compounds at present manufactured, and with the exception of No. 11 the composition of each is given in the original paper:—(1) Black gunpowder, (2) diorrexin, (3) haloxylin, (4) petralite, (5) janite, (6) carboazotine, (7) azotine, (8) amidogène, (9) lederite, (10) vulcanite, (11) myline. In the second series are (1) Nobel's new dynamite, Nos. 1 to 3; (2) white dynamite, Nos. 1 and 2; (3) rhexite, Nos. 1 to 5; (4) Arlberg dynamite, Nos. 1 to 3.

Several instances of the spontaneous inflammation of sponges employed for the cleansing of vessels which had contained nitroglycerin, have recently occurred in several factories where it was the practice to wash the sponges after use in tepid water, then in dilute soda, and dry. It is recommended to lay the sponges immediately after use in water, cleansing them ultimately by soaking in dilute hot soda solution, wringing out several times, and only, after this, to permit them to dry.—*W. D. B.*

#### The Manufacture and Application of Explosive Substances. *Dingl. Polyt. J.* 255, 337.

NORDENFELT and Menrling (*Ger. Pat.* No. 30,676, Aug. 21, 1884) prepare a carbonaceous substance by subjecting cotton or wood cellulose, loosely packed in a vessel, to the action of a stream of hydrochloric acid gas. The cellulose soon becomes friable, and when the process has been carried sufficiently far, the hydrochloric acid gas is expelled by passing a stream of air. The carbonaceous substance obtained is impregnated with the requisite amounts of sulphur and potassium nitrate, by treatment with solutions of these substances respectively in carbon bisulphide and water; the powder mixture obtained by the evaporation of these liquids is manipulated in the usual manner.

Nitro-compounds for explosive purposes, one in the solid, the other in the fluid condition, are prepared by Gilles (*Ger. Pat.* No. 27,969, April 14, 1883) by the nitration of molasses. To obtain the solid compound, the molasses, without further preparation, are mixed with the nitrating mixture, the whole thrown into water, and the precipitate washed first with cold then with warm water. To obtain the liquid compound, the patentee

advises the nitration of moist molasses of such ultimate composition, that the ratio of carbon to oxygen—taking the oxygen of the water into account—shall approximate 2:3. According to stillles, the liquid nitro-compound is yellow, boils when heated gradually between 180° and 200°, and detonates between 220° and 250°.

An apparatus for the preparation of nitroglycerine, patented by Schroeder (Ger. Pat. No. 29,130, December 28, 1883), presents few novel features. An arrangement, by which the glycerine sprayed by means of compressed

air was introduced at the bottom of the nitration vessel, was described by Kurtz in 1879.

The following independent analyses of samples, taken from the same bulk of a consignment of Himly's powder, point to the difficulty of properly incorporating the coal-tar pitch with the requisite oxidising salts. One hun-

dred parts of the powder gave to three analysts widely differing results:—

	1.	2.	3.
Potassium chlorate .....	45.50	33.50	62.50
Potassium nitrate .....	34.38	48.78	25.00
Coal-tar pitch .....	20.12	17.72	12.50

—W. D. B.

## XXII.—GENERAL ANALYTICAL CHEMISTRY.

*Separation and Estimation of Methyl- in presence of Ethyl-alcohol.* C. de Poncy. *Dingl. Polyt. J.* **254**, 500.

THE method is based on the different solubilities of the oxalic ethers prepared from oxalic acid in presence of HCl—methyloxalate being easily soluble, ethyloxalate difficultly soluble in water; further, on the insolubility of the amide in water, formed by the action of ammonia upon the ethers.—J. B. C.

*Quantitative Determination of Phosphoric Acid in Superphosphates.* C. Mohr. *Zeits. Anal. Chem.* **23**, 487.

THE author finds that the method for directly determining the amount of soluble phosphate in commercial "supers" by the ammonium citrate method does not give exact results if the citrate solution is precipitated at once by magnesia mixture, a considerable quantity of phosphoric acid remaining in solution.

The new method is as follows: 5grm. of the superphosphate, or artificial manure, is treated in a mortar with hot water, and filtered into a 4-litre flask. After extracting three times in this way the insoluble portion is collected in a flask, and digested with 25cc. of an alkaline solution of ammonium citrate for one hour at 60-70°. The alkaline solution is filtered into the first portion, washed, and filled to the mark. If not acid, it should be previously acidified slightly with nitric acid.

To 10 to 20cc. of this solution an equal volume of fuming nitric acid is added, and a large excess of molybdate solution. The whole is digested an hour at 85° on the sand-bath. After cooling, it is filtered, the yellow residue dissolved in ammonia, again filtered, and precipitated with magnesia mixture. The precipitate is either weighed or titrated with uranium solution. The results of analyses by this method agree well with those calculated by difference—i.e., by subtracting the phosphoric left undissolved in ammonium citrate from the total phosphoric acid in the sample—whereas the numbers obtained by the old direct method are in every case about two per cent. too low.

Another advantage of this method is that it can be employed in the case of all manures in which magnesia is present.—J. B. C.

*Precipitation of Manganese with Bromine.* C. Holthof. *Zeits. Anal. Chem.* **23**, 491.

THE author's method of precipitating manganese with bromine in presence of ammonia and ammonium chloride is a modification of that of Wolff (*Zeitschr.* **22**, 520). It is as follows: If iron be present, it is first precipitated with ammonium carbonate, and the filtrate acidified. The solution is then diluted, so that about 1dgm. of Mn is contained in  $\frac{1}{4}$  litre of liquid. Bromine is gradually added in the cold, until the solution is distinctly red. A large excess of concentrated ammonia is added, when the peroxide at once falls down. The solution is heated and filtered. The filtration is done by the pump, and the damp filter transferred to a platinum crucible, dried, and ignited. If only Fe is present the operation is a simple one. With small quantities of CuO, CaO, and MgO, the method gives good results. BaO, CuO, and ZnO may be previously eliminated. In presence of the alkaline earths, peroxide of manganese carries down a quantity of these oxides, as also of the alkalis, CuO, ZnO, and MgO. This error may be partly avoided by re-dissolving the precipitate in HCl, and precipitating with  $(\text{NH}_4)_2\text{CO}_3$ ; but the separation is not

complete, especially when large quantities of  $\text{CaO}$  are present.

When, however,  $\text{NH}_4\text{Cl}$  is added, and after precipitation, the solution heated, these oxides, if present, are re-dissolved as double chlorides.  $\text{ZnO}$  and  $\text{BaO}$  are best separated first.

If  $\text{CaO}$  may be determined in the filtrate from  $\text{MnO}_2$ . If relatively large quantities of  $\text{CaO}$  and  $\text{MgO}$  are present, it is necessary to re-dissolve the first precipitate in dilute nitric acid, with a slight excess of formic or oxalic acid to prevent reduction. The excess of organic acid is then destroyed by the addition of a crystal of  $\text{KClO}_3$ , and the solution concentrated. By a further addition of  $\text{KClO}_3$  the manganese is completely precipitated as  $\text{MnO}_2$ .—J. B. C.

*Fusion Reagent for Silicates.* C. Holthof. Zeits. Anal. Chem. **23**, 498.

The author recommends sodium bicarbonate, 12-15 parts of which are used with the finely-pulverised silicate, a portion being placed at the bottom of the crucible and another portion mixed with the silicate. The crucible is then heated below fusion heat for a short time, and finally the mass is allowed to fuse quietly.—J. B. C.

*Substitute for Calcium Chloride Tube.* S. Schmitz. Zeits. Anal. Chem. **23**, 513.

The construction of the apparatus is shown in the diagram. At *b* a piece of platinum gauze is placed, upon which rests a stick of glacial phosphoric acid. The limb *d* contains strong sulphuric acid, and is furnished with an arrangement similar to that of Schrötter's desiccator

(the sulphuric acid is filled to a mark previously determined, so that the acid cannot run back). The limbs of the tube are closed by hollow ground stoppers, smeared with a solution of gutta-percha in heavy petroleum. The stopper at *e* is furnished with a conical tube *g*, which prevents bubbles of sulphuric acid being carried away. The bulb retains any liquefied phosphoric acid.—J. B. C.

*Titrations with Potassium Permanganate Solution.* W. Lenz. Zeits. Anal. Chem. **24**, 34-41.

PERMANGANATE solution, when used for estimating organic substances in water, is untrustworthy, since only those bodies which are very easily oxidised are completely burnt up to carbonic acid. With grape sugar, great discrepancies were noticed; the greater the excess of permanganate, the greater the amount used. In no case, however, was the theoretical quantity of permanganate reduced, although about five times the calculated quantity was added. The experiments were repeated by varying the amount of grape sugar added to a constant quantity of permanganate solution, and then boiling for ten minutes, but with similar discordant results. With glycerine the experiments yielded results still further from the truth. The grape sugar never used more than 54 per cent. of the theoretical quantity of permanganate, and the glycerol (glycerine) never more than 34 per cent. under like conditions. The permanganate process is, therefore, useless for either absolute or relative estimations of organic matter. With decinormal perman-

ganate and glycerine equally unsatisfactory results were obtained. With oxalic acid and strong alkaline permanganate solution  $\frac{1}{100}$  normal, containing 40 grm. of  $\text{KHO}$  to the litre, after twenty-four hours before titrating back, 2 out of 9 experiments were near the truth. The best results were those obtained when twice the theoretical quantity of permanganate had been employed. The oxalic acid solutions used for titrating permanganate should be freshly prepared, as the author finds that centinormal acid loses 15 per cent. of its strength in one week, when exposed to diffused daylight. Normal solutions will keep in the dark if stored in full bottles. Centinormal solutions, even in the dark, lose strength after a few weeks. The addition of 10 grm. of boric acid per litre prevents the decomposition of the oxalic acid, and does not impair its value for titrating purposes. It is best, therefore, to keep decinormal acid containing 1 per cent. of boric acid, and dilute it as required.

—S. R.

*Funnel for Filtration in Absence of Air.* F. Allihn. Zeits. Anal. Chem. **23**, 517.

THE arrangement of the apparatus is given in the diagram. The funnel has a cylindrical rim 1-2 cm. high, covered with a lid provided in the centre with a neck. Into this fits a cork and bent glass tube. The funnel is fitted into a filter flask, which has a side tube. By con-

necting the tube of the funnel with that of the flask by a piece of indiarubber tubing, the exterior air is excluded. In case a particular gas is required, the funnel is then provided with a double-bored cork. Through one opening the gas is introduced, and it passes out by the other, a connection being made with the filter flask as before.—J. B. C.

*Method for Estimating Nitric Acid Volumetrically.* A. Longi. Zeits. Anal. Chem. **24**, 23-26.

STANNOUS salts destroy the blue colour produced by diphenylamine in solutions of nitric acid. The stannous solution employed is made by dissolving 40 grm. of potassium stannous sulphate (Marignac) in 500 cc. of water, then adding an equal volume of dilute sulphuric acid, and a little concentrated hydrochloric acid. The solution is then titrated, and diluted with weak sulphuric acid, till decinormal. The accuracy of the method depends on the amount of sulphuric acid present. From numerous experiments, the author shows that when 3-5 volumes of concentrated sulphuric acid are added to each volume of the solution to be tested before titrating, the method is quite accurate. Large quantities of ferric salts prevent the application of this method. Concentrated solutions of nitrates should be diluted with water before adding the concentrated sulphuric acid, and in all cases the mixture should be cooled before adding the diphenylamine solution.—S. R.

*A Thermostat of Simple Construction which can also be used as a Registering Thermometer.* E. H. von Baumbauer. Zeits. Anal. Chem. **24**, 42-46.

AN ordinary glass cylinder *A* is connected with a cork, or, better, fused to a narrower glass tube *B* open at both ends, but drawn out at the lower extremity. To the

upper end a brass knee-piece is cemented. A round hole is bored in this brass piece immediately above the tube B, so as to allow of the passage of a long graduated tube C into it. The tube C fits air-tight by means of a well-greased leather washer, but can be raised or lowered to any desired height. The gas passes through this tube, and is shut off all but from a small hole in its side about 1½ in. from its lower end by the rising of the mercury in the tube B from the expansion of the air in the glass cylinder. The instrument is graduated by first removing the tube C, and immersing it in a bath at the maximum temperature for which it is required, and then whilst hot filling the tube B with sufficient mercury to prevent air being drawn into the air chamber on cooling. The tube C and the brass piece are next connected, and the gas passes in from the upper end of C, and out from the brass piece by the indiarubber tube Z. On gently heating, the mercury rises in the tube B, and nearly shuts off the gas from time to time as the tube C is raised, the division on the scale coinciding with the mark *m* at the different temperatures being noted. Fig. 2 shows how a fine adjustment can be adapted to the instrument in cases where small changes of temperature are important. In most cases, however, the regulation by hand is all that is needed. To make the instrument self record the maximum temperature, a small plug of indiarubber is placed in the lower end of tube B which, whilst allowing

but if treated whilst warm with water, becomes transparent, and has the appearance of swollen-up gelatin. The product is scarcely dissolved by water, ether and alcohol, but readily by alkalis on warming, and is acted upon by concentrated sulphuric acid. The alkaline solution, when concentrated, becomes pale green after some days. If the excess of ammonia be removed from the original solution and hydrogen peroxide be added, the green is produced at once. Fuming nitric acid gives also a green colour, which changes to a blue on warming. When using these reactions as a test for citric acid, the proportion of 1 part of crystallised citric acid to 6 or 5 of glycerol is found to be the best. Tartaric and malic acids give no similar reactions.—S. R.

*Soap Analysis.* A. Gawalowski. Zeits. Anal. Chem. **24**, 219.

IN estimating the fatty acids, the author decomposes with sulphuric acid, transfers to a folded filter, washes and shakes the filtrate and wash-water with light petroleum, separates, and then evaporates the petroleum portion; next he dissolves the fatty acids on the filter with light petroleum, and mixes with the first portion of the fatty acids before finally drying and weighing. The filter need not be dried before dissolving the acids in the light petroleum.—S. R.

*Apparatus for Filtering and Drying very Oxidisable Precipitates.* W. Bachmeyer. Zeits. Anal. Chem. **24**, 59-61.

THE apparatus is shown in the accompanying figure, and is constructed of glass with the exception of the cover C, which is of brass. The tube *g*, which is connected with the brass tube *m* by the cork *f*, is bent over and unites with a small flask containing the precipitate. This small flask has a cork with three holes, one for the tube *g*, a second for a glass funnel, and the third for a tube connecting with a gas generating apparatus. When

FIG. 1.

FIG. 2.

the mercury to rise freely as the temperature increases, prevents its return. The tube C, which is then connected by a pulley with a counterpoise, rises with the mercury, so that the final position of the scale gives the maximum temperature reached.—S. R.

*Test for Citric Acid.* C. Mann. Zeits. Anal. Chem. **24**, 201.

CITRIC acid mixed with glycerol and evaporated to dryness at a low temperature, yields a porous light yellow mass which becomes hard and brittle on cooling;

all connections are found to be air-tight the tube *c* is connected with a water pump and the cock *c* is opened, the precipitate is drawn over by lowering the tube *g* into the precipitate in the flask as soon as the apparatus is filled with the indifferent gas. The precipitate collects on the funnel *d*, and distilled water can be drawn over to wash the precipitate there, by pouring down the funnel in the small flask. By opening the tap *d* instead of *c*, the filtration can proceed more slowly, and this tap is also useful with very muddy precipitates. To dry the precipitate the cork *k* is replaced by another without an

opening, the glass tube *g* is fused off, and the upper part *B* of the apparatus removed from the lower part *A*, and transferred afterwards to a drying oven.—S. R.

*A New Separation of Nickel and Cobalt.* M. Hinski and G. von Knorre. Ber. 18, 699.

If an alcoholic or acetic acid solution of nitroso- $\beta$ -naphthol be treated with a neutral or hydrochloric solution of cobalt, a bulky purple precipitate is obtained, which resists all action of alkalis, acids, oxidation or reduction. The precipitate is cobalti-nitroso- $\beta$ -naphthol

If a solution of nitroso- $\beta$ -naphthol, in 50% acetic acid, or an aqueous solution of nitroso- $\beta$ -naphthol sodium, be treated with a solution of a nickel salt, a brownish-yellow precipitate is produced, which is slightly soluble in water and alcohol. Hydrochloric and sulphuric acids deprive it very easily of its metal, leaving behind nitroso- $\beta$ -naphthol, which remains in solution if sufficient acetic acid is present. If, therefore, an acetic acid solution of nitroso- $\beta$ -naphthol be treated with little hydrochloric acid, and then with the solution of a nickel salt, no precipitate is produced. On these reactions the following method of separating cobalt from nickel compounds is based:—The solution containing these metals, as sulphates or chlorides, is treated with a few cc. of hydrochloric acid. The liquid is warmed, and a hot solution of nitroso- $\beta$ -naphthol in 50% acetic acid is added in excess. The precipitate is allowed to settle, and after cooling the supernatant liquid is examined whether it gives a turbidity with a new addition of nitroso- $\beta$ -naphthol solution. If the precipitation is complete, the precipitate is filtered, after some hours' standing, and washed at first with cold, then with warm 12% hydrochloric acid, until all nickel is removed, and at last with hot water. The filter is allowed to dry, and a few grammes of pure crystallised oxalic acid are added to it. It is then slowly burned in a tared Rose crucible, and the residue ignited in an atmosphere of hydrogen, when pure metallic cobalt is obtained. In the filtrate from the cobalt precipitate, after evaporating the bulk of acetic acid, the nickel can be quantitatively separated by the addition of potassium hydrate. But it is preferable to precipitate in a measured portion of the solution both cobalt and nickel, and, after reducing them in a hydrogen current, to weigh the metals. In another portion, the weight of cobalt is determined by the process as mentioned above, and the amount of nickel can then be estimated by difference. The authors give the results of several analyses, which prove the method very trustworthy indeed. It is also shown that the reaction is far more sensitive than Portman's process with potassium nitrite and acetic acid. Small quantities of cobalt can be determined very accurately when mixed with large quantities of nickel.

—S. H.

*A New Method of Estimating Nitrogen, of General Application.* Carl Arnold. Ber. 19, 806.

The author proposes the following method of estimating nitrogen in inorganic and organic substances, with which he has obtained very accurate results with nitrates, nitro-compounds, azo-compounds, amido-compounds, etc. The method is based on the methods which have been already proposed by Tamm-Guyard (combustion with a mixture of soda-lime and sodium-hypophosphite), and by Ruffe (combustion with a mixture of soda-lime, sodium-hypophosphite, carbon and sulphur), but which do not give good results with all substances. It consists in heating the substance with a mixture composed of equal parts of soda-lime, sodium-hypophosphite, and sodium formate, the operation being performed like an ordinary soda-lime estimation. The combustion tube is charged with 12 to 15 cm. of the mixture and substance, 15 to 20 cm. of the mixture alone, and 5 to 10 cm. of soda-lime, and heated to a moderate red heat. The operation should last about an hour, and at the termination air is drawn through for five minutes to clear out the last traces of the am-

monia. In order to obtain good results, it is essential that the mixture should be packed tightly into the tube (by tapping it in an upright position) and not leave a channel along the top. The proportions of the reducing mixture can be varied considerably, and the sodium hypophosphite can be replaced by 10% of sulphur.—A. G. G.

*On a Colour Reaction of some Diketones.* Eng. Bamberger. Ber. 18, 865.

A FEW drops of aqueous caustic potash are added to a hot alcoholic solution of the diketone (air being excluded as far as possible); if a dull red colouration is produced, which vanishes on shaking with air, it may be concluded that the diketone used has its two CO groups adjacent. The absence of a colouration, however, is not a positive proof that the CO groups are not adjacent.—A. G. G.

## New Books.

ON CERTAIN INDICATIONS OF THE EXISTENCE OF AN ALLOTROPIC MODIFICATION OF ELEMENTARY NITROGEN, AND ON THE SYNTHESIS OF AMMONIA. By GEORGE STILLINGFLEET JOHNSON. London: J. & A. Churchill, 11, New Burlington Street, 1885.

This is an 8vo volume, bound in cloth, containing 32 pages of subject matter. The work is divided into four chapters, and is illustrated by three woodcuts. The chapters are headed as follows:—Chapter I. Historical Electro-chemical Researches. (i.) Direct Synthesis of Ammonia by means of the Silent Discharge. (ii.) Observations of MM. Dehéram and Maquenne, and of MM. P. and A. Thénard, on the Action of the Silent Discharge upon Water Vapour, and upon a Mixture of Nitrogen Gas and Water Vapour. (iii.) Action of the Electric Spark. Chapter II. Researches on the Synthesis of Ammonia from the Gas evolved by the action of Heat upon Solutions of Ammonium Nitrite. Chapter III. Further Experiments on the Nature of the Gas produced by action of Heat upon Solution of Ammonium Nitrite, conducted in 1883. Chapter IV. Experiments with Atmospheric Nitrogen.

The book contains mainly the subject matter of two papers published in the *Journal of the Chemical Society* of 1881, as well as that of three as yet unpublished papers.

LESSONS IN ELEMENTARY PRACTICAL PHYSICS. By BALFOUR STEWART, M.A., LL.D., F.R.S., Professor of Physics, Victoria University, The Owens College, Manchester, and Mr. W. Haldane Gee, Demonstrator and Assistant Lecturer in Physics, The Owens College. Vol. I. General Physical Processes. London: Macmillan & Co., 1885. [All rights reserved.]

This small 8vo volume, bound in red cloth, and comprising besides Preface, Table of Contents, and a List of Tables, 291 pages of subject matter, is the first of three volumes, of which the remaining two, yet to follow, will treat respectively of "Electricity and Magnetism" and "Heat, Light, and Sound."

The work is illustrated by 103 well-executed woodcuts, and the concluding 33 pages of subject matter are usefully devoted to an Appendix, in which the following items receive attention: A. On the Selection, Conduct, and Discussion of operations suitable for the Physical Laboratory. B. Centimetre, Gramme, Second (C.G.S.) System of Units. C. Practical Notes.

As regards the matter in the body of the work, the arrangement, and to some extent the treatment of this, may be conceived from the chapter headings, which follow:—Chapter I. Measurement of Length. Chapter II. Angular Measurements. Chapter III. Estimation of Mass. Chapter IV. Measurement of Area and Volume. Chapter V. Determination of Density. Chapter VI. Elasticity, Tenacity, and Capillarity. Chapter VII. Determination of Atmospheric Pressure. Chapter VIII. Time, Gravitation, Moments of Inertia. Appendix.

## Monthly Patent List.

### ENGLISH APPLICATIONS.

1855.

#### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

- 5119 H. E. Newton, London.—Communicated by A. L. G. Delme, Germany. Improvements in the method of and apparatus for purifying the feed-water for steam boilers. April 25  
5340 J. Laidlaw, Glasgow. Improvements in centrifugal machines, otherwise known as hydro-extractors. Complete specification. April 30  
5816 F. J. Austin and S. Low, jun., London. The prevention of the formation of boiler crust. May 12  
5305 O. Imray, London.—Communicated by H. B. Scott, France. An improvement in filter presses. Complete specification. May 13  
6053 E. Burton, London. Improvements in furnaces for the combustion or destruction of refuse. Complete specification. May 16  
6065 W. P. Thompson, Liverpool.—Communicated by A. Buttner and C. Meyer, Germany. Improvements in concentrating aqueous solutions and the like, and in drying the resultant products, and apparatus therefor. Complete specification. May 18  
6066 W. Weldon, Burston, Surrey.—Communicated by A. R. Pechiney et Cie, France. Improvements in apparatus for cooling gases and vapours. May 18

#### II.—FUEL, GAS, AND LIGHT.

- 5413 F. Leslie and J. A. Wanklyn, London. Improvements in the treatment of gas and in the materials and apparatus employed therein. Complete specification. May 2  
5638 F. Lennard, Westminster. Improvements in apparatus for converting oils into gaseous fuel, and in its application to the heating of boilers, stills, and other similar plant. May 7  
5645 C. Marquis de Montgrand, London. A new or improved process and apparatus for the production at will of heat and cold, dry or moist, by the compression and rarefaction of the air or of gases. Complete specification. May 7  
5955 F. Snelling, London. Improvements in artificial fuel. May 14  
5980 A. Wilson, London. Improvements in gas producers. May 15  
6050 J. McNair, Glasgow. Improvements in furnaces of retort chambers used in gas manufacture, and in means for supplying heated air thereto. May 16

#### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, ETC.

- 5002 H. Simon and W. Charlton, London. Improvements in hydraulic mains and valves for conducting gases and other products of distillation from coke-ovens, gas-retorts, gas-producers, or other apparatus for the distillation of carbonaceous substances. April 22

#### V.—TEXTILES, COTTON, WOOL, SILK, ETC.

- 1953 E. de Pass, London.—Communicated by F. Kugelmann, France. A process of heating and utilising the fruit of the *Mauritia vinifera* or *Mauritia flexuosa* to render it fit for industrial purposes. April 21  
5312 B. Hallett and T. F. Wiley, London. A new or improved method of applying water-proofing material to pile and other goods. May 5

#### VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

- 5779 J. Hobbleswaite and E. Holt, Manchester. Improvements in means employed for the production of designs on textile and other fabrics or surfaces. April 22

- 5110 J. K. Kaye, Halifax. An improved method of dyeing a fast yellow colour on cotton and other vegetable fibres.  
5782 O. Imray, London.—Communicated by The Farbwerke vormals Meister, Lucius, and Brüning, Germany. Process for printing textile fibres by means of lacvulic acid. May 11  
6013 T. J. Hutchison, Bury. An improved method of preparing waste for bleaching purposes. May 16  
6057 W. Stewart, Glasgow. Improvements in calico-printing machines. May 16

#### VII.—ACIDS, ALKALIS, AND SALTS.

- 1902 A. Neilson and J. Snodgrass, Glasgow. Improvements in obtaining ammonia in connection with the distillation of oil-yielding or carbonaceous minerals. April 21  
4908 G. A. Jarvis, London. Improvements in the manufacture of nitrous and nitric acids. April 21  
5064 A. A. Coll, London. Improvements in the manufacture of muriate of ammonia and alum. April 23  
5180 W. A. Hills, London. Improvements in the treatment of phosphates of alumina. April 27  
5216 W. P. Thompson, Liverpool.—Communicated by L. Imperatori, Germany. A new or improved process for the production of phosphate of soda or of potash from basic process slags and other phosphatic materials. Complete specification. April 28  
5260 J. Brock and W. A. Rowell, London. Improvements in the manufacture of certain chromates and acid chromates. April 28  
5280 W. L. Wise, London.—Communicated by R. Hadot, France. Improvements in effecting the decarboxation of earthy carbonates, such as carbonate of barium, carbonate of strontium, and the like, and apparatus therefor. April 28  
5290 A. H. Fort, John, Billinge, and James Billinge, Liverpool. Improvements in caustic or other drum heads, and lids therefor, and in tools or appliances for adjusting the lids. April 29  
5388 H. Bollmann, London. Improvements in the manufacture of hypophosphites and sulphates of alkalis. May 1  
5391 G. H. Binkinson and J. G. Gordon, London. Improved process for calcining sulphides, arsenides, and analogous compounds. May 1  
5436 W. S. Squire, London. Improvements in the manufacture of sulphuric acid. May 2  
5441 R. H. Thwaite, Tranmere, Cheshire, and J. Pedder, Appleton-in-Widnes. The utilisation and method of using liquid hydrocarbons as carbonising and neutralising agents in the alkali processes. May 5  
5553 W. R. Lake, London.—Communicated by the Bonislate Company, United States. Improvements relating to the treatment of alkaline silicates and other materials, and to the formation of various articles therefrom. Complete specification. May 5  
5620 C. Wigg, Liverpool. Improvements in the utilisation of certain residues obtained in the manufacture of copper and alkali. May 7  
5783 O. Imray, London.—Communicated by The Farbwerke vormals Meister, Lucius, and Brüning, Germany. Improvements in the production of lacvulic acid. May 11  
5882 H. Roake and F. G. A. Roberts, London. Improvements in the manufacture of potassium sulphites. May 13  
5949 J. F. Chance, Liverpool. Improvements in the production of nitrate of ammonia and bicarbonate of soda. May 11  
5920 J. F. Chance, Liverpool. Improvements in the purification of the alkaline lees known as tank or vat liquors. May 11  
5915 A. French, Glasgow. Improvements in obtaining ammonium chloride and cyanogen compounds. May 11  
6066 W. Weldon, Burston, Surrey.—Communicated by A. R. Pechiney et Cie, France. Improvements in apparatus for cooling gases and vapours. May 13

#### VIII.—GLASS, POTTERY, AND EARTHENWARE.

- 5012 R. Clark, Longport, Staffordshire. Improvements in machinery for bating potters' clay. April 23

#### IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

- 4931 W. C. Murdoch and E. F. Murdoch, London. Improvements in pavements. Complete specification. April 21  
5004 W. R. Lake, London.—Communicated by A. van Berckel, Germany. Improvements relating to the preservation of wood for paving or similar purposes. April 22  
5187 A. W. Lake, London.—Communicated by T. Hyatt, United States. Improvements in illuminating tiles, and constructions made therefrom, and in the mode or process of manufacturing, and in constructing with the same. April 27  
5188 A. W. Lake, London.—Communicated by T. Hyatt, United States. Improvements in illuminating combination tiles. April 27  
5189 A. W. Lake, London.—Communicated by T. Hyatt, United States. Improvements in concrete lights. April 27  
5213 T. C. Fawcett and J. D. Fawcett, Belper. Improvements in machinery for pressing bricks, bickettes, tiles, and other articles. April 28  
5351 E. Robbins, London. The novel manufacture of a new decorative concrete of slag combined with similar and other materials. April 30  
5412 F. Ransome, London. Improvements in the manufacture of cement. May 2

- 5338 P. Walker, Glasgow. Improvements in making lithographic stones, baths, washing tubs, sinks, and other articles of Portland cement. Complete specification. May 5
- 5339 A. Hiss and H. Goodey, London. Improvements in the construction and use of fire-proof hearths and other fire-proof parts of buildings. Complete specification. May 6
- 5340 A. Ford and J. A. Archer, London. An improved material applicable as a waterproof covering for roofs and other such like purposes. May 15
- 5345 W. Montgomery, London. An improved fire-resisting cement. May 16
- 5347 J. Tulloch and T. Tulloch, Glasgow. Improvements in the construction of fire-proof buildings. Complete specification. May 16
- 5355 H. H. Lake, London—Communicated by J. Leiter, Austria. Improvements relating to the protection of wood from moisture. May 18

## X.—METALLURGY, MINING, Etc.

- 1909 G. A. Jarvis, London. Utilisation of basic slags. April 21
- 1925 L. Roberts, D. Roberts, and J. Colquhoun, Sheffield. Improvements in furnaces and appliances connected therewith for smelting, puddling, rolling, heating, or otherwise treating minerals, metals, and the like substances, such improvements being likewise applicable to other classes of furnaces. (April 21)
- 5303 W. Coccaro, London. An improvement in moulds for cooling and discharging slag. Complete specification. April 22
- 5316 L. A. Groth, London—Communicated by R. Yerkebeck, Luxembourg. A new or improved apparatus for manufacturing steel direct from the iron ore. April 23
- 5302 W. E. Wynne, London—Communicated by H. W. Oliver, jun., and J. P. Witherow, United States. Controlling and regulating the volume and pressure of the blast in converters for heating molten cast iron. April 24
- 5303 T. Massingham, London. Improvements in protecting lightning conductors from the action of atmospheric acids and other destructive influences. April 24
- 5310 J. Gilligan, London. Improvements in the manufacture of puddled iron and steel. April 25
- 5371 A. Davy, London. Improvements in apparatus for making steel by the Bessemer process. April 28
- 5385 E. Morewood, Llanelli. Improvements in coating plates or pieces of iron, steel, or other metal with tin, terne, zinc, or other metals. May 1
- 5340 E. Branwell and J. Kynaston, Liverpool. Improvements in the treatment of or treatment of valuable products from mixed or composite metallic ores. May 9
- 5442 L. A. Groth, London—Communicated by C. G. Delhous, France. An improved method of extracting copper, nickel, cobalt, silver, or gold from their ores. Complete specification. May 7
- 5346 C. Scheibler, London. Improvements in the manufacture of steel and iron, and in obtaining by-products of such manufacture. Complete specification. May 7
- 5360 T. Timothy, Briton Ferry. Improvements in annealing pots. May 8
- 5392 D. Edwards, R. Lewis, and P. Jones, London. Improvements in coating metal plates with tin or other metal. May 8
- 5304 G. A. Goddwin and W. F. How, London. Improvements in foundry ladles and crucibles. May 8
- 5317 L. Roberts and H. Tonkins, London. Improvements in furnaces for re-heating steel ingots or wrought-iron piles also applicable for the manufacture of iron and steel, and for other purposes. May 9
- 5351 T. R. Baylis, London. Improvements in the manufacture of ordnance and projectiles, which improvements are also applicable to the manufacture of metallic tubes and hoops for various purposes. May 9
- 5356 J. S. Williams, Riverton, New Jersey, U.S. Improvements in methods or means of conducting metallurgical or chemical processes and in apparatus or means employed therewith. May 9
- 5391 J. T. King, Liverpool—Communicated by H. W. Oliver, jun., and J. P. Witherow, United States. Improvements in regulating the blast for steel converters. May 12
- 5330 W. E. Gedge, London—Communicated by S. Trayner, Spain. Improvements in the manufacture of metallic lead. May 14
- 5353 C. H. McEwen, London. Improvements in the manufacture of metallic antimony. May 15
- 5377 H. Minton-Schoups, London—Communicated by H. Capelle, Paris. Improvements in coating copper printing plates to render them more durable. May 15
- 5386 T. Jack, jun., Glasgow. Improvements in treating aluminous iron ores to adapt them for smelting. May 15
- 5397 L. A. Groth, London—Communicated by R. Weckbecker, Luxembourg. A new or improved chemical process for manufacturing steel direct from the iron ore. Previously included in No. 5316. April 23
- 5393 J. Heath and W. Frost, London. An improved method of blasting and shelling iron mines. May 16
- 5395 H. Aitken, Glasgow. Improvements in the treatment of carbonaceous, bituminous, calcareous, and other substances, such as ores, in order to obtain products therefrom. May 16
- 5375 J. B. Jackson, London. Improvements in and apparatus for hardening or tempering articles of sheet steel. May 18

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

- 5382 A. G. Brookes, London—Communicated by R. Giebermann, United States. Improvements in the distillation of glycerine, and in means or apparatus employed therein. May 1
- 5383 A. G. Brookes, London—Communicated by R. Giebermann, United States. Improvements in the refining or separation of glycerine from fats and oils. May 1
- 5386 A. Haacke, London. A lubricant called milk-oil. May 13
- 5396 M. S. Gosling, Birmingham. An improved soap paste for cleansing woollen and other kindred fabrics. May 15
- 5374 W. H. Stratton, London. An improved composition for washing dogs and other animals. May 18

## XII.—PAINTS, VARNISHES, AND RESINS.

- 5302 H. W. Smith, London. The manufacture of an improved paint or pigment. April 21

## XIII.—TANNING, LEATHER, GLUE, AND SIZE.

- 1921 A. G. Brookes, London—Communicated by G. H. Maddock, United States. Improvements in means or apparatus for brushing and cleaning or treating leather. Complete specification. April 21
- 5333 H. E. Howe, London. An improved method of rendering leather best for the inner or outer soles of boots and shoes flexible or pliable, and proof or more durable or resistant against water or damp. April 23
- 5359 W. R. Lake, London—Communicated by J. B. Dupret, Belgium. Improvements in and relating to impermeable and preservative compositions for use in the preparation of leather, and for other purposes. Complete specification. April 30

## XV.—SUGAR, STARCH, GUM, Etc.

- 1918 W. R. Lake, London—Communicated by W. T. Jebb, United States. Improved starch-meal. April 21
- 1954 W. R. Lake, London—Communicated by W. T. Jebb, United States. Improvements in the manufacture of starch-meal. April 21
- 5339 W. R. Lake, London—Communicated by F. Napravnik, Austria. Improvements in the manufacture of sticks or bars of sugar, and in apparatus therefor. Complete specification. May 1
- 5363 J. Duncan and B. E. R. Newlands, London. Improvements in centrifugal apparatus for use in the refining of sugar. May 16
- 5362 J. Duncan and B. E. R. Newlands. Improvements in moulds for use in the refining of sugar. May 16

## XVI.—BREWING, WINES, SPIRITS, Etc.

- 1956 W. R. Lake, London—Communicated by W. T. Jebb, United States. Improvements in or relating to the manufacture of malt liquors. April 21
- 1957 W. R. Lake, London—Communicated by W. T. Jebb, United States. Improvements in or relating to the treatment of maize in the manufacture of spirits. April 21
- 1988 H. J. Hadden, London—Communicated by P. Lauth, France. Apparatus for drying malt and other granular materials. April 22
- 5350 H. E. Brittin, Swindon. An improved kiln for drying brewers' grains, malt, wheat, barley, oats, and other materials. April 23
- 5300 J. H. Loder, Utrecht, Netherlands. Improvements in the manufacture of alcohol and beverages. April 24
- 5385 A. E. Avery, London. Improvements in the method of manufacturing aerated or carbonated waters or beverages. Complete specification. May 1
- 5339 C. D. Abel, London—Communicated by Dr. C. Meyer, Germany. Process for fermenting subsidiary fermentations in substances employed in the various manufactures based on fermentation. Complete specification. May 2
- 5343 M. Binmenthal, London. Improvements relating to the preparation of ferments. May 4
- 5347 J. Barker, London. Improvements in apparatus for aerating malt and other liquors. May 7
- 5350 T. T. Cough, London. Improvements in the process of drying malt and grain, and apparatus therefor. May 9
- 5383 A. Isaack and F. G. A. Roberts, London. Improvements in brewing. May 13
- 5372 A. Swonell, London. An improvement in the manufacture of brewers' finings, wine finings, and jellies, being a perpendicular sieve. May 18

## XVII.—FOOD PRESERVING, MEATS, Etc.

- 5295 J. W. C. Mocler, London. Improvements in malt cocoa. April 29
- 5305 L. Mancinno, London. A new or improved composition of chocolate. Complete specification. May 7
- 5306 A. Collingridge, London—Communicated by V. Cornet and A. Jones, France. Improvements in treating salt intended for consumption as an ordinary condiment, or to be exhibited medicinally. May 9
- 5319 D. Kerr, London. Making an extract of coffee. May 16

9644 S. Pitt.—Communicated by E. A. Mabus and J. W. de Castro. Manufacture of carbonate of strontium from sulphate of strontium. 4d

9688 W. Weldon.—Communicated by A. R. Pechiney et Cie. Manufacture of chlorine and hydrochloric acid from chloride of magnesium. 4d  
11222 W. P. Cochrane and W. Bramley. Method of treating ammonium chloride. 4d

1885.

2048 A. McDougall. Obtaining hydrochloric acid in the manufacture of soda from sodium chloride by the ammonia process. 2d

2478 W. Weldon.—Communicated by A. R. Pechiney et Cie. Obtaining solid caustic soda from fused caustic soda. 4d

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

1884.

9992 H. Knowles. Kilns or ovens for burning bricks, tiles, and pottery, and for other like purposes. 6d

9999 S. Frankenberg. An improved damp-proof compound. 2d

14365 W. Dawson. Mills or triturators for reducing cement or other hard substances. 6d

15036 R. W. Goodison. Manipulation of cements to form a composition which shall be "stonecrete." 4d

1885.

2886 W. Millar and C. F. Nichols. Accelerating the setting and hardening of cements. 2d

## X.—METALLURGY, MINING, ETC.

1884.

6114 L. A. Groth.—Communicated by R. Gratzel. Process and apparatus for the extraction of metals from alkaline combinations by means of the electrolyte. 6d

6736 C. Hoepfler. Decomposing metallic haloid salts by electrolysis. 6d

7977 W. A. Tnoth and J. E. Rooker. Method and apparatus for treating lead, zinc, arsenic, sulphur, and other volatile metals, or the ores or minerals containing such volatile metals. 6d

8890 E. Capitaine.—Communicated by M. Nahsen. Process for the treatment of the slag formed in the dephosphorisation of iron. 4d

11120 A. O. Walker. Process for the condensation and deposition of particles of metal and metallic compounds dissolving in air or other gases. 4d

16321 P. Botcharoff. Manufacture of steel. 4d

1885.

1038 C. Bramall. Compound or lining to be used in lining or constructing smelting and other furnaces. 2d

2338 J. Gjers. Means or apparatus for the treatment of steel ingots. 8d

3808 W. E. Wynne.—Communicated by H. W. Oliver, jun., and J. P. Witherow. A new and useful improvement in the manufacture of steel. 4d

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

1884.

9950 G. H. Goodman. Manufacture of soap adapted for purifying the skin or for the teeth; also for scouring purposes, cleaning and polishing plate, etc. 2d

10208 F. Seltsham. Process for extracting fat from, and drying bones, and the like. 6d

1885.

3101 F. V. Greene. Process for extracting oil and albumenoid matter from maize and other grain. 4d

## XIII.—TANNING, LEATHER, GLUE, AND SIZE.

1885.

3108 L. Simpson and J. Davis. Improvements in tanning apparatus. 6d

## XV.—SUGAR, STARCH, GUM, ETC.

1884.

9243 C. D. Abel.—Communicated by H. Leplay. Improvements in osmose apparatus. 10d

## XVI.—BREWING, WINES, SPIRITS, ETC.

1884.

8916 J. Walker. Making an extract and beverages from clover. 4d

9397 J. C. Mewburn.—Communicated by E. A. Barbet. Process for the continuous distillation and rectification of alcohols or other volatile substances, and apparatus for the purpose. 6d

9546 E. G. Brewer.—Communicated by L. Koppel. Cooling and ventilating apparatus for use in malting establishments. 6d

1885.

3193 A. Behr. Apparatus and process for producing malt. 8d

## XVII.—FOOD PRESERVING, MEATS, ETC.

1884.

16376 F. Walton. Preservation of meat extracts. 4d

## XVIII.—SANITARY CHEMISTRY, DISINFECTANTS, ETC.

1884.

9538 G. R. Tweedie and Hartin's Crimson Salt Co. Improved disinfecting, deodorising, and antiseptic compounds. 4d

9587 J. Hanson. Treatment of sewage or foul waters, or other solid and liquid impurities, or foul matters, for the purpose of deodorising the same, and for the prevention of the formation of sewer gas. 4d

10045 H. B. Condy. Manufacture of disinfectants. 4d

11901 W. Astrop. Process of deodorising, disinfecting, precipitating, drying, and pulverising the solid portions of sewage to render it a marketable manure. 6d

## XIX.—PAPER, PASTEBOARD, ETC.

1884.

9509 S. Pitt.—Communicated by R. P. Pictet and G. L. Bredaz. Manufacture of pulp from woody matter by chemical process. 6d

9714 T. A. Reid. Gas-fired digester for use in the manufacture of pulp from wood, etc. for paper making. 8d

797 A. Behr. Process and apparatus for the manufacture of cellulose and glucose from wood and other vegetable products. 8d

14735 T. Graham Young and J. Pettigrew. Treating vegetable substances in order to obtain fibrous materials for textile purposes, and pulp for making paper, etc. 4d

## XXI.—EXPLOSIVES, MATCHES, ETC.

1884.

6315 T. Nordenfelt and V. A. Meurling. Manufacture of gunpowder and like explosive compounds. 4d

7108 H. H. Lake.—Communicated by H. Gruson. Presses or apparatus for the manufacture of compressed gunpowder. 6d

9096 W. A. Barlow.—Communicated by A. Gacon. Manufacture of explosives. 4d

### NOTICE.

Notice is hereby given that the resolution, embodied in the Report of Council to the Annual General Meeting, 1884, which forbids the publication of communications other than those read before the Society or its Sections, is now rescinded. Communications bearing upon Technical Chemistry can now be sent to the General Secretary, and, if they be approved by the Publication Committee, will be inserted in the Journal.

#### LIST OF MEMBERS ELECTED JUNE 23rd, 1885.

G. S. Bowler, 21, Pembroke Square, Kensington, W., demonstrator of chemistry.  
J. A. Bradburn, c/o Brunner, Mond & Co., Northwich, chemist.  
Jno. C. Cottam, The Hyde Side, Lower Edmonton, chemical engineer.  
F. E. Goodhart, 11, Great George Street, Westminster, S.W., solicitor.  
John Gray, 25, Southampton Buildings, W.C., examiner of patents.  
Dr. H. Kuperberg, chemical works, Blackley, near Manchester, chemist.  
Geo. A. Liddle, Falkirk, N.B., chemist.  
T. G. McKean, 33, New Road, Commercial Road, E., chemical engineer.  
Jno. Tuscoe, Albion Works, Henry Street, Hyde, near Manchester, engineer.  
Hermann Voss, Holstein House, Whitworth Road, South Norwood, S.E., manager of manure works.

#### CHANGES OF ADDRESS.

W. H. Allen (c/o Church Street), 97, College Street, Toronto, Canada.  
Wm. Brathy (c/o Pott Street), Sandford Street, Ancoats, Manchester.  
E. Colless (c/o Birmingham), Vinegar Works, Stourport, Worcestershire.  
W. R. Dunstan (c/o Oxford), 17, Bloomsbury Square, London, W.C.  
H. E. Edmunds (incorrectly spelt "Edwards" in printed list), 10 Primrose Hill, 90 State Street, Brooklyn, U.S.A.  
J. A. Graham (c/o Werter Road), 20, Disrach Road, Putney, S.W.  
S. L. Howard (c/o Loughton), 4, Cranley Mansion, Gloucester Road, London, S.W.  
L. Johnstone (c/o Caroline Park), c/o Mrs. Johnstone, 6, Mayfield Terrace, Edinburgh.  
A. Liebmann (c/o Manchester), 62, Meckenheimer Strasse, Bonn.  
Wm. Martyn (c/o Boston, U.S.A.), c/o Messrs. Tennant, Hebburn-on-Tyne.  
C. D. McAllum (c/o Wentworth Place), 7, Dean Street, Newcastle-on-Tyne.  
N. Nutter (c/o Cornhill), 8, New Broad Street, London, E.C.  
A. G. Ronaie (c/o Royal Terrace), 27, Lansdowne Crescent West, Glasgow.  
J. G. Richardson (c/o Hebburn Hall), 24, Windsor Terrace, Newcastle-on-Tyne.  
F. T. Schreiber (c/o Bolton), Auckland Villa, Auckland Hill, Lower Norwood, S.E.  
Jos. Stapleton (c/o Shepherd's Bush), 3 Lower Sackville Street, Dublin.  
D. Stewart (c/o Wemyss Bay), Kincaid House, Milton of Campsie, N.B.  
G. R. Tweedie (c/o Brixton), 2, Torriano Villas, Broadstairs, Kent.  
A. J. Watts (c/o South Hampstead), Engo Central de Bom Gorto, Agua Preta, Pernambuco, Brazil.

## CHANGES OF ADDRESS REQUIRED.

W. Arthur, 10 Ringsend, Dublin.  
E. T. Brewis, 10 Great Brunswick Street, Dublin.

## Death.

Edgar Hall, sen., 10 Queenboro', Kent.

## London Section.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE.

Chairman: David Howard.

## Committee:

Sir F. A. Abel.	B. E. R. Nowlands.
H. E. Armstrong.	B. Redwood.
W. Crowder.	T. Royle.
C. Graham.	John Spiller.
S. Hall.	G. C. Trewhby.
A. R. Huntington.	W. Weldon.
R. Messel.	J. Williams.

Local Sec. and Treasurer: Thos. Tyrer,  
Garden Wharf, Church Road, Battersea, S.W.

MEETINGS, SESSION 1885.—First Monday in each month  
(unless otherwise indicated).

July.—The Annual General Meeting.  
Notices of papers and communications for the meetings to be sent to the Local Secretary.

Meeting held June 1, 1885.

DR. CHAS. GRAHAM IN THE CHAIR.

THE INFLUENCE OF PHOSPHATES UPON  
FERMENTING WORTS.

BY ALFRED GORDON SALAMON, A.R.S.M., F.C.S.; AND  
W. DE VERE MATHEW, F.I.C.

The various considerations which might suggest themselves as affording scope for argument in connection with the research, which we have the honour of submitting to you to-night, are necessarily of a most complex and intricate character; because of the veil of mystery which still envelopes so many of the phenomena, collectively constituting the process of fermentation. Hence it is that we feel the necessity of at once disposing of the possible charge of having aimed at too much, and of stating emphatically that our object has been to solve a problem savouring rather of industrial than of purely philosophic interest; to offer a few contributions which may possibly be capable of direct assimilation to the work of the practical brewer, rather than discuss the abstruse biological and physiological aspects of a subject, of which the sum total of our information must still be said to be represented more by its high-flown nomenclature, than by the extent of knowledge which such nomenclature might be assumed to imply.

If we examine the analysis of the ash of the yeast plant, we shall find that phosphorus enters very largely into its composition. The exact condition in which it exists is probably unknown; but inasmuch as potash is present in notable quantities, and cannot be satisfactorily accounted for in combination, unless by reference to the contained phosphorus, it is assumed, and probably correctly, that the phosphorus of yeast is chiefly combined with mineral bases; and, indeed, that it exists almost entirely as phosphate of potash.

Inasmuch as there is no record of a sample of yeast ever having been isolated of which the ash could not

be proved to contain phosphorus; and since experience has proved that no satisfactory growth of the plant takes place in a medium devoid of a certain quantity of this element, it is further assumed—and again we must agree with the deduction—that it constitutes a nutritive element, which is absolutely necessary to a favourable growth and development of the yeast.

If the assumption had been carried no further than this, we should have had no occasion to trouble you with our observations to-night; for we should scarcely have ventured to attack the very difficult, but exceedingly interesting, problem of determining what *role* it is that phosphorus actually plays in the nutrition of the plant. But matters have not been allowed to rest here; and it has been urged—apparently with the idea that one cannot have too much of a good thing—that it is advisable to introduce additional phosphate into the medium in which fermentation takes place. We find, for instance, that bone ash is often added, in certain of the wine districts of France, with a view to accelerate the action of the ferment; and, further, that several of the authorities, to whom the brewers look for scientific instruction, advocate the addition of certain phosphates to fermenting worts, in order to increase the efficiency of the action of the yeast. Of late this practice has become so pronounced that there are now several so-called yeast-foods in the market, the active principle in all of them consisting of some form of phosphate.

Now, so far as our reading carries us, we can find no record of any systematic series of experiments having been undertaken, with a view to determine whether any benefit really results from such an addition; and in its absence we are led to the conclusion that the practice is one which is absolutely empirical. In saying benefit we must be understood to limit the expression to the *ultimate product of the manufacturer*; for it would be obviously difficult, if not impossible, to separate the newly-formed cells from the old in such a manner as to determine whether the young cells assimilated more phosphorus than the parent cells. Such a consideration would constitute a type of what we have termed the biological, or physiological, aspects of the question. But it does seem possible to investigate the matter so as to arrive at results which shall have some distinct practical value, and which shall decide whether the use of such "foods" is objectionable or commendable.

In view of the great importance which the subject of yeast nutrition and development possesses for the brewer, we have been induced to undertake the experiments which we now submit, in order to assist him in forming some reliable opinion upon the matter. The vast scope of the subject has, however, compelled us to limit our experiments to brewing operations, and we would state that although they may have some bearing, they have no *direct* reference to the work of the distiller, or the producer of wine.

Granting that the presence of a certain amount of phosphorus, in some combined form, is necessary to the due activity of yeast, it becomes important to inquire to what extent this element is present when brewing operations are conducted under *normal* conditions; how much is assimilated during the process of fermentation; and, further, whether any remains unused in the finished beer.

If it can be shown that finished beer contains a notable amount of phosphorus, originally derived from the malt, and subsequently passing into the wort; that some of the phosphorus of this wort has been absorbed or assimilated during fermentation, and that a considerable proportion has been left untouched; then—inasmuch as the finished beer has no opportunity of obtaining any phosphorus which it did not contain in the wort—unless it can be proved

that the phosphorus, which is left, has undergone some modification of combination, which has rendered it inert for purposes of yeast assimilation; or that it originally existed in an unavailable condition, it would certainly appear, *prima facie*, that there can be no object in adding a further supply.

The following tables of analyses which we have performed, are instructive upon this point:—

## ANALYSIS OF SAMPLES OF 1884 MALT.

No.	LOCALITY.	ON DRY SUBSTANCE.			
		Ash	Total N	Soluble N	P <sub>2</sub> O <sub>5</sub>
		Percent	Percent	Percent	Percent
1.	Austria .....	2.51	1.180	356	1.101
2.	Moravia .....	2.17	1.371	382	935
3.	Hertfordshire .....	2.29	1.385	1.103	917

The phosphoric acid estimations contained in the above tables, as indeed all similar analyses to which we shall have occasion to refer in the course of this paper, were made gravimetrically upon the ash yielded by a given quantity of the liquid, or the malt. The phosphate was precipitated with ammoniac molybdate solution, and allowed to stand in a warm place all night, and then filtered off. The precipitate was next dissolved on the filter with ammonia and reprecipitated with magnesia mixture. After allowing to stand in the cold for at least twelve hours, the resulting ammoniac magnesian phosphate was filtered, thoroughly washed, strongly ignited, and the resulting magnesian pyrophosphate weighed.

An inspection of the table showing the amount of P<sub>2</sub>O<sub>5</sub> removed during fermentation, proves that the quantity required for yeast nutrition, or whatever function it may perform, is exceedingly small. We have never met with a case in which, during what we may term the commercial limits of attenuation, the quantity thus removed has exceeded '03 gramme per 100cc. of wort fermented.

Again, the table clearly shows that in every case, at the conclusion of the fermentation there exists a quantity of unabsorbed, or unremoved, phosphorus. As we have stated, this *may* exist in some form of combination different to that which *has* been removed; and consequently it may be present in an absolutely inert condition; but we are ourselves unaware of any reliable arguments, which could be adduced to support such a contention.

The practice, now almost universal in English breweries, of employing a certain quantity of some ready-made brewing sugar in the process of manufacture, will undoubtedly have the effect of reducing the amount of phosphorus present in the wort. Advantage has been taken of this fact to urge the desirability of adding yeast-foods to supply this deficiency. In order to test the value of this assertion, we have estimated the amount of phosphorus (as P<sub>2</sub>O<sub>5</sub>) in worts containing brewing sugar, and obtained from various parts of the country; and it will be seen that in every analysis we have made, we have found considerably more phosphoric anhydride present in the wort than we have found to be removed during the normal period of fermentation.

Hence it would certainly appear that English beer worts do contain much more phosphorus than is required for fermentative purposes.

The analyses of the malts have disclosed certain facts, so distinctly at variance with the doctrines promulgated by some of our leading authorities; that at the risk of a somewhat serious digression from the true scope of our paper, we feel compelled to direct attention to them.

In a paper upon lager beer read before this Society by Dr. Graham, the following statement occurs:—Speaking of the analyses of lager beer, he says: "In these analyses the nitrogen has been determined by the soda lime process which is employed by most German analysts, by whom the factor 6.25 is used to convert the nitrogen into albumenoids. This is misleading, and gives results far too high, since all nitrogenous compounds are thus calculated as albumenoids. For many years past I have used boiling alkaline permanganate as a more correct method of arriving at the albumenoids, and in the analyses of the English ales and German beers made by me, the albumenoids so found were given. Though the process is far from being scientifically accurate, yet the method, from a technical point of view, has been of great service to me in forming an opinion as to the relative merits of *malt* from an English brewing point of view; and of equal service in deciding as to the keeping qualities of store ales. Thus with English ales I have, for some years past, adopted the factor '01 of albumenoids, as given by the moist combustion process, as the standard for sound English ales per 1lb. per barrel original gravity;" and again further on he states that "we find English brewers competing with each other for the finest barleys, *that is, for those with least yield of soluble albumenoids.*" (The italicised portions of these quotations are underlined by us.)

Now those who have had any experience with the moist combustion process, as applied to the determination of nitrogen in malts and worts, will cordially agree with Professor Graham, when he speaks of its scientific inaccuracy; and, unless it be upon the

score of convenience, we cannot see that it is to be preferred to the old-fashioned soda-lime process. Undoubtedly, it may afford comparative results, and would seem to have induced Dr. Graham to form the opinion—which is the only one to be inferred from the above quoted passages—that for the purposes of the English brewer the best malts are those which yield the least amount of soluble albumenoids; and inasmuch as he has fixed a standard of soluble albumenoids for ales, above which he would not pass them for store purposes, we feel further justified in concluding that he would condemn, as unfit for use by the English brewer, a malt giving a high yield of soluble albumenoids.

Now this decision, coming from so great an authority, is of such importance to English brewers and maltsters, that we would ask your indulgence while we examine into its accuracy.

The nitrogen determinations, as represented upon our table of malts, were made in the following manner:—

For the total nitrogen, about 2 grm. of the finely-ground malt were washed into a combustion tube with copper oxide, and the usual roll of copper was inserted in the tube. The unsealed end of the tube was then drawn out, and connected with a Sprengel pump; the furnace being lighted at the end farthest from the malt, the pump was started and a vacuum obtained; and the combustion was then effected in vacuo. Over the mouth of the delivery tube of the pump was placed a tube containing mercury, and also some strong caustic potash, to absorb the carbonic anhydride, evolved as a product of the combustion of the malt. The resulting nitrogen gas, collected over mercury and caustic potash, was next transferred to a gas apparatus, and, after all necessary corrections had been made, the volume of nitrogen thus measured was converted into its corresponding weight in grammes.

For the soluble nitrogen, a mashing of the malt upon the small scale was made; but inasmuch as we preferred to work with small quantities of material, we did not dilute the extract until it obtained the quantity of soluble nitrogen, that would be represented by an English wort. Such a dilution was quite unnecessary for our purposes. In each case, the method of procedure was absolutely the same, so that the results are rigidly comparable. We proceeded as follows:—A grist corresponding to that in use in breweries was made of each sample of malt; 25 grm. of malt were weighed into a beaker, into which 125 cc. of distilled water were introduced, at such a temperature that the initial heat was about 50° C. This was maintained for about twenty minutes. The temperature was then raised to about 60° C., and thus maintained until the iodine reaction showed that a complete conversion had been effected. The temperature was then raised to about 70° C., and then the water in the bath was made to boil for about five minutes. The extract was next filtered off hot, and washed out in each case to the same extent. It was cooled, and then 1 cc., after well stirring, was evaporated gently, and the residue submitted to combustion in vacuo, as before.

The resulting soluble nitrogens, thus obtained, were not multiplied by us by the factor 6.25; because, with all deference, we regard the use of such a factor as simply effecting an increase in the possible error of experiment; and, at the same time, as expressing the ignorance, which we share in common with other chemists, as to the true mode of combination of nitrogen, and more especially of soluble nitrogen, in malts and worts.

Dr. Graham maintains that the total soluble nitrogen estimations, as indicated by the soda-lime process, are far too high, since all nitrogenous compounds are thus calculated as albumenoids; but we take it that Dr. Graham would scarcely contend that the nitrogen results, as yielded by the moist combustion process, give a reliable indication of the *nature* in which the nitrogen is combined—that they show any distinction between the amides and proteins and peptones. Dr. Graham's results being lower than those obtained by the soda-lime process, it would be interesting to know in what manner he accounts for the remaining nitrogen, which is undoubtedly present. In what form does it exist? It is certainly in a soluble condition; and what reasons are there for regarding it other than as soluble albumenoid matter? If there are any reasons, are they sufficient with it to build up a standard which shall condemn or pass malts for brewing purposes? In the absence of further information we are inclined to think they are quite insufficient; and we can further state that results which we have seen obtained by this moist combustion process are simply mystifying.

We have felt it necessary to take these preliminary objections, because the results which we have obtained show that on no account should a malt be condemned for English brewing purposes because it contains a high amount of soluble nitrogenous matter.

In order to give our results some practical value, we decided to obtain the opinion of experts upon the physical appearances of the malts upon which we experimented, and to see how their verdict would correspond with our analyses. Among others we submitted them to Mr. Frank Wilson, the head brewer to Messrs. Combe & Co., who kindly undertook to classify them for us. The sixteen malts (supplied from the bins of different breweries) were laid out upon a table, and the laboratory number was placed upon each sample. The malts were not placed in what we considered their order of merit, but indiscriminately, and Mr. Wilson had no information, other than his experience to guide him. The numbers upon the Table of Malt Analyses represent the exact order in which he placed them. The sample of Smyrna malt being so different from the others could be at once detected, and was, therefore, placed out of the competition. Now, looking at the amounts of soluble nitrogen in the fifteen remaining malts, and further, having reference to the order in which they were placed, it will at once be seen that the best malts are among those containing the highest percentages of soluble nitrogen, and that the worst of all (No. 15) contains the least. This last was declared by Mr. Wilson to be *very deficient in germinating power*.

We do not go so far as to reverse Professor Graham's statement, and declare that the more soluble nitrogen a malt yields the better it is for brewing purposes; but we do think that such an assertion would be nearer the truth than the converse.

A practical result, arising from Mr. Wilson's verdict upon the malts, is that a malt, which appears to have been well nourished upon cultivated land, is other things being equal, richer in soluble nitrogen than a poorly grown malt, and this is probably the reason why the malts are placed as they are in the table.

The amount of nitrogen in malts and worts is undoubtedly of the very greatest moment; but we submit that very little is to be gleaned from its estimation until we are in a position to determine the mode of combination in which it is actually present.

We should add that other gentlemen who were good enough to examine the malts, placed them almost exactly in the same order as did Mr. Wilson.

[Mr. Salamon here asked the Chairman's permission to inform the meeting that he had that day seen Mr. Wilson, and had read the paper to him. Mr. Wilson had authorised him (Mr. Salamon) to express to the meeting his regret at being prevented by indisposition from attending; and further, to state that he entirely agreed with the interpretations which had been placed upon his classification of the malts as given in the table.]

It has been repeatedly stated that the standard of a good malt, when considered with reference to its fitness for use in the decoction process, does not necessarily constitute a standard for judging of the suitability of a malt for use by the method of infusion. This arises from the fact that beer produced by the decoction process contains more nitrogenous matter in solution than does the beer prepared by the process of infusion. If this statement be rigidly correct, it detracts to a certain extent, in the eyes of the English brewer, from the value of the researches, which have been conducted by foreign observers upon this question; but it can scarcely interfere with the importance attaching to the results which they have published respecting yeast nutrition.

So far as the nitrogen in malts and worts is concerned, we find that they substantially agree with our own observations. Let us briefly glance at some of them.

K. Reischauer (*Bied. Centr.* 1882, 42) finds that malting barleys differ very materially in their composition. He summarises his results as follows:—

	Nitrogen.	Ash.	P <sub>2</sub> O <sub>5</sub> .
Maximum ...	2.856	3.340	1.145
Minimum ...	1.282	2.120	.614
Mean ...	1.729	2.739	.902

Dr. C. Lintner, an authority of great repute, goes so far as to state (*Dingl. Polyt. J.* 251, 225-228) that the amount of nitrogen in barley or malt bears no relation to its diastatic action, and he also expresses it as his opinion (*Dingl. Polyt. J.* 247, 350) that barley should contain at least 1.67 per cent. of nitrogen in order to produce a good beverage.

Thausing, whose book upon brewing is so highly esteemed in this country, makes a statement (*Dingl. Polyt. J.* 247, 350) which will surprise not a few of you here to-night, to the effect that a wort will not form a good nutrient for yeast unless it contains a comparatively large amount of soluble nitrogenous matter. It is only within recent years, he says, that this fact has received the attention which it deserves; and it is now recognised that barley containing little proteid matter gives malt, the starch of which is with difficulty convertible into sugar.

It is interesting to compare this statement with Mr. Wilson's opinion upon No. 15 malt as analysed by us.

Heinzelmann (*Bied. Centr.* 1880, 475-478) finds that the yeast-producing power of grain is not proportionate to the quantity of nitrogen it contains, but to the amount of soluble protein. This he states to be a very variable quantity.

Some chemists consider the presence of soluble nitrogen of such importance in promoting germination, that they go so far as to recommend its addition to the steep-water used in the production of malt. Thus, Mills and Pettigrew (*Chem. Soc. J.* 1882) advise the use of small quantities of calcic nitrate for this purpose, and they are confirmed in their view by Michel and Jaeckel-Handwerk (*Dingl. Polyt. J.* 217, 82-85, 168-173, 214-218), who state that the reputation of the Burton steep-water is attributable to the fact that it contains nitrates, which promote germination.

[We have not had an opportunity of repeating these last interesting experiments, and therefore we merely quote them.]

A question which has not yet received its due share of attention, but which is undoubtedly of the greatest importance, arises out of the influence of kiln-heat upon the nitrogenous constituents of malt. It is found that the amount of nitrogen diminishes with the increase of heating, but (*Bied. Centr.* 1881, 357) that the change in the amount of nitrogen produced by malting at a high temperature, does not correspond with a change in the diastatic action of the malt. Hence it is necessary to examine malt, with respect to its firing, before forming any opinion as to the amount of nitrogen present in it.

We have again to request that the importance of the subject into which we have digressed may be considered as a sufficient excuse for our having committed the offence.

In making the estimations of soluble nitrogen in the malts, we were under the impression that we might possibly discover the existence of some relation between the quantity of nitrogen and of phosphorus. In this view we were mistaken; no such relation exists; and we have since found that we are confirmed in this opinion by L. Marx (*Bied. Centr.* 1884, 853-855), who made no less than 400 analyses of different malts with an exactly similar object. All that we can say is, that the amount of phosphorus in malts varies within very wide limits; and that when the barley is grown on a highly cultivated land, the amounts of phosphorus and of nitrogen will both be high; and that when the land is poor, as in the case with Smyrna malt, the amount of phosphorus will be low. When the phosphorus is low, the yield of barley will probably not weigh so much per acre; but for brewing purposes, as regards the quality of beer obtainable, the malt produced from it may be equally good. Thus, the first two malts upon the list are both classed as No. 1 for brewing purposes, because they are equally good as judged by external appearances; but Mr. Wilson is of opinion that the yield per acre of Austrian malt would have been much greater than of Moravian; and we find that the former is much higher in phosphorus and soluble nitrogen than the latter. Again, Smyrna malt, which is exceedingly useful in some cases, would not yield a large crop by weight; and we find that it is low in its percentage of phosphorus.

But although good malts in many cases yield a high percentage of phosphorus, it by no means follows that an excess of it exerts a favourable action either upon the character of the wort or the subsequent fermentation. Indeed, we have every reason to believe that the contrary is the case.

It is known that certain of the soluble nitrogenous bodies, germane to worts, are exceedingly rich in phosphates. This is especially the case with the unreal peptones, which are said to contain the phosphorus in the form of a compound ether. One of these unreal peptones—viz., gluten-casein—frequently exists in considerable quantities in worts. It is decomposed on boiling, so that when the wort "breaks" the phosphorus passes into solution in the form of acid phosphates; and Thausing states that they are in a great measure responsible for the acidity of worts, and ascribes to such decomposition of certain nitrogenous combinations the fact, which he has noted, that the longer a wort is boiled the more acid it becomes.

If this be so, it can scarcely be urged that the presence of phosphates constitutes an unmixt bless-

ing. W. Detmar (*Bied. Centr.* 1883, 71) is still more emphatic in his view, for he states that phosphoric acid, if present in worts in large quantities, completely destroys the action of the diastase.

So much, then, for the phosphates in malt and worts. Let us now proceed to ascertain the influence which they exercise upon the subsequent fermentation.

The preliminary experiments which we conducted upon this subject, were performed upon materials over which, we considered, we could exercise absolute control. We were anxious to eliminate every possible source of error, arising from the varying composition of commercial worts; and we therefore employed artificial nutritive media similar to that of which "Pasteur's solution" is a type. We added varying quantities of different phosphates to equal quantities of the same solution, fermented with the same amount of yeast in each case; and noted the variation which had been exercised upon the separate fermentation of each series, by estimating the amount of cane sugar which had been decomposed in a given time. This, of course, corresponds to the production of comparable quantities of alcohol during the same period; for we thought that we might disregard the energy involved in the inversion of the cane sugar by the yeast prior to fermentation, because the error, if any, was constant throughout. The sugar was, in each case, estimated gravimetrically by Fehling's solution. The solutions were thoroughly sterilised, and subsequently cooled, before the addition of the yeast. The vessels containing the varying quantities of phosphates in the artificial solutions were all kept under exactly similar conditions of temperature. The temperature of pitching was in all cases 60° F.

The amount of yeast added corresponded to 1½ lb. avoirdupois per barrel, which may be taken as the average quantity used upon the commercial scale.

The ingredients used in the preparation of the solutions were chemically pure.

Appended are some of the typical results actually obtained, together with details as to the varying quantities of solution and yeast employed, and as to the time during which fermentation was allowed to proceed:—

#### POTASSIUM PHOSPHATE.

Potassium Phosphate in solution, in grammes per 100cc.	Equal to P <sub>2</sub> O <sub>5</sub> in grammes per 100cc.	1st Series. Sugar used, grammes per 100cc.	2nd Series. Sugar used, grammes per 100cc.	4th Series. Sugar used, grammes per 100cc.

		300cc. solution, 1½grm. of yeast. Time, 60 hours.

In this experiment the amounts of potassium and calcium phosphates, normal to Pasteur's solution, were employed in addition to the magnesium phosphate.

Now, whatever may be the value attaching to these preliminary experiments, from the practical brewers' standpoint, it will not be denied that they possess a certain value: for they show, clearly enough, that the presence of a certain amount of potassium and calcium phosphates is advantageous in promoting the decomposition of cane sugar by yeast in a given time; and that beyond a certain limit, which very nearly approaches the normal amount of such bodies prescribed by Pasteur for addition to his solution, a decided decrease takes place in the amount of cane sugar so decomposed. They further show that the addition of magnesium phosphate to such solutions is of no use; inasmuch as it would appear to be practically inert as regards the decomposition of cane sugar in a given time.

We have next to decide whether a similar result attends the introduction of such phosphates, and of other forms of phosphates, into worts prepared in the brewhouse for conversion into beer.

In order to arrive at a satisfactory conclusion in the matter we have proceeded as follows:—

In all cases commercial worts were employed—i.e., worts obtained from breweries, and prepared for fermentation with a view to the production of beer. Much larger quantities were operated upon than in the preliminary experiments, no less than 1000cc. being used in each case. The yeast was also what may be termed commercial yeast—i.e., it was fresh yeast, actually used in brewing operations. It was always freed from associated liquid by pressure prior to pitching, but the pressure was never allowed to be sufficient to injure the cells. In every case a microscopic examination of the yeast and measurement of the cells were made prior to use. If any cells were burst the samples were rejected, and a similar treatment followed the discovery of any dead or weak cells, as disclosed by staining with soluble aniline blue.

The wort was always examined microscopically prior to use, and if impure was rejected; if pure, it was heated to 75° C. for some time, and then cooled down to 15° C. It should be added that the wort was always obtained by us after it had been passed through the refrigerator, so that it had been both boiled and hopped.

After the wort had been cooled, it was thoroughly mixed, a portion retained for immediate analysis, and three separate quantities of 1000cc. each introduced into large open-mouthed glass vessels (resembling fermenting tuns in shape), kept as nearly as could be under identical conditions of temperature, and certainly under conditions favourable to fermentation. The vessels were numbered. To the first no combination of phosphorus was added; to the second was added sufficient of the combination to produce the equivalent of  $P_2O_5$  of soluble phosphate in normal Pasteur's solution; and to the third was added double that amount.

With each 1000cc. of wort, 3.5gm. of yeast (equal to 1½ lb. avoirdupois per barrel) were then mixed, and fermentation was allowed to proceed during forty-eight hours. We found this time best suited to the manipulation of such comparatively small quantities of wort; although we did not find any variation in the ultimate results by allowing a longer period of time for fermentation.

The three vessels being under identical conditions, containing equal amounts of wort, equal amounts of yeast, and only varying in the amounts of phosphorus which they contained (which amounts we had under our own immediate control), we were in a position to note the comparative effects produced by increasing quantities of the phosphorus combination.

At the conclusion of the fermentation a measured quantity of beer from each vessel was passed through a fine filter, after well stirring up the beer and yeast in the vessel; and the yeast, so obtained, was calculated after making due corrections for moisture. The results thus obtained as to yeast quantity were necessarily very inaccurate; but they furnished us with comparative results of great value.

The remainder of the beer from each vessel was filtered, and a measured quantity retained for analysis.

The yeast, after fermentation, was examined under the microscope, and the comparative size of the cells noted.

We considered it necessary, for the purposes of this research, to obtain answers to the following questions:—

(1) Does the addition of any combination of phosphorus to a beer-wort cause any more phosphorus to be removed from the wort during fermentation, than would be removed if no such phosphorus were added?

(2) Does the addition of phosphorus, in combination, to a wort cause a greater amount of soluble nitrogenous matter to be removed, or assimilated, during fermentation, than if no combination of phosphorus were added?

(3) Does the addition of phosphorus, in combination, to a wort cause the production of a greater amount of alcohol in a given time, than would be the case if no such phosphorus were added? In other words, does it produce a more rapid attenuation of the wort?

(4) Does the addition of phosphorus, in combination, to a wort effect an increase in the amount of yeast produced in a given time?

(5) Is the yeast so produced better adapted for pitching purposes than if no such phosphorus were added? In other words, is it more vigorous and has it assimilated any of the elements necessary to its growth in greater quantity than would otherwise have been the case?

Unless some, or all, of these questions could be answered in the affirmative, we hold we are justified in concluding that, for the purposes of the brewer, the addition of phosphates to fermenting worts is unjustifiable.

We attempted to obtain answers to these questions in the following manner:—

The wort, before being fermented, was examined:—

1. For gravity.
2. For nitrogen.
3. For phosphorus (as  $P_2O_5$ ).
4. The amount of yeast added was noted, and the size of the cells measured.

The resulting beers were examined for:—

1. Alcohol per cent. by weight.
2. Nitrogen.
3. Phosphorus (as  $P_2O_5$ ).
4. Weight of yeast produced, and size and condition of growth of resulting cells.

Unless a greater quantity of yeast resulted from the addition of phosphorus, the first question, as to the amount of phosphorus assimilated by the yeast, would certainly be answered by estimating the  $P_2O_5$  in the wort, and comparing the amounts contained in the three beers produced from it. If, on the other hand, more yeast were produced, more phosphorus would be required, and the result would point in favour of the use of phosphates.

The estimation of nitrogen is of the greatest value, because it settles the question of yeast production. M. Delbrick and others (*Biol. Centr.* 1880, 217-222) have found as the result of a very beautiful investigation, that the chemical composition of a definite sample of pitching yeast remains absolutely constant during its development in the wort; and that the new yeast produced is identical in chemical composition with the old, so that the amount of nitrogen removed from a wort during fermentation, becomes an exact measure of the amount of yeast produced during that period. They find this process exceedingly accurate, and further add that the formation of the yeast-cells has practically no connection with the visible working of the wort.

We may state at once that in no case did we find any alteration in the size and condition of the yeast-cells, upon the addition of phosphorus combinations, unless we added a great excess, when we found the cells to be stunted in growth and shrivelled.

The combinations of phosphorus with which we worked were the following:—

1. Ortho-phosphoric acid.
2. Meta-phosphoric acid.
3. Potassium phosphate.
4. Magnesium phosphate (a) in powder,  
(b) dissolved in sulphurous acid.
5. Calcium phosphate.
6. Ammonium Phosphate.
7. Ammonium-magnesium phosphate.

The most reliable, and the most typical, results obtained by us are shown in the tables on this and previous page.

There can scarcely be two opinions as to the interpretations which should be placed upon the results, which we have obtained, and so far as the matter has been investigated by other chemists, their observations tend precisely to the same conclusions as our own. Thus:—

M. Hayduck (*Bied. Centr.* 1881, 782) finds that fermentation is retarded by 4 per cent. to 5 per cent., and is suppressed by 1.2 per cent. of phosphoric acid.

W. Detmer (*Chem. Centr.* 1882, 461) finds that concentrated phosphoric acid is destructive of ferment life.

A. Mayer (see Thausing, p. 536) states that it is

potassium phosphate which furnishes the nutriment to yeast; and that its place cannot be supplied by any other phosphate.

We are now in a position to summarise the results of our experiments as follows:—

1. There is no relation to be found between the phosphorus and nitrogen of a malt, or of a wort prepared from such malt.

2. The amount of phosphorus in a malt, and consequently in a wort, is a very variable quantity. There is no evidence to show that a large amount acts beneficially, either upon the wort itself, or its subsequent fermentation; but there is abundant evidence to show that its effect is decidedly injurious to both.

3. The presence of increasing quantities of phosphoric acid does not increase the growth of yeast, as indicated by the size or appearance of the cells beneath the microscope, or by the amount of nitrogen removed from the wort, which amount has been found to be a rigid measure of the yeast-growth. On the contrary, a decrease in such quantities occurs, and further, no more phosphorus is assimilated by, or removed from, the yeast than would have been the case if no artificial addition of phosphoric acid had been made.

4. The same remarks apply to the effect of increasing quantities of potassium and of calcium phosphates;

also of magnesium phosphate, and of magnesium phosphate dissolved in sulphurous acid.

5. The addition of ammonium phosphate, and of ammonium-magnesium phosphate, causes a slight increase in the amount of  $P_2O_5$  removed, or may be assimilated, during fermentation; but there is no evidence to prove that it exercises any improvement in the yeast-growth. On the contrary, the amount of nitrogen removed does not increase, as it should do, if the yeast-growth underwent any *variation* favourable to the use of such phosphates, and the attenuations do not point to a marked increase of alcohol in a given time.

6. Ammonium phosphate and ammonium-magnesium phosphate are the only two combinations which can be said to effect any improvement at all; and in any case it is so slight as to be almost negligible.

7. The amount of phosphorus required for assimilation during fermentation is very small, and, as a rule, very much less than the nitrogen weight for weight.

8. The amount of phosphorus present in worts, made from malt alone, and in worts containing added brewing sugars, is always, so far as we can ascertain, in excess of the quantity assimilated by the yeast, during the normal period of fermentation.

When first we announced our preliminary experiments upon this subject it was claimed that they were incomplete; and would not apply to the work of the brewhouse, inasmuch as they were not performed upon materials actually employed in the brewery. We were well aware at the time of the difficulties in the way of making the experiments upon worts; but we have ventured to overcome them, with a view to afford the brewer the information necessary to enable him to form a reliable opinion as to the merits of a question, which exercises much more influence upon his operations than he may hitherto have been prepared to admit.

If we have succeeded in this endeavour, we shall consider ourselves well repaid for the time, and trouble, we have expended upon the experiments.

#### DISCUSSION.

Dr. GRAHAM said: In calling upon those, who desire to discuss the valuable paper we have had the pleasure of hearing this evening, I take the opportunity of remarking that the very many representatives of the brewing and allied industries present, prove that, at the establishment of the Society of Chemical Industry, we did well to include fermentation processes among the subjects of applied chemistry, which the Society was established to study and promote. Brewing, distilling, and other industries allied to these, are well represented among the members of our already large Society, and as there are many present to-night specially competent to discuss the authors' contribution to the chemistry of fermentation, I have much pleasure in now asking them to do so.

Mr. CHARLES F. THATCHER, speaking as a practical brewer, and from the experience gained during the last eighteen or twenty years, said: Some years since, when in the West of England, I was advised by a well-known authority on brewing to use bone ash as a yeast-food or stimulant; after giving it a comparative trial, extending over some weeks or months, failing to trace any direct beneficial result I discontinued the use of it. Now, with regard to Smyrna malt, I have had, I believe, a rather exceptional experience, as at the brewery before alluded to I produced all classes of ale and stout for a period of over nine months with *Smyrna malt alone*, combined with a certain percentage of *lævo- or dextro-saccharum*. The reasons which induced me to adopt

this course were, first, economy; and, secondly, the satisfactory nature of the article produced. I believe I am correct in stating that the same principles are still continued at the brewery I refer to. An important point, as bearing upon the subject before us, is, that I always found the yeast obtained from fermenting wort in which Smyrna malt was employed, both vigorous, well-developed, and solid in character, and also abundant in quantity; therefore, taking into consideration the fact, as stated by Messrs. Salamon and Mathew, that this malt contains only a small percentage of phosphates, as compared with English malt, I think we may fairly assume, that beyond a certain point, phosphates are not necessary to the production and development of the yeast plant.

Mr. SHEARER: It would be interesting to know whether Messrs. Salamon and Mathew had made any experiments with the view of determining the vigour of the yeast crops obtained in their miniature fermentations. The production of yeast fitted for continuing the successive fermentations was, to the brewer, a matter of the highest importance; and although fermentation was carried on with the object, primarily, of converting sugar into alcohol, the operation was one which by the formation of a yeast, vigorous and otherwise suitable, the continuance of the brewing operations in the immediate future depended. The authors of the present paper appear to have depended solely upon the measurement of the cells and their hereditary characteristics, as evidences of the fitness of the yeast for future pitching purposes. Would it not be desirable to have the more direct testimony afforded by pitching the collected yeast once more in wort and recording the results? In the first series of experiments, the authors dealt only with the effects of phosphates added in various proportions to what is known as Pasteur's solution. The results they obtained, upon fermenting the solutions just mentioned, the authors have expressed in terms of sugar decomposed, and although for many technical purposes this method expresses with sufficient accuracy the relative vigour of the yeast dealt with, yet it is to be regretted, in view of the disturbing influences likely to be present when carrying on fermentations upon such a small scale, that Messrs. Salamon and Mathew did not, in addition, record the increase in weight of yeast at the conclusion of each fermentation. The greatest objection to be raised to the first series of experiments was, however, connected with the nature of the solutions fermented. In the fermenting fluids were to be found none of the bodies present in the wort actually produced in the brewery. Albumenoids, peptones, principles derived from the hops, carbohydrates, even maltose, etc., were absent, so that little of practical utility could be adduced from the experiments, however interesting in themselves. We have to thank Messrs. Salamon and Mathew for continuing their experiments under conditions more closely approaching to those existing in the brewery. In the face of the results obtained, from which the authors draw the conclusion that the amount of  $P_2O_5$  existing in the ordinary wort of the brewer (wort of about 1.060 sp. gr.) is always rather in excess of what is desirable for the most favourable results in the way of yeast development; it would be interesting to learn how these gentlemen can explain the apparent anomaly that yeast, which from any cause has become weakened, if pitched in *strong* wort, much stronger than ordinary, or normal 1.060, wort, is greatly strengthened, and that generally fermentations are more vigorous when yeast is pitched in a very strong wort, than when the same yeast is employed to excite fermentation in one of normal gravity. Yet accord-

ing to the deductions drawn from Messrs. Salamon and Mathew's results, wort of a gravity of 1.120, containing double the proportion of phosphoric anhydride, as compared with ordinary wort, and, therefore, a very undesirable excess of that body, would be ill fitted for the carrying on of a strong and powerful fermentation. As a matter of fact, however, brewers are in the habit of using strong wort for the purpose of invigorating weak yeast, and also for inducing a strong fermentation prior to pitching the bulk of the wort to be fermented. Messrs. Salamon and Mathew's statement that the  $P_2O_5$  in the ash of yeast is present mainly as phosphate of potash may possibly be correct; but, if so, the phosphate must be of a very complicated formula, one that has hitherto been unknown, the ratio subsisting between the phosphoric anhydride and the potash not admitting of the acid and base being united to form any ordinary phosphate of potash.

Dr. E. R. MORTZ said: From the results of Messrs. Salamon and Mathew's investigation, it appears that the addition of phosphates to the fermenting wort causes no increase in the quantity of nitrogenous matter absorbed by the yeast; but granting this to be so, there is yet one other point to be considered—viz., the quality of nitrogenous matter so removed. It has come under the notice of others and myself, that an addition of assimilable phosphates, applied in a manner specially adapted to the cases in question, has promoted the stability and clarification of beers, which without this addition were found deficient in these respects. This property has been most marked in the case of beers brewed with soft waters (especially those containing carbonate and sulphate of soda) and malts insufficiently exposed to high temperatures on the kilns. In the ordinary way, these circumstances would tend towards unstable and cloudy beer, but the addition of phosphates previous to the fermentation was found to produce a marked benefit as regards stability; and the conclusion to be drawn would be that the added phosphates, if not stimulating the yeast to absorb greater amounts of nitrogenous matter, caused it to assimilate that kind which specially favours the development of the microbes of beer disease.

Dr. W. S. SQUIRE said he fully agreed with Mr. Salamon in his view that malt worts contained sufficient mineral constituents for the growth of yeast. Pressed yeast contains from seventy to eighty per cent. of water, and the solid substance of yeast contains from six to seven per cent. of ash, consisting mainly of phosphate of potassium, with a certain quantity of the phosphates of magnesium and calcium; so that pressed yeast does not contain more than about two per cent. of ash. It happens that the composition of the ash of malt resembles in a rough sort of way that of the ash of yeast, and of this ash, malt contains about two per cent. It is evident, then, that if the whole of the mineral constituents of the malt passed into solution, they would be sufficient to produce a weight of pressed yeast equal to that of the original malt. Of course, the whole of these mineral constituents does not pass into solution, but a considerable proportion does. It is chiefly the calcium and magnesium salts which remain behind, while the greater part of the phosphate of potassium dissolves. In any case, the wort will contain mineral matter amply sufficient for the quantity of yeast which would be obtained under normal circumstances. Of course, this would be somewhat different if large quantities of sugar containing little or no phosphates were added to the wort. I am speaking of beer worts, and a fermented solution of sugar is not, in my opinion, beer. Even in distilleries where a considerable proportion of raw grain is used in the com-

position of the worts, a very large crop of yeast, as much as eight or nine per cent. of the materials used, may be obtained by particular management, without any addition of mineral matter. This is generally known as pressed or German yeast, and is in no way inferior to beer yeast, produced under the most favourable circumstances. On the contrary, it is far more active and healthy than beer yeast, and is on that account preferred by bakers and confectioners. I am, therefore, of opinion that the addition of phosphates is totally unnecessary for the manufacture of beer from malt and hops. What it might be necessary to add, when a fermented liquor other than beer (though bearing that name) is prepared from materials other than malt and hops, I am unable to say.

The CHAIRMAN said: It is now my pleasing duty to conclude the discussion. I think we must all be of opinion—no matter how we may differ in our interpretation of their bearing—that the authors have made a valuable contribution to the chemistry of fermentation. The numerous analyses made must prove of use to many of us hereafter for reference, and assistance in other work; and while I congratulate the authors upon their valuable work, I hope they will continue their investigations. In regard to the use of phosphates, I agree with the authors, at least with reference to worts from well-harvested barleys and well-grown malts, but where large quantities of sugars, whether cane, invert, or of starch origin, are used, I have found the occasional use of phosphates beneficial. The authors have misunderstood the bearing of the empirical deduction made by me from the moist combustion process as applied to malt worts and beers. This process gives results, which have no relation to those obtained by the soda-lime process, which, though not giving the absolute nitrogen in all cases, still gives much more than the Wanklyn method. In my experience of malt analyses, I have found the Wanklyn *aluminoids* to be a useful factor, taken with many others, in arriving at a practical conclusion as to the merits of various malts for different kinds of beers. I beg to move, gentlemen, that the thanks of this meeting be given to the authors for their valuable paper, which I hope may be followed by further contributions.

Mr. SALAMON said, in reply: The experience of Mr. Thatcher with Smyrna malt is of great interest, when considered with reference to our paper; because, as he states, it clearly shows that good results may be obtained from a malt abnormally low in phosphorus. It will also generally be found that the soluble nitrogen of a Smyrna malt is of low percentage; much lower indeed, in many cases, than the sample the analysis of which we have recorded. This would seem to give the key to the whole question—viz., that high soluble nitrogen and high phosphorus indicate a malt grown upon a highly cultivated land; but it by no means follows that such malt is the best for brewing purposes. Indeed, there is a very increasing opinion that much of our land is over-cultivated for purposes of barley growth. Smyrna malt is generally used, in this country, for blending. May it not be that one of its functions is to dilute the amount of phosphorus present in malts derived from very highly cultivated land? Mr. Shearer asks if we have pitched with the yeast obtained in our laboratory fermentations? I do not hesitate to say we have not done so. It would have been obviously ridiculous to have attempted to pitch upon such a scale with yeast so produced. If gentlemen present this evening have any doubt as to phosphate-treated wort producing better pitching yeast than ordinary wort, it would be well for them to repeat our experiments upon the large scale. It is in this way that the brewer

can lend a helping hand to the chemist. But it is necessary to see that the conditions are under control. For instance, I have been in several country breweries, where they looked favourably upon the addition of solutions of phosphates to fermenting worts. I questioned them as to their mode of use; and found that, in every case, they added them to the wort, when the attenuation was about half completed. In fact, they roused the solution into the wort, thus re-aërating it, and so re-invigorating the yeast. It is scarcely necessary to add that the appearance of a more vigorous crop of yeast does not, under such circumstances, indicate that it is due to the addition of phosphates; but it does show that no scientific attention was paid to the details of the work. If we have proved, that the addition of phosphates does not affect the size or appearance of the yeast cells, that the thickness of its walls remain unaltered; that no more, and sometimes less, alcohol is produced in a given time; that no more, and sometimes considerably less, nitrogen is removed from the wort, this nitrogen so removed having been found to be a rigid measure of the yeast produced; that no matter how much phosphorus is added, the same amount, or practically the same amount, is removed from the wort, and no more, — then, granting the accuracy of our observations, it would indeed require very strong practical testimony to effectually contradict them. The fact that weak yeast revives under treatment with strong wort is surely no proof that its revival is due to the presence of the phosphate. Mr. Shearer complains that our experiments upon Pasteur's solution were made under conditions which had no relation to malt worts in a brewhouse; that we did not in that instance take into consideration the influence of the carbohydrates and of the various nitrogenous constituents of a wort; but if his contention held good in that case, it must be equally applicable to the one he cites; and I can best answer his question by asking him how he will deny the possibility of the increased quantity of these bodies providing additional nourishment for the yeast; and, moreover, holding the increased amount of phosphates in check, and thus preventing them from exerting any injurious influence. At any rate, we have proved that, under ordinary conditions, they do no good; and it is difficult to see why the experiment he cites should prove an exception to a rule which we have found to be so constant. Mr. Shearer is in error with respect to the phosphate of potash. We have only stated that it is generally returned as phosphate of potash existing in the ash; but inasmuch as we commenced by stating that the exact

condition of the existence of phosphorus in yeast was unknown, we have throughout alluded to it as phosphorus in combination. Dr. Moritz has alluded to experiments which he has made, inducing him to think that phosphates exert an action favourable to the removal of certain kinds only of nitrogenous matter. It is to be regretted that he has not seen fit to publish the result of these experiments; for if he has, as he states, made this discovery, he has mastered the very facts and gained the very information for which brewers have so long been waiting. If Dr. Moritz has found out what kind of nitrogenous combination it is, which produces stability in beer; and what kind it is that induces an opposite effect, then, in view of the importance of the subject, he is scarcely justified in keeping the information to himself; and I submit that he should be induced, at an early opportunity, to communicate the results of his experiments to this Society. If his remarks are merely inductive, and are not derived from absolute experiment upon the nitrogenous matter, then in view of the many experimental proofs we have offered to the contrary, and of the fact that he has submitted none at all in support of his contention, I do not think it will be necessary to trouble the meeting with further criticism respecting them. I am glad to find that Professor Graham's views upon the question of phosphates are practically identical with our own. As regards the matter of the soluble albumenoids, we are content to let our results speak for themselves. They were certainly made without bias on either side; and Mr. Wilson's past experience is certainly not to be ignored in the matter, especially as he states that in no case was there any room for hesitancy or doubt. I do not, however, wish to dogmatise upon a subject still involved in difficulties, and I hope that before long I may be in a position to contribute some further information bearing upon this question to the Society.

#### ADDITIONAL NOTE ON ALUMINA IN SUPERPHOSPHATE.

BY H. B. YARDLEY.

SOME time after the publication of my paper on this subject in the Society's Journal of August, 1881, it was suggested to me that a sufficient period had hardly elapsed between the tests of the mixtures.

Having the experimental samples still by me, I again retested the principal ones, with results stated in Table 1 as nine months after making. I also made the further experiments given in Table 2.

TABLE 1.

One month " "	2.04	0.81	2.47	4.00
Three months " "	2.45	1.02	1.28	3.20

All of these confirm the conclusion drawn in the first instance, viz., that *provided there is a sufficiency of free acid in the manure, no reduction takes place from the presence of alumina.*

In No. 13 the alumina will be seen to be in very large quantity (11½ per cent. in the phosphate) and the acid insufficient, hence the slight reduction in this case.

I may as well state that the free acid was determined by alkalimetry to complete neutrality as indicated by cochineal. In presence of iron and alumina there is always a faint cloudiness after the first few drops of alkali are added, which scarcely increases until the liquid becomes alkaline. In commercial superphosphates I have found this cloudy precipitate consists wholly of phosphate of iron, but in the experiments containing alumina a similar cloudiness occurred, which, however, I did not test, but the presumption is that it was phosphate of alumina, as those containing neither iron nor alumina gave no precipitate whatever until alkalinity was reached.

In conclusion, the condition of the samples No. 7, *et al.*, was very good indeed, and even No. 5 was not so wet as might be expected from the large excess of acid.

#### DISCUSSION.

Mr. T. W. B. MUMFORD gathered from the author's figures, given now and in his former paper, that in the ordinary method of manufacturing superphosphates in saleable condition and free from excess of sulphuric acid, the presence of iron and (or) alumina in the raw material, tended after the lapse of a short time to render its equivalent of monocalcic or soluble phosphate insoluble. It certainly had been proved beyond question, whatever might be the deduction which the author could draw from his experiments, that when iron and (or) alumina were not present no diminution in the solubility of a superphosphate took place, even after storage for some years.

Mr. HUGHES asked whether the author considered that his experiments afforded evidence that alumina was an unobjectionable constituent of mineral phosphates in the face of the contrary view held by manufacturers at the present time. The figures on the board went to show that no reversion into the insoluble state took place so long as a large excess of "free acid" was present. What did the author mean by "free acid"? Surely 4 or 5% of free sulphuric acid would completely unfit a manure for storage, and indeed all agricultural purposes. What practical value could experiments have which depended on a physical condition of the superphosphate impossible in practice!

#### ON A NEW FORM OF PETROLEUM LAMP.

BY PERCY F. FRANKLAND, PH.D., B.Sc., F.C.S., ASSOCIATE ROYAL SCHOOL OF MINES.

THE rapid advances which have been made during the past twenty years in the construction of petroleum lamps has resulted in the almost exclusive use of mineral oil in all places where gas is either out of reach or not desired. The use of colza lamps in the house is now almost solely adhered to by timid persons who regard petroleum with suspicion, and who, therefore, prefer to remain satisfied with the inferior light, great cost, and unnecessary labour which lamps consuming vegetable oils entail. Colza and other fatty oils, however, still retain their place in lamps of another class, such as railway lamps, hand lanterns, and the like, owing to the difficulty which is experienced in burning mineral oils in places exposed to

draught and violent vibrations, or in lanterns in which the use of chimneys is inadmissible.

I have the pleasure of bringing before the notice of the Society a form of burner which has been specially designed for the consumption of mineral oil in lamps of this latter class, and which possesses some points of interest and novelty.

This burner consists of a hollow porcelain cylinder (A) from 2·3 inches in length, the upper extremity (B) of which is flattened and has a notch cut in it. The interior of this cylinder is fitted with a mixture of plaster of Paris and charcoal, and its axis is penetrated by a glass tube (C) about ¾-inch diameter, which serves to hold the wick. This cylinder is cemented into a metal screw which fits on to the oil reservoir, so that the lower extremity of the cylinder almost touches the bottom of the reservoir. The wick used is a mere cotton string, the thickness of which is practically immaterial, and is so arranged as to very slightly project in two or more loops above.

When the lamp is first lit it burns but dimly, until the porcelain cylinder becoming strongly heated the flame gradually enlarges, expanding in the direction of the flattened upper extremity of the burner, the height of the flame depending upon the extent to which the wick projects. The flame produced is flat and slightly pointed towards the top, and the height should be so arranged that it is just below the smoking-point. When thus adjusted, the lamp continues to burn without any attention until the last drop of oil in the reservoir is consumed, the illuminating power remaining nearly constant throughout.

A charge of 1 fluid ounces of kerosene oil was found to last 13 hours, and the light yielded towards the end of this period amounted to 0·93 standard candle. In other words, 1 fluid ounces of kerosene when burnt in this lamp produce a light of one candle for 12·9 hours, or 1 gallon of oil will give a light of 484 candle-hours. The oil used was the best kerosene, flashing at 107° F., and obtainable for 10d. a gallon; 484 candle-hours would thus cost 10d., or 12 candle-hours about one farthing. This is not so cheap as the light yielded by petroleum lamps provided with a chimney, for I found that the smallest and commonest lamp of this kind which I could purchase, in which the wick was ½-inch in width, consumed 4 fluid ounces of kerosene in 12·25 hours, giving during this period an average light of 1·44 candle; 1 gallon of kerosene burnt in such a lamp would give 706 candle-hours, or 12 candle-hours could be obtained at a cost of 0·17d.

I have also compared the cost of the light obtained from the new burner with that yielded by a colza-oil lamp without chimney. This lamp, which was provided with a ½-inch wick, was allowed to burn for thirteen hours, and at the end of four hours it was giving a light of 0·86 candle, whilst at the end of twelve hours the light had fallen to 0·21 candle. Assuming, how-

ever, that the light of 0.86 candle had been maintained for thirteen hours, then 4 fluid ounces would yield 1292 candle-hours, and 1 gallon 517 candle-hours; taking the price of colza-oil to be 2s. 9d. a-gallon, the cost of 12 candle-hours would be 0.77d., or more than three times as much as the cost of the same light produced by the new burner with kerosene oil.

The new burner gives a flame which is not extinguished even when exposed to exceedingly violent vibrations and shocks, a circumstance which renders it particularly fitted for lanterns and carriage purposes. The light appears to be a perfectly safe one, and all experiments undertaken with a view to producing an explosion of the petroleum vapour and air inside the reservoir proved unsuccessful. Thus the burning lamp was heated in an air-bath so that the oil in the reservoir was at 138° F., and although the flame was violently blown about by the currents of air no flashing of the petroleum-vapour took place, notwithstanding that only a small quantity of oil had been put in the reservoir so as to leave a large air-space, and thus facilitate the formation of an explosive mixture.

A weak point in the lamp is that a small amount of petroleum-vapour escapes combustion and causes a slight smell; this is, however, of comparatively little importance, as the lamp is not intended for use indoors.

## SUMMARY OF PAPER ON THE PRESENT POSITION AND FUTURE PROSPECTS OF ELECTRIC LIGHTING.

BY A. BROMLEY HOLMES, ASSOC. M. INST. C.E.

THE author first pointed out the advantages of electricity over gas and oil as a source of light indoors, owing to the fact that no oxygen was consumed and all noxious products of combustion were avoided.

The manufacture of electricity on a large scale was stated to be much simpler than that of gas, the difficulties of electric supply being chiefly the absence of practical means of storage and the cost of distribution.

Primary batteries would be of great use in small installations, and the accumulators at present obtainable were very imperfect. Electrical engineers naturally looked to chemists for the improvement of primary and secondary batteries, and the progress made in this direction at present was lamentably small.

The methods of generating electricity for lighting purposes were explained, and the various classes of dynamos were described, together with the devices employed to make these machines self-regulating so

as to automatically adjust themselves to a varying number of lamps.

It was mentioned that machines were now made so perfect in this respect that it was possible to turn out 50 lamps out of a hundred without affecting the brightness of the remaining one lamp.

The storage cells at present in use were stated to consist generally of glass or earthenware vessels, containing in a dilute solution of sulphuric acid one or more pairs of lead plates, the surfaces of which have been oxidised by the action of an electric current or otherwise. The charging current from the dynamo causes the formation of peroxide on one plate, and reduces the surface of the other to a less oxidised condition. When the dynamo is disconnected, and the cells are coupled up with the lamps, the current flows in the reverse direction to that of the charging current. To increase the storage capacity of the lead plates, they are sometimes perforated, and the holes so formed filled up with oxide of lead.

The desiderata in an accumulator are, moderate first cost and reasonable durability, combined with a high electro-motive force, low internal resistance, and considerable storage capacity.

A hope was expressed that members of the Society of Chemical Industry would direct their attention to this important detail connected with the advance of electric lighting.

The principle of action of arc lamps and incandescent lamps was fully explained, and also the various plans of coupling up the lamps for work.

The difficulties connected with the distribution of electricity were alluded to, and also the means adopted to overcome these obstacles.

It was mentioned that the electric light was now being supplied from central stations at a cost from one and a-half times to twice that of gas of equal illuminating power, and the author indicated the directions in which the cheapening of the electric light was possible, and concluded by stating his belief that within a limited period incandescent lamps would be obtainable, so far improved in efficiency as to bring the electric light within the reach of all.

## DISCUSSION.

MR. SIMPSON said: He always had been surprised at the blind support given by the public to all sorts of electrical schemes, more especially in connection with accumulators. Sir Wm. Thompson had pointed out that in charging and discharging these latter there was a loss of power of about 25%; and in the case of tramcars propelled by them this loss even amounted to 50%, without any counterbalancing advantage. Dynamos too seldom gave a return of more than 85% of the power expended. He would, however, be glad to see the large dynamos in use mentioned in Mr. Holmes' paper. He had himself gone to some expense in electrical experiments on caustic soda, but the want of a diaphragm capable of withstanding its action caused the experiments to be abandoned.

THE CHAIRMAN asked Mr. Holmes if electric lighting had made commercial progress. He thought that in the future, electricity would play a part in chemical operations in spite of the unfortunate experience of workers like Mr. Simpson. A member, who had visited some electrolytic works in London, had been favourably impressed with what he saw there. Messrs. Siemens had also fitted up plant in Germany, by which electricity did the work of scrap-iron in the wet-copper process, but the large capital outlay required had hitherto prevented its adoption for that purpose in England. He had also read lately of an improved primary battery, of a portable nature, capable of supplying light on a small scale.

Mr. THOMPSON suggested the use of aluminium in primary batteries. By the action of caustic soda a very considerable temporary effect was produced, but the rapid destruction of the metal had hitherto stood in the way of complete success.

Mr. HOLMES, in reply, said that recent experience had hardly confirmed the anticipations formed with regard to accumulators. He had calculated that 18,000 tons of accumulators would be required to take the place of engines of 3000 horse-power in the case of Atlantic liners. With tramcars the case was better. To work a tramcar for five hours, a ton weight of accumulators would be needed, and would replace, say, two horses. To this must be added the weight of the dynamo, which was comparatively small. There was no reason why a tramcar should not carry storage batteries sufficient to propel it for three or four hours, and this had often been tested in practice in London and elsewhere. As to cost, a steam-engine was far more economical than horse-traction. Suppose that a steam-engine were put down at the tram stables to accumulate the electricity, they could change batteries as quickly as horses—even more so, were they to adopt the simple expedient of running the accumulators in trams under the cars.

Mr. SIMPSON: Would not compressed air do better?

Mr. HOLMES: The cost of plant had prevented this having a fair trial up to the present. Then, in Liverpool, see how the tramways were laid, and the cruel strain put upon the horses to start the cars, the latter of which would be obviated by the use of electricity. Mr. SIMPSON wished to know what horse-power would be required to work these large dynamos. The largest in Liverpool now was at Messrs. Tait's sugar refinery, and showed to what perfection these engines had been brought, for it started a month ago, had worked continuously ever since, and was in perfect order now. He thought that a machine capable of running 600 lights would soon be made. Messrs. Siemens would have in the Inventions Exhibition three dynamos, each producing 300 lights and driven direct by three pairs of high-pressure and low-pressure engines. In practice about eight lights could be run per horse-power. Regarding the commercial side of electric lighting, taking for granted that the steam-engine is about as good as it can be, and that water is to be had for the pumping, then the dynamo would utilise about 90% of the power, and no better than that could be done. As to the mains, there must be a central station, from which they should be laid so as to annihilate distance as much as possible. Edison had tried an ingenious plan called the "three-wire system," but in Liverpool it would be necessary to adopt the "parallel system" for simplicity's sake. Even with this occasional breakdowns occurred, as in everything where dependence had to be placed on inexperienced persons. As to the incandescent lamp, he believed it had a great future, but there was great scope for economy yet. The cost per light could be reduced to one-half of that formerly incurred.

## INAUGURAL MEETING.

The proceedings of this Section were inaugurated on Friday, June 5, by a *Conversazione*, in the University College, Nottingham, which attracted a

numerous assemblage. In the Chemical Laboratory was placed a series of exhibits collected by the various members of the local committee, illustrating some of the industries comprised in the Society's programme, and which included various methods of lighting by gas and electricity, coal-tar and other colours, analytical and optical apparatus, and many other objects of chemical and scientific interest, all of which reflected great credit on their exhibitors.

At eight o'clock an inaugural address was delivered by the Chairman, Professor Clowes, in the large lecture theatre of the College.

Professor Clowes said: It falls to my lot, as the present representative of the Nottingham Section of the Society of Chemical Industry, to address a few words to you this evening. And speaking, as I do, not only to members of this young, and I trust vigorous Society, but to friends who have honoured us with their presence, my first duty is certainly to give to our guests in the name of the Society a most sincere and hearty welcome. We will venture to hope that many of you will, at future gatherings of this kind, have exchanged your present condition of guests for that of entertainers—a change which our Secretary will, I am sure, do his utmost to facilitate. And now, speaking to a gathering of friends interested in the progress and welfare of chemistry and of chemical industries, and met together in this capacity probably for the first time, and in a somewhat informal manner, I trust you will allow me to depart from the formality of an ordinary President's inaugural address, and to state to you in a brief and simple manner our reasons for starting this Society, and the directions in which we hope and expect that it will be useful to Nottingham and the surrounding towns and district. History tells us that in early times men worked most indefatigably, but in a somewhat haphazard manner, to improve and discover various processes of manufacture; their main object being, not so much the discovery of the secrets and laws of nature and the benefit of mankind, as the improvement of their own finances. In later ages many men of energy and intellect have placed before themselves in their labours a more lofty and less selfish aim: they have spent themselves in attempting to learn what are the unchangeable laws of nature. At first sight it might appear that these two classes of workers had little in common: and, unfortunately, this opinion has always in some degree existed,—the natural philosopher engaged in prosecuting his researches being almost contrasted with the energetic and intelligent manufacturer endeavouring to improve and discover processes; or, as it is put in the present day, the *theoretical* man is too often considered to be out of touch with, and to have nothing in common with, the *practical* man. It must, however, be very evident to those who will carefully consider the case, that the interests of both these classes of workers are to a great extent identical: thus, only can the practical man work most surely, most directly, and most economically when he works with a knowledge of nature's laws; equipped with this knowledge also, he is in a better position to insure advance and improvement. We are told on the highest authority that England is suffering in competition with some of her Continental neighbours, by not appreciating as fully as they do the advantage of blending theory with practice, and the necessity of the co-operation of the scientific and practical man. In what way it is best to blend in chemical training the scientific and the technical elements, will certainly be debated in our new Nottingham Section of the Society of Chemical Industry, as it has been already discussed in many other similar societies in this country. I may therefore leave this

subject for the present, with the remark that it is one of paramount importance to the success of this town, and of the greatest interest to me personally in my capacity of a chemical teacher in your midst. But fortunately there are already in Nottingham and its neighbourhood men who fully appreciate the importance of enabling the rising generation to engage in our important industries with a knowledge of the scientific principles which underlie them, and who desire to aid this enterprise by every possible means; there are also not a few who have already passed through a very creditable scientific training in this building or elsewhere, and we have several gentlemen here this evening who are carrying on large and important industrial enterprises with a sound knowledge of scientific laws and principles. Representative men of these various classes have agreed that by associating themselves together, and bringing forward for discussion matters of novelty and importance, much may be done towards mutually aiding and informing one another, and towards arousing and stimulating a desire for the advantageous blending of theory with practice. Nottingham has already societies of a scientific character. The one which appears to be most nearly allied to our own is that known as the Chemists' Association. Its main object is, I believe, to secure efficient training to the pharmaceutical apprentices of this town, and those who best know the important and necessary work it is doing will most earnestly support this Association and endeavour to secure its permanency. But it will be evident to you that our Society should embrace many applications of chemistry besides pharmacy, and should gather in the trained and experienced as well as the student and the novice. There is then, as far as I can see, no existing association in this district with which we shall compete, whilst there are several societies, many members of which we should embrace. In comparison with the largest industrial centres of this country, Nottingham of course does not contain a numerous population, but the size of our town is decidedly respectable; it has increased considerably of late, and we are loyal enough to believe it will yet increase much more largely. Still, the question has been asked, Can we maintain a Section of the Society of Chemical Industry? I am sanguine enough to say undoubtedly we ought to do so, and that we will certainly make the attempt. But fortunately we have this great advantage, that we can start in connection with a large and important Society already organised, which will aid us financially, by its prestige, and still more by furnishing each of our members with a monthly Journal, which is unequalled as a record of the industrial chemistry of the civilised world. This Society further accords to each member of the Nottingham Section the privilege of attending its own meetings in London, as well as the sectional meetings in other large towns in the United Kingdom. We are therefore members of a large confederation, whose object it is to study, discuss and record the improvements and progress in applied chemistry, and in all matters related thereto; and I need not point out to you how greatly this may further our own personal ends, and, better still, how it may promote the efforts now being made to promote and maintain the supremacy of this country in the many industries involving the application of chemistry. For personal, as well as for patriotic reasons, this Society has therefore powerful claims on your co-operation and support. Some of you may ask what industries in the Nottingham district are capable of being advanced by a knowledge and application of chemical principles. Well, really the difficulty in answering this question arises rather

from the doubt as to which industries can fairly be omitted. However, to name some of the principal, we have the manufacture of gas and the utilisation of its residuals, the bleaching and dyeing processes, colour making, pharmacy, brewing, baking, tanning, iron smelting, coal mining, and, as I have already said, a host of others in which chemical knowledge must be of great advantage. But whilst chemical principles are thus widely applicable, it will be readily granted that applied chemistry cannot be divorced from scientific chemistry, from physics, and from mechanics, and we therefore invite and welcome into our Society those who can best aid our discussions from the physical and mechanical side, although our discussions will probably mainly be on applied chemistry. And I therefore do not hesitate, in the name of the Society, to invite communications of a purely scientific character, as well as papers on applied physics and mechanics. Our vast metropolis may support separate and distinct associations of scientific chemists, industrial chemists, scientific physicists, telegraphic engineers, and civil and mechanical engineers, all more or less distinct in their objects, but also more or less merging into one another. Such a sub-division would be at present impossible in our own town; but may we not fairly embrace in our Society of Chemical Industry the consideration of matters chemical, mechanical and physical, whether in a purely scientific way or in their applications, and make the Society for this town at least representative of what we may term the industrial sciences? Surely this blending of aims would be desirable. With regard to the advantages of association, few of us need any information. In one sphere or another we must surely have felt the wholesome emulation and stimulation derived from mingling with those of kindred aims and pursuits, especially when the common aim is that of advancement and improvement. And here let me say a word respecting what, to some, may appear a fatal hindrance to such association amongst those who are engaged in a keen competition and rivalry in their industrial pursuits. It is frequently urged that important trade secrets may be divulged, to the detriment of the individual, and to the advantage of his rival. True science has no secrets; the aim of the scientific man is to learn fresh truth, and to scatter it broadcast. On this side, therefore, you *must* be gainers by association with men of scientific training, thought, and habit. And surely, regarding special unpatented processes, our very interests would for the time keep us silent. There are few of us who have not frequently to harbour a secret; and if we are successful in doing so elsewhere, why not in our Chemical Society? It cannot be maintained that the advances in industrial science are invariably or even mainly for any length of time in this secret state; and if we help to keep each other informed of the open and published advances, and develop by discussion their important bearings, we shall find plenty of most important and useful occupation in our meetings. May we not also look for advantage from the association of teachers with old students, both gaining thereby by ideas of the practical and broader application of scientific laws and principles.

The whole Society of Chemical Industry assembles every summer alternately in London and in some important provincial centre of industry. These gatherings serve partly as conferences, but they also enable members to visit important works of various kinds, and of the most approved and modern types. Last year a most important visit was made to the industries of the Tyne-side. This year the meeting will be held in London in next July, and will naturally find its quarters in the neighbourhood of the Inven-

tions Exhibition, in which not a few members of the Society are exhibitors. This will doubtless prove an attraction. It is hoped that the members of our local Section may be able to obtain in their own district the practical education given by visiting model industrial works; and an attempt will be made, from time to time, to organise such a system of *field instruction*, as the naturalist would term it. We shall be thankful to receive invitations from the proprietors and managers of large works, and shall quite appreciate their kindness in allowing us to see of their best. And now I have placed before you our ideas regarding the infant, at whose formal christening you are present this evening. If you like his looks, and think he shows promise of developing into a useful member of society, do not stand aloof; but, by constantly showing the interest you have evinced in his cradle days, aid his growth into a strong and useful member of your community, and give those of us who look upon the babe with proud and partial eyes of parents and sponsors, reason to rejoice over his rapid development and useful career.

On the motion of Mr. LEWIS T. WRIGHT, a vote of thanks was passed by acclamation to Professor Clowes for his able address, and to the Chairman and Committee of the College for their courtesy in granting the use of the building.

After the address, Mr. LEWIS T. WRIGHT described in detail the various gas lighting arrangements shown in the laboratory, and exhibited a series of models of gas works and processes. At the same time Mr. A. H. SIMPSON was explaining in another part of the building systems of lighting by electricity, illustrated by various types of dynamos and lamps, both arc and incandescent.

Addresses on TISSUE Silk, by Mr. T. WARDLE; on Luminous Paint, by Mr. J. B. COLEMAN; and on Dyeing and Bleaching Processes, by Mr. R. LLOYD WHITELEY, served to complete the interest of a most enjoyable evening.

### I—GENERAL PLANT, APPARATUS, AND MACHINERY.

*Ebullition of Water considered in regard to Steam Engines.* H. Walther-Meunier. Bull. Soc. Ind. Mulhouse, 1885, 113.

This is a discussion of evidence from various sources as to the cause of boiler explosions. The ebullition of water, from this point of view, has been investigated by Donny (Ann. Chim. Phys. [3], 16, 177, 1846), Dufour (Archiv. Bibliothèque Univ. 1864, and Pogg. Ann. [5], 4), Kayser (Zeits. Verein. Dent. Ing. 9 and 10), Colm (*Ibid.* 14), and Gernez (Ann. Chim. Phys. [5], 4). By their experiments two main results are established:—(1) for the production of the phenomenon of the super-

heating of water, the condition of perfect repose of the liquid mass is indispensable; (2) the presence of minute quantities of gases is sufficient to maintain a normal ebullition. These considerations are applied in an exhaustive discussion of the conditions of ebullition in steam generators of the various types now employed, which, the author shows, are such as to practically exclude the possibility of superheating. He maintains, on the other hand, that boiler explosions are referable either to defects in materials or construction, or to want of observation of necessary precautions.—C. F. C.

*On the Construction of Boiler Chimneys.* P. Huth. Chem. Zeit. 9, 692.

A DISUSED chimney, 20 metres high, 0.5 metre lower, and 0.35 metre upper diameter, was connected with a boiler 8 metres long, 1.6 metre diameter, with an inner flue 0.5 metre diameter, the total length of flue being about 30 metres. The chimney was found inefficient, and a new one was built, the length of flue being 20 metres, and the width at least 0.65 metre square. With the increased dimensions of flue, a chimney 12 metres high was found to be fully equal to the former chimney of 20 metres, and when it reached 16 metres it was again tested and found fully efficient; the smoke being white, free from soot and flue dust, and the heating effect of the boiler excellent. The coal used was also reduced 15 to 20 per cent. The damper was only required to be one-quarter open. The principal factor therefore to be considered is not only the height of a chimney, but also its proportional width. High chimneys are, on the whole, too narrow, and it would be useful to determine the most effective relation of height to width in the construction of chimneys.—J. B. C.

*Improvements in the Process of and Apparatus for Producing Cold.* J. H. Johnson, London. From J. C. Rossi, U.S.A. Eng. Pat. 8777, June 10, 1884.

The apparatus consists of a series of two or more concentric annular vessels, provided with stirrers, the outer vessel containing the vessels of water or the liquid to be cooled. Nitrate of ammonium, equal in weight to the water in the vessel, is dissolved in the innermost vessel with agitation. The solution of the salt may be recovered by evaporation. The cold in the liquid finally discharged is recovered by causing it to cool either air or water to be used in the various parts of the machine.—C. C. H.

*An Improved Non-conducting Composition for Protection Against Heat.* S. P. Wilding, London. From Wirth & Co., Ludwigshafen, Germany. Eng. Pat. 9063, June 17, 1884.

THE inventors aim at producing a non-conducting composition, the bases of which is granulated cork, in a condition in which it can be painted or coated on to the surfaces it is intended to protect. Such a composition is light, tough, highly elastic, and a very bad conductor of heat. They proceed as follows:—40 parts well-loosened asbestos fibre is mixed in a wet condition with 150 parts fossil meal, to which has been added 3 parts clay and 2 parts solution of soluble glass; the whole is intimately mixed with 150 parts of disintegrated cork. The mixture is dried quickly at a temperature of 100°, and the cakes ground fine. When the composition is used it is mixed with water into a thin paste, and applied to the heated surfaces with a brush. The patentees claim the manufacture of a non-conducting composition substantially as described.—C. C. H.

*Apparatus for Drying in Vacuum.* H. J. Haddan, London. From E. Passburg, Moscow. Eng. Pat. 1997, February 12, 1885.

THE apparatus described in this specification is an improvement on that described in a former specification for effecting the same work. The vacuum vessel is a horizontal cylinder, steam-jacketed on the exterior, and also

heated in the interior by an annular cylinder capable of being heated by steam and revolving on trunnions. The exterior of the annular cylinder is provided with arms for the agitation of the material under treatment. The untreated material is fed into one end of the cylinder from a vessel which is isolated by a valve, when necessary, so that the introduction of fresh liquid does not destroy the vacuum. The evaporated material is removed from the other end on the apparatus by a similar appliance, so that the working is continuous and without a break. The whole apparatus and its several details is covered by six different claims.—C. C. H.

## II.—FUEL, GAS, AND LIGHT.

*Observations upon a Proximate Constituent of Coal.* P. F. Reinsel. Dingl. Polyt. J. 256, 224.

IN the course of recent observations upon the microscopic structure of coal, the author found that alkaline solutions dissolved out a certain constituent, leaving a large proportion of insoluble matter morphologically unchanged. The nature of the soluble constituent is now further investigated. By boiling coarsely powdered coal with strong potash solution, diluting, and allowing to stand at rest for some time, a sediment is deposited, which contains the insoluble constituents, and which is suitable for microscopic examination. The supernatant, opaque, dark brown liquor is passed through a filter, saturated with a dilute acid, and the solution put on one side. After a short time a voluminous jelly-like mass of dark-brown colour will have settled down. The precipitate so obtained shrinks to one-tenth of its original volume when dried, is unaffected by concentrated sulphuric, nitric, and hydrochloric acids in the cold, is attacked by warm nitric acid with evolution of nitrous fumes, dissolves gradually and completely in ammonia solution, burns without swelling up when heated on platinum foil, leaving a slight residue, and evolving a small amount of ammonia. In the ordinary yields of the bituminous coal seams of Saarbeck, Ruhrbeck, Belgium, Silesia, Bohemia, Newcastle, Pittsburg, Indiana, Illinois, in so-called "whitecoal" and Tassmanite, the author has either failed completely to detect this soluble constituent by the above process, or has found it to be present in amounts certainly less than one per cent. In the leaf or paper-coal of the carbon formation of central Russia, this amorphous constituent has up to the present been found to occur most abundantly, several experiments giving 85 to 95 per cent. of insoluble matters, and 15 to 5 per cent. of the amorphous body soluble in alkalis, and precipitated from the alkaline solution by acids. This substance likewise occurs in the bituminous coal from Metschowk, which contains about 10 per cent. of the so-called "soot-coal," and the author considers it probable that it is present in many coals, but in such a form that it cannot be isolated by the action of alkalis alone.—W. D. B.

*The Utilisation of Coke-dust.* P. Koehler. Chem. Zeit. 9, 726.

THE dust left in gas retorts after withdrawing the coke, or accumulated at the bottom of long-standing coke heaps, when mixed with one-fourteenth its volume of soft clay, subjected to strong pressure and dried in the air, forms hard blocks of good combustible material, which may be transported without breaking up.—J. B. C.

*Improvements in the Manufacture of Gas applicable for Heating Purposes.* Michael Cahen, Brussels. Eng. Pat. 11,335, August 15, 1884.

THIS is a process for the production of pure carbonic oxide gas by passing pure carbonic acid gas through coal or other solid fuel in a chamber externally heated. This chamber is built in three parts, the lowest being designed to hold the ashes and scorie, the middle one, wherein the conversion of the carbonic acid mainly takes place, and an extension, as it were, of this above for the introduction of coal, etc., and carrying off of the evolved gases. The middle part, where, of course, the heat is

most intense, is of fire-clay; the other two of cast-iron. When the carbonic acid is conducted into the glowing fuel it is not only converted into carbonic oxide, but it also assists in carrying off the hydrocarbon vapours and ammonia there disengaged. A good deal of the tar deposits on the coal fuel in the higher part of the generator, so that only the more volatile products escape with the carbonic oxide gas. These may be recovered by the usual means, in addition to which a passage through chloride of calcium solution is recommended to remove the ammonium carbonate. The pure carbonic acid used in this process is obtained by the combustion of the heating-gas, by subjecting the gaseous mixture to the pressure of one atmosphere in the presence of water, which under these circumstances absorbs 1·185 times its bulk of carbonic acid, against 0·016 time its bulk of nitrogen. The absorption is effected in a closed water-conduit, so constructed that the stream of water passing through it rises in one place to a height of at least forty feet above the level of the main body of the conduit. This column of water maintains in the horizontal portion of the conduit a minimum pressure of 1 atmosphere. From this elevation the water, having yielded up its carbonic acid, is brought down again, and kept in continuous circulation. It will thus be seen that the water in the lower portion is subject to a sufficient pressure to effect the separation of the carbonic acid and nitrogen. The latter passes away into the air by a pipe leading upwards from the conduit; this pipe, of course, being high enough to allow the required pressure to be maintained in the conduit. Circulation is kept up partly by the injection of the gaseous mixture, which it is desired to separate, and partly by a revolving screw. As the water moves upwards in the raised portion of the conduit it becomes subject to a reduced pressure, and the carbonic acid is disengaged. It is then collected by suitable means, and used as above for the production of carbonic oxide. The inventor gives figures showing by this process a saving of 74 per cent. on coke, and 65 per cent. on coal. Another most important advantage is that sufficient heat is generated by this pure carbonic oxide to enable a hot blast of air to be dispensed with under practically all circumstances.

—A. R. D.

*Improvements in the Treatment of Petroleum.* L. A. Groth. From Mrs. T. N. Flesch, Annweiler, Germany. Eng. Pat. 12,457, September 16, 1884.

To a litre of petroleum is added 500gm. of green vitriol, and the mixture is boiled for twenty minutes. This takes place at a temperature above 100° C. The liquid is now separated from the hard mass formed during the boiling, and mixed with twice its volume of petroleum. This yields a clear product without smell, which may be burned with safety, and gives a clearer and brighter light than ordinary petroleum. —A. R. D.

*Improvements in Fire-lighters.* E. G. Brewer. From Camille Savarre, Capelle au Bois, Belgium. Eng. Pat. 15,972, November 15, 1884.

Dry breeze, dry pitch, resin, petroleum, straw, refuse of flax, sawdust, chips of wood and cork, or other easily combustible materials, preferably in the proportion of 71 per cent. of resin, 15 per cent. of petroleum, and 14 per cent. of the other materials, are formed into a paste and moulded into suitable forms. Drawings are given of the shapes preferred. The lighters are bored with one or several holes to produce a current of air, that the combustion may be certain, whether the lighter be or be not covered with coal. For better ignition, wicks of some inflammable substance are provided. —W. D. B.

*Improvements in Apparatus for Purifying Coal Gas.* A. Dempster, Eland, Yorkshire. Eng. Pat. 2169, February 14, 1885.

A VESSEL of suitable size, shape, and material, standing preferably just after the condenser, is fitted with a pipe which enters at the bottom and extends to the top, its upper end being closed. This pipe has four or more

lateral openings for the passage of the gas. Around the pipe are placed perforated plates, inclined at such an angle that the streams of gas impinge against the edges of the holes, and are roughly broken up. The gas is also washed here by a stream of strong ammoniacal liquor trickling down the inclined plates. Surrounding the inclined plates, and arranged in concentric rings, are a series of vertical plates, perforated with holes increasing in size the nearer they are to the inclined plates. These vertical plates are fastened to the main vessel at the top, and stand on chairs or supports at the bottom, being luted with the strong ammoniacal liquor. After the gas has passed through all the rings of plates, it leaves the chamber by a suitable exit hole. The ammoniacal liquor is fed in by a self-acting distributor. —A. R. D.

*Improvements in Gas Producers.* C. D. Abel, London. From F. Siemens, Dresden. Eng. Pat. 9103, March 16, 1885.

THIS invention applies to those gas producers wherein combustible gases are generated by the passage of a limited supply of air through incandescent solid fuel. Ordinarily the hydrocarbon gases evolved are so mixed with carbonic oxide that it is impossible to economically treat the mixture for tar, ammonia, etc. By this invention the gas producer is arranged in compartments which approximately separate the zone where hydrocarbons are evolved from the carbonic oxide zone. The hydrocarbons may thus be drawn away and washed for tar, ammonia, etc., or brought back through the incandescent fuel, or through the outlets for carbonic oxide, and be converted by the heat into permanent gases. Of course, this conversion might be attained by conducting the heavy hydrocarbon vapours through a separate furnace. It is also proposed to arrange the upright air-supply nozzle in a column of brickwork, and to provide it with a cover or plug having openings for the distribution of the air-blast in any desired direction. The specification is accompanied by plans showing how the invention may be applied to the principal forms of producers in common use. —A. R. D.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

*On Pseudo-cinnamal.* K. Anwers. Ber. 17, 2976.

THE compounds described were obtained from pseudo-cinnamal  $C_6H_5(CH_2)_3OH$  [1, 3, 4, 6] (Ber. 11, 29 and 17, 2976). Trimethylortho-oxybenzaldehyde,

was prepared, according to Reimer-Tiemann's method (Ber. 9, 824), by dissolving equal weights of  $\phi$ -cinnamal and caustic soda in 50 parts of water, and adding gradually one part of chloroform, the mixture being heated on the water bath for three or four hours. The yellow liquid was acidified with hydrochloric acid and hydrolysed. After digesting the distillate for four hours with dilute alkali, a clear brown substance remained, while the filtrate when acidified deposited a yellow precipitate, consisting of a mixture of unaltered phenol and oxaldehyde. The substances were separated by fractional crystallisation from alcohol, in which the oxaldehyde is but slightly soluble. The pure substance crystallised in yellow needles, melting at 105–106°. It is insoluble in water, but dissolves easily in ether, chloroform, and glacial acetic acid. It forms a mirror with ammoniacal silver solution. The chloroform reaction gives only ortho and para compounds, and as the latter is impossible in this case, the constitution is proved. The oxaldehyde exhibits all the properties of an ortho compound. The brown residue insoluble in dilute alkali crystallised readily from alcohol in long lustrous prisms and tables, melting at 98–99°. It is insoluble in cold water, moderately soluble in alcohol ether, chloroform, and acetic acid. Its composition was found to be  $C_{10}H_{12}Cl_2O_2$ , but its constitution was not ascertained. The formula  $C_6H_3(CH_2)_3CHCl_2OH$  appears unlikely, on account of the great stability of the substance with

alkalis. It is more probably a dichloromethyl ether of pseudo-cumamol,  $C_6H_4(CH_2)_2OCHCl_2$ .

*Meta-nitroanilropseudo-cumamol nitric ether*,

One part of  $\phi$ -cumamol was dissolved in 6 parts of cold fuming nitric acid, and the solution was poured into water. The yellow solid was pressed between filter paper and washed with cold alcohol. It crystallised from ether in lustrous rhombic tables or prisms, melting at 84° with decomposition. The substance was analysed. It is insoluble in water, slightly soluble in cold alcohol, ether, and acetic acid, but readily soluble in chloroform. It forms a red solution, with caustic alkalis, but undergoes decomposition, for on addition of hydrochloric acid a yellow body is precipitated, and nitrous fumes are evolved. The precipitate, however, still contains nitrogen; hence the two nitro groups are differently combined, and probably the hydrogen in the hydroxyl group is replaced by  $NO_2$ .

*Meta-amidopseudo-cumamol*,

A solution of the nitric ether in glacial acetic acid was reduced with hydrochloric acid and tin, when hydrogen and nitrous fumes were evolved. The tin was precipitated, and the filtrate evaporated, when the hydrochloride of the base separated in yellow-brown crystals. The base was precipitated from a solution of the hydrochloride as a white substance which turned brown in the air. It was found to be identical with Liebmann's oxyquinidine prepared from phenylazo-cumamol (Ber. 17, 886). The substance does not form an anhydro-compound, hence the hydroxyl and amido groups are probably in the meta position.

*Diutropseudo-cumamol*,

When 5 to 10cc. of concentrated alcoholic ammonia are added to a gram of the nitric ether, the latter is dissolved with evolution of heat, but fine needles are soon deposited. The ammonia was neutralised with hydrochloric acid and the substance crystallised from alcohol. It formed yellow crystals, melting at 110°. It is insoluble in cold water, but dissolves easily in alcohol, ether, chloroform, and acetic acid. It decomposes when heated above the melting point. It dissolves in aqueous alkalis without change.

*Dipseudo-cumamol or hexamethylidiphenol*,

In the preparation of pseudo-cumamol a black-brown resin was formed, which was not volatilised by the steam. By treating the resin with alcohol, white crystals were obtained, which, when recrystallised from acetic acid, melted at 172°. The same substance was obtained by Hofmann from the resin formed in the preparation of pseudo-cumamol ether from pseudo-cumidine (Ber. 17, 1918). The product dissolves in alkalis without decomposition. The yield was only 2½ per cent. of the  $\phi$ -pseudo-cumidine employed, but Hofmann has obtained a similar compound by treating the tetramethylphenol with potassium bichromate and acetic acid. In the same way the author obtained dipseudo-cumamol by the oxidation of  $\phi$ -cumamol.

*Dipseudo-cumamol methylether*. The two substances were further identified by introducing methyl groups by means of caustic potash and methyl iodide, but the analyses left it uncertain whether the mono or dimethyl compound was formed.—S. Y.

*Separation of so-called  $\alpha$ -lutidine*. A. Ladenburg and C. F. Roth. Ber. 18, 913.

THE authors recently described the separation of a lutidine from commercial pioline; they now announce the isolation of a second lutidine from animal oil, boiling from 160° to 180°, obtained from Kahlbaum. The oil was fractionated into four portions, the lowest boiling between 158° and 160°. From this fraction two lutidines were separated, the first by means of mercuric chloride, the second with ammonium molybdate. The first of

these is described. By the addition of mercuric chloride to a strongly acid solution of the mixed hydrochlorides, a flocculent colourless precipitate was obtained. The substance melted at 125°, dissolved in hot water, and crystallised on cooling in white needles, melting at 130°. The formula was found to be  $C_{11}H_{13}N \cdot HCl \cdot 2H_2O$ . The base, liberated by caustic potash, boiled at 157°. It is more soluble in cold than in hot water, and dissolves in all proportions in alcohol and ether. The odour resembles that of fresh-cut cucumber. The formula is  $C_{11}H_{13}N$ . It is not coloured red either by concentrated hydrochloric acid or by benzoyl chloride. The crystalline platinum and gold salts were prepared and analysed. The oxidation of the lutidine was effected by boiling it with a 3 per cent. solution of potassium permanganate. When the colour disappeared the liquid was allowed to cool, filtered, neutralised with sulphuric acid and evaporated. The potassium sulphate was precipitated by alcohol, and the latter distilled off. The silver salt was prepared, washed with cold water, and decomposed by sulphuretted hydrogen. On evaporation of the filtrate the acid was obtained in lustrous scales, melting at about 235°. The formula was found to be  $C_{11}H_9NO_4 \cdot H_2O$ . It is, therefore, a pyridine dicarboxylic acid, and it is probably the  $\alpha\gamma$  compound, identical with Bottinger's pyridine dicarboxylic acid. Small quantities of impurities alter the physical properties of the acid very greatly, and a second preparation agreed very closely before careful purification with Weidel and Herzig's lutidinic acid, which the authors believe to be also identical with theirs. The calcium, copper, lead, barium and silver salts were prepared. On heating the acid slowly to 245° in a current of hydrogen, carbon dioxide and  $\gamma$ -pyridine carboxylic acid were formed. The acid was obtained from the precipitated copper salt. When crystallised from hot water, it melted at 296°, but after sublimation at 303°. It was undoubtedly isonicotinic acid, and hence the lutidine and lutidinic acids must be  $\alpha\gamma$  compounds. Five pyridine dicarboxylic acids are now known with certainty:—1, quinoline acid ( $\alpha\beta$ ); 2, cinchononic acid ( $\beta\gamma$ ); 3,  $\alpha$ -lutidinic acid ( $\alpha\gamma$ ); 4,  $\beta$ -lutidinic acid ( $\alpha\alpha'$ ); 5, isocinchononic acid ( $\beta\beta'$  or  $\alpha\beta'$ ). The reduction of the  $\alpha\gamma$  lutidine was effected by treating a hot concentrated alcoholic solution with sodium. No smell of ammonia was observed. Water was added, and the base distilled over with steam. The hydrochloride was prepared and purified, and reconverted into the base. The  $\alpha\gamma$ -lutidine boils at 140° to 142°, and is easily soluble in water, alcohol and ether. Its odour resembles that of the piperidine bases. Its formula was found to be  $C_{11}H_{13}N$ . The secondary nature of the base is shown by its compound with carbon-bisulphide and benzoyl chloride. The hydrochloride melts at 235°, and has the composition  $C_{11}H_{13}N \cdot HCl$ . The hydrobromide and picrate were prepared, also the gold and platinum double chlorides. The authors have isolated naphthalene from the animal oil boiling above 170°.—S. Y.

*Retene*. E. Bamberger and S. C. Hooker. Ber. 18, 1024.

CERTAIN facts observed by Ekstrand—viz., the reduction of retistene-quinone to retene by means of zinc dust, and the production of retene from retistene-ketone, have induced the authors to repeat their analysis of the quinone, to which they had previously assigned the formula  $C_{19}H_{14}O_2$ . The results of the later analysis shows this substance to have the composition  $C_{19}H_{16}O_2$ , the discrepancy being attributed to its difficultly combustible nature. This compound is, therefore, the quinone of retene, and not of the hypothetical hydrocarbon retistene. It yields, on oxidation with permanganate solution, oxyisopropylidiphenyleneketonecarboxylic acid, and diphenyleneketonecarboxylic acid.—J. B. C.

*On Nononaphthene*. M. Konowalow. Journ. d. Russ. Phys. Chem. Gesellsch. 1884 [2].

THIS hydrocarbon  $C_{19}H_{18}$  has been separated from the kerosene of the rock oil of Balachany, as well as from Beibatzky's rock oil. It boils at 135° to 136°, and has the specific gravity 0.7508 at 0° and 0.7652 at 20°. It is

acted on energetically by bromine, but only substitution products are formed. The presence of aromatic hydrocarbons could always be detected by Gastavson's reaction, but the amount never exceeded 0.5 per cent. Nonaphthene yields two chlorides of the composition  $C_{10}H_7Cl$ , the one boiling at  $185^\circ$  to  $188^\circ$ , the other at  $182^\circ$  to  $184^\circ$ . The latter compound, when heated in a tube with silver acetate, yielded an ether which boiled at  $200^\circ$  to  $203^\circ$ , and possessed a pleasant fruity smell. By heating the higher boiling chloride with plumbic hydrate, an alcohol was formed which yielded a ketone on oxidation, and, when heated in a tube with calcium iodide, it gave an iodide  $C_{10}H_7I$ , which distilled between  $100^\circ$  and  $110^\circ$ , at a pressure of 24mm., and was converted into an alcohol when treated with silver oxide. The chlorides in all the reactions described, yielded as a bye-product a nonaphthylene  $C_{10}H_6$  hydrochloric acid being liberated. This hydrocarbon boiled at  $135^\circ$  to  $137^\circ$ , and its specific gravity was found to be 0.8068 at  $0^\circ$ . By oxidation with chromic acid, nonaphthylene yielded ethylmethylketone, and a number of acids containing 2, 3 and 4 atoms of carbon. Nonaphthylene is reconverted into nonaphthene by heating it with hydrochloric acid in closed tubes to  $150^\circ$  to  $200^\circ$ , and finally to  $250^\circ$ .—S. Y.

*On a Homologue of Quinoline.* C. Beyer. Journ. f. Pr. Chem. 31, 47.

ANILINE was heated in closed tubes with acetone, nitrobenzene and hydrochloric acid, when an oily base, of the composition  $C_{10}H_7N$ , volatile with steam, was obtained. The hydrochloride and sulphate are easily soluble. The platinum double salt forms flesh-coloured needles, melting at  $227^\circ$ . The picrate crystallises from acetone in lustrous yellow scales, melting at  $170^\circ$ ; the chromate separates from water in yellow-red needles, which are more freely soluble than the chromates of other quinoline derivatives.—S. Y.

#### IV.—COLOURING MATTERS AND DYES.

*Compounds of Benzaldehyde with Aniline-hydrochloride and Stannic Chloride.* A. Elbers. Annalen, 227, 357.

ON adding benzaldehyde to a solution of aniline in strong hydrochloric acid, a precipitate is formed, which, on warming, redissolves, and crystallises out in the form of fine yellow needles. The compound consists of equal molecules of benzaldehyde and aniline hydrochloride, into which it is resolved by water, and is only stable in presence of strong hydrochloric acid. If stannic chloride is also present, a compound is formed, containing benzaldehyde, aniline and  $SnCl_4$  in the molecular proportion 3:2:1.—A. G. G.

*A New Synthesis of Pararosauiline.* J. Zimmermann and Albert Müller. Ber. 17, 2936.

A MIXTURE of 20grm. paranitrobenzylidene bromide, prepared as described by Wachendorf, with the action of bromine on paranitrotoluene (Ann. 185, 267), by 25grms. aniline, was heated slowly in an oil bath. The bromide first of all dissolved, then a separation of lustrous scales occurred, probably of the anilide of the para-nitrobenzylidene compound; at  $145^\circ$  a sudden and energetic reaction took place, the thermometer rising to  $200^\circ$ . The excess of aniline was then distilled over with steam, and the residue boiled repeatedly with water. The red aqueous solution imparted to wool and silk a beautiful carmine colour. The solution was precipitated by ammonia or caustic soda, and the colourless precipitate reduced with zinc dust and hydrochloric acid. It was identified as paraleucaniline. The residue, insoluble in water, dissolved easily in alcohol, and gave a bluer colour than the pararosauiline. The reaction differs from that described in a patent by Meister, Lucius and Brüning, inasmuch as a solvent is not employed. The authors attempted to prepare paranitrobenzylidene chloride by the action of chlorine at  $130^\circ$  to  $160^\circ$  on paranitrotoluene, but found that paranitrobenzoic acid was chiefly formed. The action of fuming nitric acid on benzylchloride also gave negative results.—S. Y.

*On Crystallised Methyl-violet.* A. W. Hofmann. Ber. 18, 767.

THE author has examined some samples of a new methyl-violet, which has recently been introduced by the Actiengesellschaft für Anilin Fabrikation, of Berlin. This colouring matter is obtained by the action of chlorinated methyl-formate upon dimethylaniline in the presence of aluminium chloride. (See this Journal, iv. [4], 279). In its tendency to crystallise well, it surpasses all aniline colours known. The crystals are opaque and show a peculiar greenish-brown metallic lustre. They are readily soluble in water and alcohol, the former solvent being the more suitable one for the purpose of recrystallisation. Many of the crystals were as much as 3 to 4 millimetres in diameter, and so well developed that pretty accurate measurements of the angles could be taken. The crystalline forms were those of the hexagonal prism and pyramid. The analysis of the recrystallised substance gave numbers showing its composition to be that of the hydrochloride of a hexamethylated rosaniline,  $C_{18}H_{15}(CH_3)_6N \cdot HCl$ . The composition of the platinum chloride double salt (obtained as a brick-red precipitate by adding platinum chloride to a solution of the colouring matter in concentrated hydrochloric acid) was found to agree with the formula  $[C_{18}H_{15}(CH_3)_6N]_2PtCl_6$ . The leuco compound was prepared by heating the violet with an aqueous solution of ammonium sulphide in a closed tube to  $120^\circ$ , and recrystallising the product obtained from alcohol. It melts at  $173^\circ$ , this being the same melting point as that found by O. Fischer for the base prepared from ordinary methyl-violet, considered by him to be a salt of hexamethylpararosauiline. The mode of preparation and the properties of the crystallised violet bear a great resemblance to those of a likewise well-crystallised violet-colouring matter, which is being manufactured by the Badische Anilin- und Soda-Fabrik. Their patented method (this Journal, iv. [4], 279) is founded on Michler's researches on the action of carbonyl-chloride upon dimethylaniline. The identity of the two colouring matters is therefore highly probable, and was proved by the fact that the leuco base of the latter also melts at  $173^\circ$ . The reactions which take place in the formation of methyl-violet from dimethylaniline and carbonyl-chloride are expressed by the following equations:—

The observation of O. Fischer and G. Körner, that by the action of ortho-formic ether upon dimethylaniline in the presence of zinc chloride a leuco base is formed possessing the same properties and the same melting point as that mentioned, is a further proof for the correctness of the supposition that the colouring matter is a hexamethylpararosauiline. The methyl-violet obtained by Wichelhaus's method—treatment of dimethylaniline with chloranil—seems also to be a hexamethylpararosauiline, but the author thinks that further experiments are necessary to remove all doubts as to its composition.—F. M.

*On the Action of Diazo-compounds on  $\beta$ -Naphthylamine.* T. A. Lawson. Ber. 18, 796.

THE RESEARCHES of Zincke and Bindewald on the hydrazine derivatives of  $\alpha$ - and  $\beta$ -naphthoquinones have shown that while the derivative of  $\alpha$ -naphthoquinone is identical with the phenyl azo- $\alpha$ -naphthol obtained by the action of diazo-benzene chloride on  $\alpha$ -naphthol, the corresponding derivative of  $\beta$ -naphthol is not identical with the

hydrazide from  $\beta$ -naphthoquinone, but is probably an isomeric hydrazine compound.

It appeared likely that a similar difference would be observed in the action of  $\alpha$ - and  $\beta$ -naphthylamine on diazo-compounds. The action of diazo-compounds on  $\alpha$ -naphthylamine has been frequently studied, and there is no doubt that true azo-compounds are formed. Griess and Meldola have also investigated the action of certain diazo-compounds on  $\beta$ -naphthylamine, but the nature of the products is not so certain. The researches of the author point to the fact that diazo-amido-compounds are formed by the action of diazo-compounds on  $\beta$ -naphthylamine. By boiling the products with acids nitrogen is evolved, and  $\beta$ -naphthylamine reproduced. This is the case with the compounds prepared by Griess and Meldola. These bodies are characterised by their yielding acetyl- and benzoyl-compounds, and on reduction they behave like amido-azo-compounds, yielding a naphthylenediamine.

Phenyldiazo- $\beta$ -naphthylamine  $C_{10}H_7.NHN=N-C_6H_5$  was prepared by dissolving 20 grm. crystallised diazo-benzene sulphate in 50cc. water and 50cc. alcohol, and adding an alcoholic solution of 14 grm.  $\beta$ -naphthylamine. The red precipitate was recrystallised from alcohol. It melted at  $102^\circ$  to  $104^\circ$ . It was not decomposed by boiling with alcoholic potash, or by solution in strong sulphuric acid. This solution has a fine blue colour; hydrochloric and acetic acids also give coloured solutions. When boiled with twenty per cent. sulphuric acid the substance is dissolved with evolution of nitrogen and formation of phenol and  $\beta$ -naphthylamine. The acetyl-compound  $C_{10}H_7.N(C_2H_5O)N=N-C_6H_5$  melts at  $152^\circ$  to  $153^\circ$ , and is very stable. The hydrochloride melts at  $162^\circ$  to  $163^\circ$ . These bodies were analysed.

The reduction of phenyldiazo- $\beta$ -naphthylamine was effected by boiling its alcoholic solution with stannous chloride until the colour disappeared, or by treating it with zinc dust and acetic acid. The base was set free from the hydrochloride or sulphate by addition of sodium carbonate. It melts at  $94^\circ$ , and is easily oxidised. The base has been described by Griess. It is probably an  $\alpha$ - $\beta$ -compound. The hydrochloride and sulphate were prepared and analysed; the composition of these salts is  $C_{10}H_7(NH_2)_2.2HCl$ , and  $C_{10}H_7(NH_2)_2.H_2SO_4$ . The picrate was also prepared. The acetyl-compound melts at  $234^\circ$ , and has the composition  $C_{10}H_7(NHC_2H_5O)_2$ . The benzoyl-compound melts above  $280^\circ$ , and its formula is

—S. Y.

#### On Nitroso-derivatives of Aromatic Diamines. O. N. Witt. Ber. 18, 877.

This paper contains some preliminary communications on the nitroso-amines corresponding to the nitroso-resorcinols. By adding to a cold solution of tetramethylmethaphenylenediamine in an excess of dilute hydrochloric acid, a moderately dilute solution of sodium nitrite, a deep reddish-brown precipitate is formed, which by recrystallisation from slightly acidulated hot water is obtained in a state of purity. It then forms deep garnet-red, almost black, lustrous needles, which in pure water dissolve with a claret-red colour. The analysis showed this body to be the monohydrochloride of a mononitrosotetramethylmethaphenylenediamine,

The free nitroso-base is prepared by adding sodium carbonate or hydrate to an aqueous solution of this body, and extracting the now orange yellow solution with ether. On the evaporation of the ether the base is left as a deep-brown, oily liquid, which gradually assumes a crystalline form. The aqueous solution of the nitrate of this base gradually decomposes, a reddish-yellow precipitate, probably consisting of nitrosotetramethylmethaphenylenediamine, being formed. Reducing agents quickly decolourise the solutions. The new nitroso-compound readily combines with amines and phenols to form colouring matters of different shades. Those

derived from naphthylamine, naphthol, and resorcin exhibit a strong fluorescence. The red salt described was likewise obtained by acting with two molecules of sodium nitrite upon one molecule of the diamine, no dinitroso-compound being formed in this case. The nitroso-group diminishes the basic properties of the diamine; the latter forms stable salts with two molecules of hydrochloric acid, whereas the nitroso compound combines with only one molecule. Tetramethylmethaphenylenediamine behaves in a similar manner to the phenylene-compound, but the nitroso-compound could not be separated in solid form.—F. M.

#### On Indigodicarboxylic Acid. Wilhelm Löw. Ber. 18, 917.

THE material from which the indigo dicarboxylic acid was prepared was terephthalaldehyde, which was obtained from paraxylene bromide (prepared by brominating paraxylene) by boiling it with water. The author describes the following derivatives of terephthalaldehyde:—

obtained by oxidising the aldehyde with the calculated quantity of potassium bichromate and sulphuric acid. It crystallises in needles, melting at  $255^\circ$ . The ether was prepared by passing hydrochloric acid gas into the alcoholic solution.

tion of terephthalic acid in concentrated sulphuric acid was treated with the calculated quantity of potassium nitrate dissolved in sulphuric acid. The nitro-acid forms large needle-shaped prisms, melting at  $160^\circ$ . It gives the indigo reaction with acetone. The ethyl ether is an oil.

#### (3.) Paracarboxybenzoic Acid,

heating terephthalic ether with sodium acetate and acetic anhydride, and boiling the product with dilute caustic soda. The acid cannot be fused, and is almost insoluble in most substances. It may be crystallised from hot glacial acetic acid.

#### (4.) Paradibromocarboxybenzoic Acid,

$C_6H_3 \begin{matrix} CHBr-CHBr-COOH \\ COOH \end{matrix}$ , was prepared by the direct action of bromine, at  $100^\circ$ , on the last compound. It was crystallised from methyl-alcohol.

#### (5.) Nitrocarboxybenzoic Acid,

carboxybenzoic acid with a mixture of nitric and sulphuric acids. It crystallises from hot water in needles, which melt at  $287^\circ$ , but decompose partially.

#### (6.) Dibromonitrocarboxybenzoic Acid,

direct action of bromine, at  $100^\circ$ , on the nitro-acid, yields, when treated with concentrated caustic soda, the

#### Indigodicarboxylic Acid.

(1.) Nitroterephthalic acid was treated with acetone and caustic soda, and the very dilute solution was heated for two hours to  $50^\circ$ . By the addition of dilute sulphuric

\* Note by Abstractor.—I have ventured to call this acid "terephthalic acid," because it stands between terephthalaldehyde and terephthalic acid, just as glyoxylic acid occupies a position between glyoxal and oxalic acid.—S. Y.

acid to the dark green solution, a deep blue precipitate of indigolincarboxylic acid was obtained. After washing and drying, it exhibited a coppery lustre.

(2) A very dilute solution of nitrophenylpropyl-carboxylic acid in sodium carbonate was heated with grape sugar and caustic soda until permanently alkaline. The indigo compound was separated from the green solution as before. Indigolincarboxylic acid is insoluble in ether, chloroform, and alcohol, but forms a deep blue solution with sulphuric acid, from which water precipitates the acid unaltered. The spectrum of the solution in alkalis resembles that of indigo, but the bands are nearer the red. The metallic salts are generally green or blue, but the silver salt has a sepia-brown colour. The barium salt has the composition  $C_{15}H_{11}N_2O_6Ba$ , but the silver salt contains four atoms of silver, so that the hydrogen atoms of the imido groups must also be replaced.

The ethyl ether was prepared from the nitro-terephthyllyl ether by the first method described above. It melts at a high temperature, and sublimes in prismatic crystals. It dissolves with a deep blue colour in sulphuric acid, and is reprecipitated by water, but undergoes partial saponification.—S. Y.

#### A New Group of Colouring Matters. O. N. Witt. Ber. 18, 1119.

THESE bodies are obtained by heating the amidoazo derivatives of *p*-toluidine (m.p. 118.5) with the hydrochlorides of primary amines. With *n*-naphthylamine, a product is obtained which bears no analogy to the indulines. The following is the method of preparation: 12grm. amidoazo-toluene are mixed with 18grm. *n*-naphthylamine hydrochloride, and as solvent 50grm. to 60grm. free naphthylamine are added. The mixture is warmed on the water-bath until the green colour changes to an orange-red. The calculated quantity of NaOH required to saturate the HCl present is added, and 3 to 4 volumes of alcohol. The new compound separates out on cooling. Crystallised from aniline, it forms yellow needles, having the formula  $C_{24}H_{19}N_3$ . The hydrochloride and sulphate of the base dissolve in water with a scarlet colour, and dye cloth the same shade. On soaping, the colour changes to yellow. Fuming sulphuric acid converts it into a sulphonated compound. The sulpho salt colours silk, in acetic acid solution, a fine orange. From the analysis, it appears probable that the substance is a safranine derivative of *o*-toluylenediamine. The above reaction is not limited to amidoazotoluene, but is common to all amidoazo bodies which contain the amido group in the ortho position with respect to the nitrogen atom. The azo derivatives of *β*-naphthylamine, as also the chrysoidines, give the same reaction. This reaction may be therefore used in determining the relative positions of the substituted groups in amidoazo compounds.—J. B. C.

#### *β*-Sulphophthalic Acid. C. Graebe. Ber. 18, 1126.

BINITRONAPHTHOL-SULPHONIC acid (the free acid of the potash salt, which forms the naphthol yellow S of commerce), when heated on the water-bath with nitric acid of sp. gr. 1.3, yields *β*-sulphophthalic acid. It is obtained as a syrup, which crystallises with difficulty, and is easily soluble in water and alcohol, but not in ether. The crystallised substance contains 1mol. of water. Sulphophthalic acid gives a corresponding fluoresceine derivative, which has no technical value as a colouring matter. It may be converted into *β*-oxyphthalic acid and the corresponding cosines.—J. B. C.

#### Intermediate Products of Reduction of the Nitroazo Compounds. J. V. Janovsky and L. Erb. Ber. 18, 1133.

THE paper is to a certain extent a repetition of the researches of Gerhardt, Laurent and Petrieu on the nitro derivatives of azobenzene. The authors have prepared the mono and the dinitro derivatives, the former yielding, on reduction, aniline and *p*-phenylenediamine, and the latter *p*-phenylenediamine, thus proving that the nitro groups occupy in reference to the azo group the posi-

tion 1,4. In the preparation of these nitro compounds, in addition to the above crystalline products, a considerable quantity of a red oil is formed. This, on reduction, yields *α*-phenylenediamine, and the oil is therefore a *α*-dinitroazobenzene. By further nitrating the dinitro compound, two trinitroazobenzenes are formed. By reducing mononitroazobenzene with  $(NH_4)_2S$ , azoazobenzene is obtained. From the dinitro compound, hydrazodinitroazobenzene and hydrazoazobenzene are produced. On the other hand, if an alkaline reducing agent, such as an aqueous solution of  $(NH_4)_2S$ , or alkaline solutions of  $ZnCl_2$ ,  $SnCl_2$  or grape sugar, all the nitroazobenzenes yield intermediate products, which the authors have named "nitrolic acids" of azobenzene. The constitution of these bodies is explained by the following formulae:—

—J. B. C.

#### Brasilin. K. Buchka and A. Ereke. Ber. 18, 1138.

BRASILIN gives, on heating with acetic anhydride to 130°, a tetracetyl and a triacetyl derivative. By the action of bromine on the former compound, a mono-, a tri-, and a tetrabromobrasilin were obtained. By the oxidation of brasilin with nitric acid, in an ethereal solution, brasilein,  $C_{16}H_{11}O_5$ , is formed.—J. B. C.

#### Azylines. E. Noeltzing. Ber. 18, 1143.

THE compounds obtained by Lippmann and Fleissner, by the action of NO gas on tertiary amines, were regarded as the azo derivatives of these bases. This view has been confirmed by the author, who, by the action of dimethylamine upon the chloride of the diazo derivative of *p*-amido dimethylamine, obtained a substance having the properties of Lippmann's tetramethylazylene, according to the equation

The same compound has been further obtained by the action of methyl-iodide on the base

first prepared by Meldola. The azylines are isomeric with the chrysoidines, and are similarly prepared. The primary substance of this class is the symmetrical diazidoazobenzene, which may be termed "azylene." Like the chrysoidines, these bodies have colouring properties, but owing to the costly process of preparation will probably have no technical value.—J. B. C.

#### Derivatives of Pseudoanilidine. E. Noeltzing and T. Baumann. Ber. 18, 1145.

THE authors have fixed the constitution of this substance by preparing it from *p*- and *o*-xylylene by heating the hydrochlorides of these bases with methyl-alcohol in sealed tubes. The constitution of these substances may be graphically represented as follows:—

Diazonitrobenzene is prepared in the usual way by the action of  $NaNO_2$  upon the hydrochloride of cumidine. The diazo compound is then brought into an acetic acid solution of cumidine, and sodium acetate added. Diazonitrobenzene separates out. By heating this compound with cumidine and cumidine hydro-

chloride to 60° to 80° it is converted into amidoazocumene, which crystallises from alcohol in yellow plates. By reduction with  $\text{SnCl}_2$  and  $\text{HCl}$ , amidoazocumene splits up into cumidine and cumylenediamine, which may be separated by fractional distillation with steam.

**Amidododecathylbenzene.**—If cumidine hydrochloride be heated with one molecule of methylalcohol to 200° for ten hours, and then to 300° for a further ten hours, a liquid base is obtained, boiling at 250° C., which crystallises in a freezing mixture. Mesidine, under similar conditions, gives the same compound. It must therefore be a derivative of isodurene, and has therefore the name of isoduridine.—J. B. C.

**Quinones from Para-methylated Amines.** E. Noelting and T. Baumann. Ber. 18, 1150.

The following amines were oxidised with chromic acid:—*p*-toluidine,  $\alpha$ -*m*-xylylidine and *o*-xylylidine, the former yielding quinone, the two latter toluquinone in very small quantity. Mesidine gives a satisfactory yield of *m*-xyloquinone (m.p. 72 to 73°) and pseudocumidine, *p*-xyloquinone (m.p. 123°); isoduridine gives on oxidation an oil, which may be purified by first reducing to the crystalline cumohydroquinone, which, on oxidation, forms the pure quinone (m.p. 11°).—J. B. C.

**The Influence of Light on the Course of the Chemical Reaction of Halogens on Aromatic Compounds.** I. Schramm. Ber. 18, 1272.

BROMINE when present in excess acts on ethylbenzene in the dark, forming ortho- and paraethylmonobromobenzene. The action of bromine on propylbenzene in the dark is similar, two isomeric bromine derivatives being formed. In the direct light of the sun, however, bromine enters the propyl-radical, forming monobromopropylbenzene in the first instance, and further on, dibromopropylbenzene—e.g., ethylphenyldibromoketole  $\text{C}_6\text{H}_5-\text{CBr}_2-\text{CH}_2-\text{CH}_3$ . If toluol, bromine acts in the dark on monobromopropylbenzene, produced under the influence of sun-light, bromoallylbenzene  $\text{C}_6\text{H}_5-\text{CHBr}-\text{CHBr}-\text{CH}_3$  is formed identical with that made directly from bromine and propylbenzene. Methylbenzene acts exactly like propylbenzene. Paraxylene and bromine form in the dark parabromoxylene, whereas in the presence of light the methyl-radical is attacked. The two isomeric compounds, meta- and orthoxylene, behave like the para compound.—S. H.

**Laboratory Notes.** E. Noelting. Bull. Soc. Ind. Mulhouse, 1885, 144.

(a) **New Azo Derivatives** (Sealed Note, June 1, 1881).—Thioaniline ( $\text{C}_6\text{H}_5\text{NH}_2$ )<sub>2</sub>S is converted by nitrous acid into a diazo derivative, described some years since by Kraft. This compound treated, on the other hand, with phenols or their sulphonated derivatives, in alkaline solution, yields azo derivatives constituting a class of colouring matters. When aniline is treated with  $\beta$ -naphtholdisulphonic acid, an orange-coloured body is produced; thioaniline under the same treatment yields a ponceau, equal in depth of blue to the ponceau R R R of Meister, Lucius and Brünig. Diamidodisulphobenzide under these conditions yields an orange; benzidine, on the other hand, a brownish violet, analogous to the Bordeaux of the same makers.

The constitution of these bodies is as follows:—

The bisulphonated derivative of benzidine gives with  $\beta$ -naphthol a beautiful ponceau. The chief interest of these compounds is in showing the influence exerted by the various S-groups in modifying colour.

(b) **Violet Colouring Matter from Paramidophenol** (Sealed Note, June 1, 1881).—Some time since Lanth obtained a series of violet colouring matters by treating the paradiamines of benzene and toluene with hydrogen sulphide and ferric chloride. Corresponding blue derivatives, in which two atoms of H are replaced by alkyl-radicals, have also been obtained. The author finds that paramidophenol is converted by the same treatment into a violet colouring matter. The result is probably typical.

(c) **Isobutyl Anilines** (Sealed Note, June 1, 1881).—By the action of isobutyl bromide upon aniline at 100°, or of isobutyl alcohol upon the hydrochlorate at 200°, mono- or di-isobutyl aniline is formed according to the proportions of the reagent employed. The mono derivative boils at 230–235°. Its acetyl derivative  $\text{C}_6\text{H}_4\text{N}(\text{C}_4\text{H}_9)_2\text{C}_2\text{H}_5\text{O}$  is an uncrystallisable oil, boiling at 260–265°. The latter yields a crystalline nitro derivative, which is converted by the action of tin and hydrochloric acid into monobutylparaphenylenediamine—i.e., with elimination of the acetyl group. This base, treated with hydrogen sulphide, and afterwards with ferric chloride, is converted into a blue colouring matter, soluble in water.—C. F. C.

**Pyridine Dicarboxylic Acid.** E. Noelting and A. Collin. Bull. Soc. Ind. Mulhouse, 1885, 147.

THIS acid, which is formed by the oxidation of quinoline with potassium permanganate, having its COOH groups in the ortho position, may be regarded as phthalic acid, in which an N atom takes the place of one of the CH groups of the benzene ring. In confirmation of this view the authors have demonstrated the following points of analogy in the reaction of the two acids. They both combine with phenols; heated with phenol and sulphuric acid at 120°, pyridine dicarboxylic acid yields a product of condensation which dissolves in alkalis to a red solution. Heated with resorcin and a dehydrating agent at 200°, it yields a derivative resembling fluorescein, this yielding a bromo derivative, having the properties of eosine. In this reaction, however, a considerable proportion of the acid undergoes resolution into carbonic and nicotinic acids.—C. F. C.

**Preparation of Blues from Rosaniline.** E. Noelting and A. Collin. Bull. Soc. Ind. Mulhouse, 1885, 148.

ON heating metatoluidine (50pts.) with rosaniline (10pts.) and benzoic acid (5pts.), at 180°, a blue colouring matter is produced, as in the case of ortho- and paratoluidine.  $\alpha$ -naphthylamine, under similar conditions, yields a violet,  $\beta$ -naphthylamine a blue (cf. Meldola, Ber. 16, 964). In the preparation of colouring matters of this class, on the large scale, aniline is used as the solvent, the excess being subsequently recovered. The authors have endeavoured to find a more economical substitute for the latter. In presence of phenol the desired result was not obtained; but by using naphthalene the development of a blue from aniline and rosaniline was found to follow the normal course. Experiments on the large scale, however, failed to establish any commercial advantage in the substitution of the hydrocarbon.—C. F. C.

**Transformation of Primary Amines into Mononitrophenols.** E. Noelting and E. Wild. Bull. Soc. Ind. Mulhouse, 1885, 153.

DINITRO derivatives of the phenols are formed, as was shown by Griess, when diazo compounds are boiled with nitric acid. By suitably varying the conditions from those which lead to this result, the authors have succeeded in preparing mononitro derivatives.

**Mononitrophenol** is obtained by operating in the following way:—93grm. aniline dissolved in 200grm. sulphuric acid, at 66° B., previously diluted with 2000cc. water, are diazotised at 0°, with 63grm. sodium nitrite. A quantity of nitric acid (1335 sp. gr.), containing 63grm.  $\text{HNO}_3$ , is then added, and the whole is boiled in connection with a reversed condenser, until the disengagement of nitrogen has ceased. The yield, in one experiment, was 20grm. ortho- and 15grm. paranitro-

phenol. The meta compound did not appear to be formed.

**Nitroacresylol.**—With 107 grm. paratoluidine replacing the aniline in the above, a very considerable yield of the metanitroparacresylol is obtained. In one experiment it amounted to 75 grm.,  $C_8H_7(OH)(NO_2)$ , melting at  $33.5^\circ$ . This was the sole product with exception of a small quantity of binitroacresylol and tarry derivatives. From orthotoluidine the nitro-ortho derivative (m.p.  $69.5^\circ$ ) was obtained. The yield, however, was less than in the case of the former.

$\alpha$ -Naphthylamine was converted into the nitronaphthol  $C_{10}H_7(OH)(NO_2)$ —m.p. 164—but the yield was small. Further investigations of the influence exerted by varying the conditions of these decompositions, will probably lead to their more complete realisation.—C. F. C.

**Nitration under varying Conditions.** E. Noelting and A. Collin. Bull. Soc. Ind. Mulhouse, 1885, 163.

As a contribution to this subject, the authors give the results of nitrating various compounds in presence of sulphuric acid in large excess.

**Acetanilide.**—The para derivative is easily prepared by slowly adding 500 parts  $HNO_3$  to 1000 parts acetanilide dissolved in 4000 parts  $H_2SO_4$ . The whole is cooled with a freezing mixture. The nitro compound is precipitated on pouring into water, and is obtained pure (m.p.  $207.0$ ) by once recrystallising. The yield is 95 per cent. of the theoretical. The ortho and meta derivatives are formed only in small quantity; the proportion of the latter is increased by increasing that of the sulphuric acid.

**Paratoluidine**, nitrated in presence of ten parts of  $H_2SO_4$ , yields a mixture of the isomerides  $NH_2$ ,  $NO_2$ ,  $CH_3$  (m.p.  $114^\circ$ ) and 1, 3, 4 (m.p.  $78^\circ$ ); by increasing the proportion of  $H_2SO_4$  to fifteen to twenty parts, the latter only is formed. From 100 grm. of the base, 100 grm. of the nitrotoluidine were obtained.

**Paracetotoluidine**, nitrated in presence of four parts  $H_2SO_4$ , yields, after saponification of the product, the isomeride  $NH_2$ ,  $NO_2$ ,  $CH_3$  in presence of ten parts  $H_2SO_4$ , a product is obtained, yielding, on saponification, a mixture of the isomeric nitrotoluidines 1, 2, 4 (m.p.  $114^\circ$ ), and 1, 3, 4 (m.p.  $78^\circ$ ). The proportion of the latter is increased by increasing that of the sulphuric acid.

**Orthotoluidine**, nitrated in presence of ten parts  $H_2SO_4$ , yields a new isomeride, melting at  $107^\circ$ , and for which the authors have established the formula

**Orthoacetotoluidine** yields a mixture of derivatives; but the nitration is, in this case, not so advantageous, and the authors, therefore, recommend the ordinary method.

**Metaxylene**, nitrated in presence of ten parts  $H_2SO_4$ , yields the derivative

**Metacresylolide**, nitrated as above, yields, by saponification, the same nitroxylidine (m.p.  $123^\circ$ ).

**Parabromaniline**, nitrated in presence of ten parts  $H_2SO_4$ , yields a new nitrobromaniline

The proof of its constitution is afforded by its yielding, on bromination in glacial acetic acid, the same tribromonitroaniline (m.p.  $102.5^\circ$ ), as is obtained from metaniline.

**Ethylacetanilide** is easily nitrated in presence of five parts  $H_2SO_4$ . On saponifying the product (m.p.  $115^\circ$ ),

nitroethylaniline (m.p.  $96^\circ$ ) is obtained. This compound is converted, by reduction with tin and hydrochloric acid, into a monoethylphenylenediamine. The reactions of this derivative are those characteristic of the para-diamines.

**Dimethylaniline**, in presence of a large excess of sulphuric acid, yields paranitrodimethylaniline exclusively.—C. F. C.

**Nitro-orthotoluidine (m.p.  $107^\circ$ ) and some of its Derivatives.** E. Noelting and A. Collin. Bull. Soc. Ind. Mulhouse, 1885, 193.

This compound, obtained as described in preceding abstract, crystallises in large prisms. It is soluble in alcohol, ether and acetone, but slightly in water. By diazotising and boiling the product it is converted into nitro-ortho cresol

the yield being nearly theoretical. This compound, treated with bromine in presence of water, is converted into the dibromo derivative (m.p.  $91^\circ$ ). By reduction with tin and hydrochloric acid, it is converted into the amidocresylol (m.p.  $160^\circ$ ) obtained by Wallach (Berl. Ber. 15, 2831) from metatolylenediamine. By diazotising the nitrotoluidine dissolves in nitric acid (2mol.); pouring the product into nitric acid, of sp. gr. 1.33, and boiling, a trinitro-ortho cresol (m.p.  $102^\circ$ ) is formed. This compound forms molecular compounds with hydrocarbons; thus with naphthalene the compound

crystallising in yellow needles (m.p.  $106^\circ$ ).

**Colouring Matters obtained from Metamidocresol.**—Metamidocresol resembles in its reactions metatolylenediamine and phenylenediamine. With nitrous acid it gives derivatives of the class of Bismarck browns, and with diazo compounds, chrysoidines. These latter, containing an amido group, may be further diazotised and combined with phenols, oxyacids, etc. On oxidising metamidocresylol, together with paraphenylenediamine or its homologues, a new series of neutral colouring matters is obtained; analogous compounds may be prepared directly by heating amidocresol with nitroso-dimethylaniline. These will be described in a further communication.—C. F. C.

**Nitro and Amido Derivatives of Metaxylene.** E. Grevinge. Bull. Soc. Ind. Mulhouse, 1885, 233.

**METAXYLENE**, nitrated in the ordinary way, is converted into a dinitroxylene (m.p.  $93^\circ$ ); by nitrating in presence of sulphuric acid seven parts, a second isomeride (m.p.  $82^\circ$ ) is formed simultaneously, in the proportion of about 25 per cent. of the mixed product. Both isomerides yield the same trinitroxylene (m.p.  $176^\circ$ ) on further nitration. From these and other facts subsequently detailed, the authors deduce the following constitutional formulae:—

Dinitroxylene (m.p.  $93^\circ$ ). Dinitroxylene (m.p.  $82^\circ$ ). Trinitroxylene (m.p.  $177^\circ$ ).

The isomeric dinitroxylens are difficult of separation; but the corresponding nitroxylidines, into which they are converted by the action of ammonium sulphide, are sufficiently divergent in physical properties to be easily separable. That obtained from the second isomeride (m.p.  $82^\circ$ ) is soluble in water and in petroleum spirit; it melts at  $78^\circ$ . That from the former (m.p.  $93^\circ$ ) is almost insoluble in these menstrua; it melts at  $123^\circ$ . Further, the latter dinitroxylene is much more susceptible of reduction than

the former, and, therefore, a fractional or partial reduction may be effected, in which this only is converted. The corresponding nitroxyls are easily obtained by the action of acetic anhydride upon the nitroxyls. The melting points of these derivatives are 160° and 169° respectively. The nitroxyls have been converted into the corresponding diamines; the melting points of the latter are 104 and 64 respectively. The former is obtained by the reducing action of stannous chloride; but to prepare the latter the nitroxyls require to be treated with tin and hydrochloric acid.

*Triaminodinitroxyline*, 1, 3, 4, 6, 2 corresponding to the trinitro derivatives above described, was obtained from the latter by reduction with stannous chloride. It is an unstable compound, decomposing, when heated, at 140–150°.

*Colouring Matters from the Di- and Triamines.*—On diazotizing these compounds, and employing the products for dyeing silk, in a soap bath, the shades obtained were red brown (diamine m.p. 64°); yellow brown (diamine m.p. 104°); olive green (triamine). With diazo-benzene sulphonic acid, the corresponding colouring matters obtained from these compounds were yellow orange, red orange, and reddish black. The results obtained in dyeing silk with these derivatives were, however, of a different order; the latter became a bright yellow; and deeper shades were obtained from the two former in the inverse order. The investigation of these products is proceeding.

*Nitration of Metacetylides*, 1, 3, 4. In presence of eight parts  $\text{H}_2\text{SO}_4$ , the two nitroxyls previously described were obtained; the isomeride, melting at 75°, constituted ten per cent. of the mixture. From the nitroxyls the amido group was eliminated by the action of ethyl-nitrite in presence of sulphuric acid and absolute alcohol. The resulting nitrometacetylides complete the proof of the constitutional relationships of these several compounds, which are as follows:—

	1, 3, 4, 6	1, 3, 4, 2
Dinitroxyline...m.p.	93°	m.p. 82°
Nitroxylidine...m.p.	123°	m.p. 78°
Diamine...m.p.	104°	m.p. 64°

—C. F. C.

*The Production of Violet and Blue Colouring Matters of the Rosiniline Series by treating Aromatic Amines with Alkylised Amido Derivatives of Benzoyl Chloride.* C. D. Abel, London. From the Farbwerke vormals Meister, Lucius and Brüning, Germany. Eng. Pat. 4961\*, March 15, 1884.

THIS is an amended specification of the patent No. 4961, of 1884, the amendment consisting in the excision of the second claim, and the parts relating thereto, which the inventors now declare to have been too broadly stated.—R. M.

*Process for the Partial Separation of Schaffner's Mono-sulphonic Acid from the  $\alpha$ -Monosulphonic Acid of  $\beta$ -Naphthol.* H. J. Haddan, Westminster. From the Farbenfabriken vorm. F. Bayer & Co., Germany. Eng. Pat. 8390, May 29, 1884.

THE object of this invention is to remove the greater part of Schaffner's acid from the  $\beta$ -naphthol- $\alpha$ -sulphonic acid by a cheaper process than the treatment of the sodium salts with alcohol. Three processes are given:—(1) By the fractional crystallisation of the Ba or Ca salt four-fifths of Schaffner's acid can be removed. (2) On neutralising the strong solution of the mixed acids with alkaline carbonates, four-fifths to five-sixths of the salt of Schaffner's acid separates out. (3) The mixed acids are mixed in the state of strong solution with about two-thirds the quantity of alkali necessary for neutralisation. On cooling, about four-fifths of the acid salt of Schaffner's acid separates. The filtrates obtained from either of these processes can, if necessary, be completely freed from the remaining traces of Schaffner's acid by any of the known methods, such as treatment with diazo salts, etc.—R. M.

*Improvements in the Manufacture of Colouring Matters suitable for Dyeing and Printing.* C. D. Abel, London. From the Farbwerke vormals Meister, Lucius and Brüning, Germany. Eng. Pat. 8741, June 9, 1884.

THIS invention relates to the production of azo colouring matters from the diamido derivatives of "oxy-sulpho-benzide." The preparation of these compounds is illustrated by the production of "diamido-oxy-sulpho-orthotoluide," one of the homologues, for which purpose two parts of orthocresol and one part  $\text{H}_2\text{SO}_4$  are heated to 180 to 190° C. till a sample gives a solid precipitate with water. The oxy-sulpho-ortho-toluide is then collected, washed and nitrated by boiling with dilute nitric acid. The dinitro compound is then reduced, and the diamido base is described as furnishing well-characterised crystalline salts. Substitution products, such as the dibromodiamido-oxy-sulphotoluide, etc., are obtained by brominating the dinitro compounds and then reducing. In order to prepare the colouring matters, the dilute solution of the hydrochloride of the base is diazotised and mixed with alkaline solutions of the naphthols, or other phenols, and their sulphonic acids.—R. M.

*Improvements in the Process of combining certain Diazo Compounds with Phenol, Cresol, Naphthol and the Sulphonic Acids of these Bodies for the Production of Colouring Matters.* A. M. Clark, London. From Wirth & Co., agents for Rudolph Krügener and the Farbfabrik vorm. Brönnner, Frankfurt-on-the-Main, Germany. Eng. Pat. 8806, June 10, 1884.

IN the usual processes for combining diazo compounds with phenols, the former are mixed with the alkaline solution of the latter, kept cool by ice. According to the present invention, certain of the more stable diazo compounds, such as diazonaphthalenesulphonic acid and diazobenzenesulphonic acid, combine with naphthol and other phenols when dissolved in acetic acid in the presence of sodium acetate. The colours obtained by this method are said to be purer than those given when alkali is used, and the inventor claims, as an advantage, that the use of ice can be dispensed with. The colours are, moreover, said to be isomeric, and not identical with those precipitated by the alkaline method. Detailed examples, illustrating the mode of working, are given in the specification.—R. M.

*Improvements in Producing Yellow Colouring Matter suitable for Dyeing and Printing.* John Erskine, Glasgow. From the Farbenfabriken vorm. F. Bayer & Co., Germany. Eng. Pat. 9162, June 19, 1884.

THE colouring matter in question is prepared by diazotising benzidine and combining the tetrazodiphenyl with salicylic acid, phenol or cresol. It is a fine yellow colouring matter, which dyes cotton in a boiling soap bath without the use of a mordant.—R. M.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

*Relative Value of Tartar Emetic and Antimony Oxalate as Mordants.* G. Hirzel. Chem. Zeit. 9, 725.

THE comparative tests made by dyeing with these two mordants show that for equal weights of antimony oxide in the two compounds, the tartar emetic produces the best effect, the acid character of the oxalate deteriorating from the brightness of the colour. The oxalate forms in a hot dilute solution a basic salt, which no longer combines with tannin, and, moreover, the oxalate calculated for the same weight of antimony is more costly than tartar emetic.—J. B. C.

*Improvements in Bleaching.* F. A. Gatty & Brother, Accrington. Eng. Pat. 8479, May 31, 1884.

THIS invention relates to a means of preserving the colours when bleaching fabrics made from white and

coloured yarns. The fabrics are run in an open beek or cistern for about 20 to 30 minutes in soap and water, at a temperature of 120 to 180° F., or more or less according to the colours. Oil or fat soap is used, and in such quantity as to give a froth on the water. After soaping, they are washed and squeezed, then passed through bleaching-liquor at 1' to 4' Tw., squeezed again, and then steamed for one or two minutes, as if for restoring whites after dyeing and printing. After steaming, the fabrics are washed and dried. Sometimes, when the colours can sustain it, the fabrics are passed through very dilute sulphuric or muriatic acid.—H. A. R.

*Improvements in Bleaching.* J. B. Thompson, New Cross, Kent. Eng. Pat. 9312, June 23, 1884.

THIS invention relates to improvements in the prevention of bowking stains, and the partial removal of the organic colouring matter in the material treated. Advantage is taken of the well-known affinity of aluminium in certain forms for vegetable-colouring matters. To the bowking alkali, aluminium is added in various forms—e.g., as ordinary trihydrate, finely-powdered gibbsite, or even as finely-powdered kaolin, or finely-powdered cyanite. The first two are used with an alkaline carbonate, with the last two a caustic alkali may also be used, the proportions recommended being from 60lb. to 80lb. caustic soda to the ton of cloth, with about 80lb. of gibbsite or artificial trihydrate. Quantities and proportions vary according to material treated. Artificial trihydrate may also be formed on the fibre by precipitation from aluminium chloride, or another aluminium salt, on the cloth itself. In this case the cloth is piled direct from the aluminium solution into the boiling kier, and there treated by the soda-ash solution. After boiling for five or six hours, the material is thoroughly washed, and is then ready for treatment with calcium hypochlorite in conjunction with carbonic anhydride, according to Eng. Pats. 395 of February 3, 1883, and 4707 of March 11, 1884.—H. A. R.

## VII.—ACIDS, ALKALIS, AND SALTS.

*Decomposition of Salts by Water.* H. le Chatelier. Compt. Rend. 100, 737.

FROM general principles the author comes to the following conclusions:—(1) That the quantity of free acid necessary to prevent the decomposition by water of a dissolved salt must increase with the quantity of the salt present; (2) That the decomposition of a salt is increased or diminished by rise of temperature according as the decomposition is endothermal or exothermal.

The conclusions were quite borne out by experiments with mercuric sulphate and antimonious chloride. In the decomposition of mercuric sulphate heat is absorbed, and a rise of temperature increased the decomposition, whilst with antimonious chloride a small quantity of heat is evolved and the decomposition is diminished by rise of temperature.—A. G. G.

*On the Preparation of Ammonia Gas.* Isambert. Compt. Rend. 100, 857.

THE reaction in the ordinary preparation of ammonia from  $\text{NH}_4\text{Cl}$  and  $\text{CaO}$  corresponds to an absorption of heat of 10·9cals., from which 7·55cals. are to be deducted for the formation of  $\text{Ca}(\text{OH})_2$ . At ordinary temperatures no ammonia is set free, even in vacuo, but the compound  $\text{CaCl}_2(\text{NH}_3)_2$  is formed, in the formation of which about 14cals. are evolved, and which only gives off ammonia at 180–200°. This is also the case with baryta and strontia; but with lead oxide, on the contrary, ammonia is evolved at the ordinary temperature, although the reaction requires an absorption of heat of 12·9cals. The author explains these phenomena by assuming a dissociation of the ammonium chloride; lime or lead oxide fix the hydrochloric acid even at ordinary temperatures, and cause to be yielded free ammonia or ammonia combined to form an ammonium-metallic-chloride. Barium and strontium do not act

sensibly on the free acid below 180–200°. In the foregoing reactions, therefore, the heat of combination of  $\text{NH}_3$  and  $\text{HCl}$  (42·5cals.) should not be taken into account, but the reaction is limited to the separation of the gases set free by a process of dissociation, the necessary heat being borrowed from neighbouring bodies. The formation of an ammonium-metallic-chloride rather hinders than aids the evolution of ammonia.—A. G. G.

*The Preparation of Double Cyanides of Chromium and Manganese analogous to the Ferric and Ferricyanides.* Odin F. Christensen. J. f. Prakt. Chem. 31, 163.

THE double cyanides of chromium and manganese have been already prepared by Hidsburg, Kaiser, Eaton, Fittig and Descamps.

*Potassium Chromicyanide*  $\text{K}_6\text{Cr}_2\text{Cy}_{12}$ .—A solution of chromic acetate is prepared by dissolving freshly-precipitated chromic hydrate, from  $\text{K}_2\text{CrO}_7$ , in acetic acid; after removing the excess of acetic acid, potassium cyanide is added to the nearly boiling solution, filtered and allowed to crystallise. After recrystallisation it forms light yellow crystals.

*Potassium Chromocyanide*  $\text{K}_3\text{Cr}_2\text{Cy}_{12} + 6\text{H}_2\text{O}$  is prepared by the addition of potassium cyanide to a solution of chromous acetate formed by mixing solutions of sodium acetate and chromous chloride. It forms a dark blue crystalline precipitate which is very oxidisable, so that air must be excluded in its preparation.

*Potassium Manganocyanide*  $\text{K}_3\text{Mn}_2\text{Cy}_{12}$ , prepared by dissolving manganic phosphate in potassium cyanide, and recrystallised from water containing potassium cyanide.

*Potassium Manganocyanide*  $\text{K}_3\text{Mn}_2\text{Cy}_{12} + 6\text{H}_2\text{O}$  was prepared according to the method of Eaton and Fittig. The salt is blue.—A. G. G.

*The Basicity of Hyposulphuric Acid.* H. Trey. J. f. Prakt. Chem. 31, 223.

KOLBE was of the opinion that hyposulphuric acid (dithionic acid) was monobasic, as experiments made to prepare an acid salt, a salt with two bases, an acid ether or an acid amine gave negative results. According to Oswald, a difference exists between a mono- and a polybasic acid, the latter dissolving less readily certain slightly soluble compounds, in presence of the neutral salts of the polybasic acid in question, whereas the contrary is the case with a monobasic acid. A similar result might be expected by the action of the acids with their salts on methylacetate. The action of hyposulphuric acid was analogous to that of hydrochloric acid, and it is therefore monobasic. Its composition is therefore  $\text{HSO}_5$ , according to Kolbe  $\text{SO}_5\text{OH}$ , in which sulphur acts as a pentad element.—J. B. C.

*Solubility of Salts.* Fr. Rüdorff. Ber. 18, 1159.

IF a saturated solution of a mixture of two salts is prepared, and a large excess of either of the components is then added, dissolved by heat and left to crystallise out again, in the case of some pairs of salts the resulting solution will be found to contain a larger quantity of the salt added, but a smaller quantity of the other salt than before the addition; thus a replacement of the one salt by the other has taken place. This is always the case when the two salts used form with each other a double salt, or are isomorphous. For instance, a saturated solution was made of ammonium-aluminium sulphate, and to one portion of 20cc., 6grm. of aluminium sulphate were added, and to another equal portion 4grm. of ammonium sulphate; 100grm. of the solutions at 18° were then found to contain: (a) Original solution—1·42grm.  $(\text{NH}_4)_2\text{SO}_4$  and 3·69grm.  $\text{Al}_2(\text{SO}_4)_3$ . (b) With excess of aluminium sulphate—0·45grm.  $(\text{NH}_4)_2\text{SO}_4$  and 16·09grm.  $\text{Al}_2(\text{SO}_4)_3$ . (c) With excess of ammonium sulphate—20·81grm.  $(\text{NH}_4)_2\text{SO}_4$  and 0·29grm.  $\text{Al}_2(\text{SO}_4)_3$ . Thus in (b) an expulsion of ammonium sulphate by aluminium sulphate has taken place, and in (c) an expulsion of aluminium sulphate by ammonium sulphate. Such pairs of salts are magnesium and zinc

sulphates, cupric and ferrous sulphates, potassium and ammonium nitrates, ammonium-cadmium sulphate and ammonium-cupric sulphate, iron-ammonium alum and aluminium-ammonium alum, etc. On the other hand, in the case of salts which do not crystallise together, this expulsion does not take place, but the solution will contain the same proportion of the two salts independently of whether there is an excess of one or the other. Such pairs of salts are copper and cadmium sulphates, zinc and cadmium sulphates, copper and beryllium sulphates, lithium and copper sulphates, sodium and nickel sulphates, sodium and copper sulphates, sodium chloride and barium chloride, lead and sodium nitrates, sodium sulphate and sodium phosphate, etc.—A. G. G.

*The Preparation of Strontium Oxide.* H. Leplay.  
Dingl. Polyt. J. 256, 169.

THE author, having observed that in the decomposition of strontium carbonate by means of superheated steam, the strontium hydrate formed loses water at temperatures near its melting point, and is converted into a solid mass of strontium oxide, has devised the furnace and process here described for producing the oxide. The moist strontium carbonate moulded into suitable forms is deprived of a portion of its moisture and warmed in the retorts N placed above the decomposing furnace A. The interior of A is heated to redness by the furnace B, the gases from which enter A through E, charged with native carbonate of strontium in large lumps, and when the whole is sufficiently hot, the flues E are closed and

the precipitation of sugar, a double pan of form shown in Fig. 3 is employed. The liquors flow into the inner pan A through C, are cooled by the aid of the current of water flowing through B in an opposite direction, deposit their strontium hydrate, which is collected by E, and flow away through D.—W. D. B.

*On the Densities of Solutions of Pure and Commercial Aluminium Sulphate, and on the Solubility of Alum in Solutions of Aluminium Sulphate.* Karl Reuss. Ber. 17, 2888.

THE materials from which alum was formerly prepared were Roman alunite and alum shale, both of which were roasted, the former yielding alum at once, the latter after addition of potassium sulphate. The percentage of aluminium sulphate in the alum obtained from the shale could not be determined from its density, on account of the large quantity of sulphate of iron present, and the strength of the alum was calculated from Poggiale's tables of solubility of potash alum. Now, however, alum and aluminium sulphate are usually prepared by treating bauxite and alunite with sulphuric acid. Bauxite yields a very pure aluminium sulphate, and alunite a concentrated solution of alum in aluminium sulphate, the latter being left behind in an almost pure state after crystallisation of the alum. The author gives tables representing the densities of solutions of pure and commercial aluminium sulphate, containing from 1 to 25 per cent. of sulphate, and at temperatures 15°, 25°, 35° and 45°. At 15° he finds the density of the pure solution to be re-

the hot gases from B led away through Q for purposes of evaporation. The lumps of partially dried carbonate are allowed to fall in from N, steam being introduced at F, superheated by passing through C, and liberated carbonic acid passing away through L. The strontium oxide formed is removed at the bottom of the furnace through doors H into waggons J. A fresh quantity of carbonate, equal to that removed at H, is introduced from N, the retorts in their turn being filled up. The process is thus practically continuous. Sight-holes K are provided at intervals. For separating the excess of strontium hydrate from the mother-liquors obtained in

presented by the equation  $d = 1.007 + 0.01p$ , where  $p$  = percentage of pure anhydrous aluminium sulphate. Experiments on the solubility of alum in solutions of aluminium sulphate were made by adding 4, 3, 2 and 1 per cent. respectively of anhydrous potassium sulphate to solutions of aluminium sulphate of various strengths, heating the mixture to 80° and allowing to cool. With the larger quantities of potassium sulphate, alum separated in every case; with 1 per cent. very little crystallised from a 7 per cent. aluminium sulphate solution, and none at all from a 6 per cent. solution. The density of the 6 per cent. solution after addition of potassium sul-

phate was 1.083 at 15°. The author concludes that in order to use as little potassium sulphate as possible it is necessary to employ solutions of aluminium sulphate containing more than 7 per cent.—S. Y.

*The Removal of Arsenic from Sulphuretted Hydrogen.*  
Otto Frlr. v. d. Pfondten. Ber. 17, 2897.

It is frequently necessary to obtain sulphuretted hydrogen free from arsenic, especially in cases of poisoning. Up to the present time it has been customary to employ materials perfectly free from arsenic, but ordinary ferrous sulphide is by far the most convenient substance which can be used, and it is not always easy to obtain hydrochloric acid quite free from arsenic, hence an easy method of removing arsenic from crude sulphuretted hydrogen would be of great advantage to chemists.

When sulphuretted hydrogen containing arseniuretted hydrogen is heated, three reactions may occur: The decomposition of the hydrogen sulphide, which takes place between 350° and 400°; the decomposition of arsine, which occurs at a higher temperature; and the mutual reaction of the two gases, forming arsenious sulphide and hydrogen, which is collected at 350-360°, but is not complete at this temperature, even when the gas is passed through a tube filled with charcoal. If, however, the impure gas is passed through a tube containing potassium polysulphides (diver of sulphur or potassa sulphurata) heated to 350°, the arsenic is completely removed. It was found best to heat the tube in an air bath. If the presence of hydrogen was not injurious, it was not necessary to maintain the temperature accurately at 350°. The gas was dried in the usual manner, and, after leaving the heated tube, was washed by passing it through a wash-bottle containing a solution of sodium carbonate. Numerous experiments showed that the removal of arsenic was complete, and that with ordinary reagents the tube need not exceed 30 cm. in length. The author explains the reaction by the equation  $2AsH_3 + 3K_2S_2 = 2As_2S_3 + 3H_2S$ .

—S. Y.

*On the Dissociation of Nitrogen Peroxide Gas.* E. and L. Natanson. Ann. Phys. Chem. 24, 454.

The authors have examined the specific heat and vapour density of nitrogen peroxide vapour under variable pressure and constant temperature. Kundt's method served for the determination of the specific heat. For measuring the vapour density the authors invented a special apparatus. The vapour was evolved in a closed space, which could be connected with another chamber as soon as the "equilibrium of dissociation" had taken place. In the second chamber air was approximately under the same pressure which prevailed in the first space. The small difference of pressure in the narrow connection tube, the pressure of the air in the second chamber, the cubic contents of the apparatus and the weight of the vapour are the data for calculating the vapour density. Further details, the mode of calculation and several results of experiments are to be found in the original paper. The observations were made at 21° C. and between the pressures of 43 and 640 mm. The vapour density increases between these limits from 2.024 to 2.762, whereas the specific heat decreases from 1.274 to 1.172. Nitrogen peroxide thus behaves differently from carbonic acid, nitrous oxide, ammonia or ethylene, whose specific heats increase with rising pressure. The authors think these experiments a new argument of the view that the alteration of the density of nitrogen peroxide vapour is due to the dissociation of  $N_2O_4$  in  $NO_2$ .

—S. H.

## VIII.—GLASS, POTTERY, AND EARTHENWARE.

*Process for Glazing Dutch Tiles.* Dingl. Polyt. J. 256, 191.

ACCORDING to Krzen, the air-dry tiles free from dust are washed with a solution of glue of 50° B., and allowed to

dry in the air. 100 parts of potter's glaze, with 5 parts of white burning clay, are mixed with a sufficient quantity of a solution of glue prepared by diluting 1 part of glue solution of 50° B. with 3 parts of water. The tiles are immersed in this mixture and treated subsequently as usual. An addition of acetic acid is made to the glue solution to prevent its gelatinising, and also to obviate the too rapid setting of the glazing mixture. If the solution contain too much glue the proper distribution of the glaze is rendered difficult.—W. D. B.

*On the Action of Strongly compressed Carbonic Acid on Glass under the Influence of Light.* L. Pfander. Ann. Phys. Chem. 24, 493.

THE author casually found that carbonic acid can attack glass under certain circumstances. The surface of a glass tube partially filled with liquid carbonic acid turned opaque in those places which were acted upon by the concentrated light of a Drummond lamp. This alteration already takes place after an action of a few minutes' duration. The opaque spots were always above the surface of the liquid carbonic acid, and the tube being partly immersed in a water-bath, nothing but light could have caused the opaqueness. This behaviour of carbonic acid may perhaps lead to an explanation of Bunsen's observation on the condensation of carbonic acid by glass surfaces (see Ann. Phys. Chem. N.F. xx, 545, and N.F. xxiv, 321; also Ber. 18, Ref. 249).

—S. H.

*The Production of Milk-glass.* A. Tedesco. Ger. Pat. 31,112, November 4, 1883.

THE inventor proposes to employ an alkaline fluoride in the place of cryolite. The fluoride is most advantageously prepared by the incomplete saturation of carbonated or caustic alkalis with hydrofluoric acid and subsequent evaporation of the alkaline reacting product. The ordinary mixture for milk glass consists of 25 parts of soda, 25 parts cryolite, 10 parts chalk, 170 parts sand. A precisely similar glass is obtained by the use of 33 parts of sodium fluoride, consisting of 90 per cent. of fluoride and 10 per cent. of carbonate, 5 parts of soda, 15 parts of china clay, 10 parts of chalk, 156 parts of sand. An alkaline fluoride may also be employed in the production of enamels for metallic surfaces.—W. D. B.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, CEMENTS.

*Preparation of Grey, Blue and Black Clay.* Dr. Carl Bischof, of Wiesbaden. Deutsche Topfer und Ziegler-Zeitung, 12, 1885.

THE manifold tints exhibited by different varieties of clay, as is well known, are mainly due to the admixture of carbonaceous or ferruginous matter. More particularly the latter—viz., the several oxides of iron cause the originally white silicate of alumina to change its colour, which is the more readily perceived on account of the moisture of the material. The grey, bluish, and even black colouring, caused by carbonaceous and other organic matter, disappears completely on burning with access of air. If white clay be triturated with bright and colourless water, such as distilled rain, well-, or spring-water, and then after subsidence be collected on a filter, a residue of the original colour is obtained. Blue clay is not decolourised by digesting with hydrochloric acid. On heating, the colour at first appears more intense, owing to the separation of particles of carbon, but it finally disappears. Some other curious points were observed in connection with water containing brown peaty matter, which had been filtered. Finely-decanted Bohemian kaolin settles down extremely slowly when being mixed with such water. After 24 hours' standing,

the mixture was still distinctly turbid and milky, whilst the same clay, mixed with distilled water, had settled down completely. The following table explains what took place:—

Appearance of Water.	Bright Distilled Water.	Filtered Shallow Well Water.	Filtered Rain Water.	Clear, Filtered, Brown Water from Stagnant Pond.
After 12 hours....	Almost Bright.	Almost bright (opaque).	Slightly turbid.	Very turbid (milky).
" 21 " ....	Bright.	Bright.	Almost bright.	Turbid.
" 60 " ....	—	—	Bright.	—
" 8 days ....	—	—	—	Slightly turbid.
" 12 " ....	—	—	—	Bright (faintly milky).

After such brown water has been treated several times with clay, its clarification becomes more and more rapid. The evolution of gas due to microbes, which always abound in such waters, probably tends to keep the particles of clay in suspension. Any affinity of the clay to the brown colouring matter, preventing the settling of the clay, is apparently lessened after a time, when the finest clay particles agglomerate more and more, whilst also they are saturated more rapidly with the colouring matter. Thus these particles subside more freely and rapidly. The colouration of clay, even by brown peaty water, is but a slow process. White kaolin was mixed with such a sample of water, and after eight days' standing, the slightly turbid liquid decanted. The residue having been transferred to a double paper filter, was of a brownish bluish tint, which became more distinct on being dried. Treated a second time in like manner, a brown residue resulted, and so on, until after ten repetitions of the treatment, a dark blue clay, with a brownish tint, was obtained, very similar in colour to many natural clays. The plasticity of clay is increased as the colouration gradually becomes more intense, and at the same time a faint lustre is perceived. Thus all the properties exhibited by natural coloured plastic clay are to some extent at least obtained by artificial means. As the plasticity increases, the clay after drying loses its power of staining one's fingers, but its hardness is increased.

—G. B.

*Improvements in the Treatment of Slurry or Slip in the Manufacture of Portland Cement.* H. Fajia, Westminster. Eng. Pat. 2161, February 17, 1885.

ACCORDING to this invention, the slurry, after it has left the wash mill, is treated in a centrifugal machine, revolving rapidly, and provided with a sieve, which may be of any desired fineness. The mechanical admixture of the raw materials, after they have left the wash mill, is thus completed most effectually, while small particles of chalk, such as in the wet process of manufacture would evidently be burned into free lime, and thus tend to produce a faulty cement, are removed from the slurry or slip.—E. G. C.

## X.—METALLURGY, MINING, Etc.

*Progress in Metallurgical Practice.* Dingl. Polyt. J. 256, 227.

FOR the production of aluminium, Lauterborn charges a furnace with coke, brings this up to the requisite temperature with an air-blast, and then introduces a mixture of aluminium sulphate, sodium carbonate, and antimony sulphide. The following reactions are said to occur:—

The sodium sulphantimoniate is fused with soda, and the antimony thus obtained in a condition suitable for repeated operations.

In order to obtain ammonia during the operation of removing tin and zinc from metal waste, Keimecken

(Ger. Pat. Add. 30,254, March 8, 1884) employs an alkaline solution of a nitrate as solvent, thus:

The last portions of tin are removed by treating the

waste with a solution of ferric chloride and dilute hydrochloric acid. The tin is precipitated from the liquors obtained by means of zinc.

For the removal of gold and silver from copper regulus, Mannes (Ger. Pat. 30,419, July 22, 1884) grinds the latter to a powder, mixes with from 1 to 3 per cent. of ammonium chloride, and heats in a muffle to temperatures below redness, till ammoniacal fumes are no longer given off. The regulus has not altered in appearance, but the gold and silver are now in the form of chlorides, the iron and copper being still combined with sulphur. The chlorides of gold and silver are extracted by any of their solvents, preferably sodium thiosulphate.

Probert recommends the plan of melting arsenic and sulphur ores containing gold and silver with litharge or lead in crucibles lined with dolomite.

According to Howard's patent, copper ores are decomposed with a mixture of potassium hydrogen sulphate, fluoric acid, sodium nitrate, sulphuric acid, and water. The electricity thus generated is utilised in the precipitation of copper in another bath.

Referring to recent discoveries of gold in the island of Bommelöen on the west coast of Norway, Weltz considers that there are slight grounds for the hope of obtaining the same in noteworthy amount. Traces of native gold have been found in Norway for forty years past.

Symons describes a plan adopted at Maidanpee, Servia, for the extraction of copper from poor ores, containing, upon an average, copper sulphide 1.05, blue and green carbonate 0.30, red copper ore 0.95, water 16.00 per cent. The ore was made into heaps of 300 tons, allowed to dry for a month, then roasted with seven tons of dry beechwood. The roasted mass was lixiviated, the copper precipitated from the liquors by cast-iron rods, cast into blocks, and brought into the market as black copper.

Brand contributes his experiments in relation to the steel melting processes in acid and basic crucibles. The puddled iron (I.) and spiegel iron (II.) employed were composed as follows:—

	I.	II.
Silicon .....	0.079	0.888
Copper .....	0.090	0.141
Manganese .....	0.140	12.07
Nickel and Cobalt .....	0.043	0.169
Sulphur .....	0.030	0.012
Phosphorus .....	0.231	0.076
Carbon .....	0.020	4.25

Experiments were made with three different "acid" crucibles, and one "basic." The composition of the substance of the crucibles was found by analysis to be as under:—

	Acid.			Basic.		
	(1) Coke-Clay.	(2) Graphite.	(3) Clay.	(1) Coke-Clay.	(2) Graphite.	(3) Clay.
Silicic Acid .....	42.78	24.63	53.92	4.8	—	—
Alumina .....	34.71	27.89	40.57	2.49	—	—
Magnesia .....	—	—	—	92.62	—	—
Sulphur .....	0.49	0.27	0.23	0.009	—	—
Carbon .....	18.60	40.43	—	—	—	—

The constituents of the charge worked in the coke-clay crucible, and of the steel obtained, were as under:—

	Charge.	Steel.	
		Sampled when fusion was complete.	Sampled 2½ hours' fusion.
Silicon .....	0.119	0.096	0.091
Copper .....	0.092	0.092	0.091
Manganese .....	0.74	0.360	0.380
Nickel and Cobalt .....	0.049	0.045	0.047
Sulphur .....	0.029	0.036	0.051
Phosphorus .....	0.223	0.223	0.224
Carbon .....	0.230	0.380	0.530
	1.482	1.232	1.623

The silicon, sulphur, and carbon in the charge, and steel of the graphite crucible were:—

	Charge.	Steel.	
		Sampled 1½ hr. after fusion.	Sampled 1½ hr. after fusion.
Silicon .....	0.119	0.211	0.296
Sulphur .....	0.029	0.035	0.039
Carbon .....	0.230	0.840	0.950

In the clay crucible the charge was made up of ninety-two parts soft iron, eight parts of spiegel iron. The analytical results were:—

	Charge.	Steel.	
		0.130	0.178
Silicon .....	0.143	0.037	0.041
Sulphur .....	0.028	0.037	0.041
Carbon .....	0.360	0.330	0.280

The steel from these three crucibles was found to possess a medium grain on fracture, but owing to the high percentage of sulphur showed a tendency to "red-shortness." The above experiments, with different "acid" crucibles, lead to the following general conclusions: High quality steel is adversely affected most of all by sulphur, next by phosphorus and silicon. Copper, nickel, and cobalt have but slight influence, unless they are present in large amount. Their adverse influence can thus be readily prevented. Excess of manganese causes brittleness, but in amounts less than 1.5 per cent. this element partly neutralises the bad effects of silicon, sulphur, and phosphorus. The likelihood of phosphorus increasing during the melting process is but small, since the materials of which the crucible is ordinarily composed do not contain sufficient of this element in the forms of combination in which it can combine with iron. On the other hand, silicon and sulphur readily migrate from the crucible to the steel. Whilst silicon and phosphorus are able in some measure to perform the functions of carbon, carbon, and carbon alone, imparts to steel its elasticity. It follows that the crucible mass should contain as little sulphur as possible; it is also of importance that the amount of carbon should not exceed that which is actually required to give the clay porosity. In the experiments with the basic crucible the charge was composed of ninety-five per cent. of puddled iron, five per cent. of spiegel iron, lime being added to assist the formation of slag, and oxide of iron as the oxidising agent. The following are analyses of the charge and of samples of the steel taken at different intervals:—

	Charge.	Steel I.	Steel II.	Steel III.
Silicon .....	0.119	—	—	—
Copper .....	0.092	—	—	0.097
Manganese .....	0.740	trace	trace	—
Nickel and Cobalt .....	0.049	—	0.050	—
Sulphur .....	0.029	0.063	0.065	0.077
Phosphorus .....	0.223	0.090	0.050	0.043
Carbon .....	0.230	trace	—	0.018

The steel obtained in this experiment was soft and malleable, and a rolled plate of 1.75mm. in thickness could be subjected to much bending and twisting without fracture; owing, however, to the high percentage of sulphur, the tendency to "red-shortness" was distinct. From a comparison of the above four analyses it is

evident that the reaction was practically completed during the melting up, the percentage of phosphorus alone subsequently undergoing any marked diminution. The difficulty with which phosphorus is oxidised and removed is explicable when it is remembered that ferric oxide is the oxidising agent. Copper, nickel, and cobalt have suffered no reduction; silicon has been completely removed, and the carbon in samples I. and II. is only present in traces. The increase of carbon in sample III. is ascribed by the author to accidental introduction. The increase in the percentage of sulphur is remarkable, and proves with what facility that element is transferred from the crucible to the charge. In this case the sulphur was derived from the tar employed in conjunction with the dolomite. The advisability of substituting other carbonaceous substance—as syrup—in place of tar is thus apparent. For the production of a chemically pure iron by a fusion process, a material free from copper, nickel, and cobalt, and containing only moderate amounts of sulphur and phosphorus, should be selected. The sulphur is eliminated by the addition of a considerable amount of manganese before the iron has lost its easy fusibility by removal of its carbon; the sulphide of manganese formed rises to the surface, and either unites with the slag or forms a regulus. The iron now contains only phosphorus, silicon, manganese, and carbon, and these can be eliminated by oxidation with oxide of iron in a basic crucible.—W. D. B.

*Extracts from the Review of the Mining Industry during the first Quarter of 1885. (Chem. Zeit. 9, 745.)*

P. MANHES, of Lyons (*Chem. Zeit.* 1885, 9, 81; and Ger. Pat. 29,006) obtains nickel and cobalt (after fusion to eliminate gangue), by heating the polybasic sulphur and arsenic compounds of nickel, cobalt, and copper in the Bessemer converter until the iron is almost got rid of. The regulus is then treated with HCl or submitted to electrolysis or fusion. To obtain malleable ferro-nickel and ferro-cobalt from crude nickel and cobalt ores, the latter are fused with cyanide of iron or yellow prussiate of potash and oxide of manganese, and a small quantity of aluminium is added before tapping.

Basse and Selve (*Berg- und Hütten-Zeit.* 1885, 44, 128) in Altena have taken out a patent for the manufacture of cube nickel and cobalt directly from the oxides, and from these malleable alloys may be prepared.

Stetefeld (*Chem. Zeit.* 1885, 9, 233) has sent several communications on the subject of Russell's process for extracting silver from ores in which the solubility of silver chloride in hyposulphite (thiosulphate) solutions is utilised, and the precipitation of such solutions by alkaline sulphides, the hyposulphite being reproduced. If the ore contain lead, the latter dissolves in the hyposulphite, and is precipitated with the silver. Russell found that lead carbonate is insoluble in sodium hyposulphite, silver and copper carbonate being soluble. The lead is therefore precipitated by sodium carbonate. A further factor to be considered in this method is that whereas a complete chlorination of the silver is necessary to the success of the process with hyposulphites (thiosulphates), the solution of double salts of copper and sodium hyposulphite dissolve considerable quantities of silver, silver sulphide and the compounds of silver with arsenic and antimony.

Möbns (*Chem. Zeit.* 1885, 9, 160; and Amer. Pat. 310,302) gives methods for purifying silver by electrolysis, and for the separation of gold with bromine and hydrobromic acid.

P. Manhès, of Lyons (*Chem. Zeit.* 1885, 9, 339; and Ger. Pat. 30,419), heats powdered gold and silver ores, without previously roasting with ammonium chloride, in order to convert the noble metals into chlorides.

Katterfeld, of Strassburg (*Chem. Zeit.* 1885, 9, 435), has published an interesting report on the platinum production of Russia, an industry which has increased largely in recent years.

N. W. Perry (*Chem. News*, 1885, 51 [1], 19, 31) has given an account of the occurrence, properties, and processes of fusing, casting, dephosphorisation and moulding of iridium.

F. A. Reinecken (*Chem. Zeit.* 1885, 9, 196; and *Ger. Pat.* 30,254) combines the process of recovering tin and zinc from metallic residues with the production of ammonia by heating these metals with nitre and alkali, thus forming sodium and ammonium stannates.—J. B. C.

*Cellular Structure of Cast Steel.* Osmond and Werth. *Compt. Rend.* 100, 450.

SMALL plates of cast steel, from 0.02 to 0.03mm. thick, fixed to glass by means of Canada balsam, were treated with cold dilute nitric acid, when the iron dissolved, leaving a carbon compound behind. A microscopical examination of the plates showed that cast steel possesses a cellular structure, the iron occupying the interior, and the carbide of iron forming the cell wall. The cells unite to form groups, which, in the thin plates, are seen to be separated by empty spaces, and therefore possess no walls. If a bar of cast steel is dissolved at the positive pole of a Bunsen cell in dilute hydrochloric acid, the residue, consisting of small sponges, preserves the original form. These sponges form a network, the meshes of which were filled with iron. If a polished surface of cast steel is etched with concentrated nitric acid, the dendritic structure of the cell-groups is seen. In tempered steel, only simple cells are found. The interior of the cells is obliterated by hammering, and the cell walls, which are but little extensible, more or less obliterated.—S. Y.

*The Treatment of Basic Slags.* H. Schüchtermann. *Ger. Pat.* 30,891, April 8, 1884.

SLAGS obtained from the basic process are finely divided, freed as far as possible from metallic iron, mixed with solution of calcium chloride, dried and calcined in presence of water vapour. Sulphuric, phosphoric and silicic acids, previously combined with oxides of the heavy metals, now enter into combination with lime, and the phosphates may be readily obtained therefrom by proceeding according to well-known methods.—W. D. B.

## XL.—FATS, OILS, AND SOAP MANUFACTURE.

*Experiments with Lubricating Oils.* S. Lamansky. *Dingl. Polyt. J.* 256, 176.

IN the experiments of which the results are to be enumerated first, the apparatus of Napoli and Deprez was employed, since with this it was possible always to subject known quantities of oil to the test. From the tabulated results of these experiments, the conclusions to be drawn are:—The coefficient of friction is dependent upon viscosity; liquid oils will not carry a heavy load, but have the smallest coefficient of friction; viscid oils, such as ricinus, among organic, and Glück cylinder oil among those of mineral origin, show a large coefficient of friction with a proportionately small load. These oils can only be employed successfully for the lubrication of light machinery when the parts in contact therewith are warmed. Experiments were also made by the aid of the same apparatus with oils of small viscosity—viz., sperm, olive, and a light mineral oil "oleonide,"—with a view of determining what relation obtained between velocity and friction. It was found that an increase of friction corresponds with an increase of velocity, but that the influence of velocity upon friction is more marked with small and heavy than with medium loads. The influence of temperature upon the lubricating powers of a large number of oils was studied by the aid of Thurston's apparatus. The coefficient of friction of mineral oils is easily influenced by changes of temperature, increase of temperature resulting in decrease of viscosity. In fact, the viscosity of ricinus, and the majority of mineral oils, is too readily affected by temperature for these to be regarded as first-class lubricants. In this respect sperm and olive oils show their superiority. The lubricating power of different mineral oils in the market, the viscosity of which varies between 55 and 70, differs very slightly, although these

are sold at widely different prices. Among mineral oils, the author has found that petroleum residues will carry the greatest load, and on this account, and their low price, he recommends their employment in railway axle lubrication. A mixture of equal parts of rape oil and petroleum residues has a smaller coefficient of friction with all loads than the residues alone, but after a certain limit of load is reached, the coefficient of friction of the mixture is more sensitive to an increase of load than the petroleum alone. The author's experiments lead him to recommend, for heavy work, a mixture of equal parts of rape and "waggon" (mineral) oils; this is confirmed by practical experience on the French railways. Mineral and ricinus oils, which, by the aid of Thurston's apparatus, were found to possess a high coefficient of friction, when heated to 75° to 83°, gave excellent results, owing to their thereby decreased viscosity.

—W. D. B.

*Extraction of Fat from Bones.* Dr. Lorenz. *Chem. Zeit.* 9, 484.

THE author has tested the efficacy of the benzene fat-extraction process, introduced by Seltsam in 1850, and finds that the bones after treatment with benzene still contain 1.6 to 2.5 per cent. (on the raw material) of fat, which can be extracted by a further treatment with benzene and 0.48-0.8 per cent., which is dissolved out by ether or a total of 2.08-3.2 per cent. of fat, which is lost in the actual process. This represents a loss of about 25 per cent. of fat. The author concludes that there is still room for considerable improvement in the method of extraction.—J. B. C.

*On the Insoluble Residue formed by the Distillation of Castor Oil in Vacuo.* F. Krafft and Th. Brunner. *Ber.* 17, 2985.

THIS subject has been studied by several chemists, but their analyses of the product do not agree. The authors distilled castor oil both under reduced and at the ordinary pressure. The residue in the retort, which solidified suddenly, was extracted repeatedly with ether, and macerated between each extraction. The product, now scarcely elastic, was dried in two cases in the desiccator, in three others on the water-bath at a pressure of 15mm. The analyses agreed well together, and fairly with the composition  $(C_{11}H_{20}O_2)_n$ . They differ widely from those previously published. It appears from them that the product is a polymeric modification of undecylenic acid  $C_{11}H_{20}O_2$ ; it shows *ex* resemblance to Fittig and Engel's methacrylic acid. The product, which resembles caoutchouc, is easily saponified by alkalis, and when fused with potash yields nonylic acid. When heated to 50-60° with four times its weight of fuming nitric acid for several days, it forms sebacic acid. Undecylenic acid when similarly treated gives the same acids, so that the nature of the product is confirmed. When pure undecylenic acid is heated in closed tubes for some hours to 300°, and subsequently distilled, the residue in the retort solidifies suddenly to a light yellow amorphous mass. If, however, the acid, after being heated, is distilled under a pressure of 15mm., unaltered undecylenic passes over first, the temperature then rises rapidly 100°, and between 255° and 275° a product distils over which readily crystallises on cooling, while the above-mentioned yellow solid remains behind. The crystalline body was redistilled, the temperature being allowed to rise to 250°, pressed, and recrystallised from dilute alcohol in a freezing mixture. It melted at 29.30°, and its composition was found to be  $(C_{11}H_{20}O_2)_n$ , or the same as undecylenic acid. The silver salt has the composition  $C_{22}H_{39}O_4Ag$ . The acid is therefore monobasic.—S. Y.

*Improvements in the Manufacture of Soap.* W. Rodiger. *Eng. Pat.* 9012, June 16, 1884.

IN order to neutralise the free caustic alkali usually present in soap, a strong solution of a bicarbonate of the same alkali (usually soda) is incorporated with the soap-paste at a temperature not far removed from 90° C.

—W. L. C.

*Improvements in the Manufacture of Soap.* A. Domcier and B. Nickels. Eng. Pat. 9375, June 24, 1884.

A COMPOUND termed in the specification "resinate of glycerine" is prepared by adding excess of powdered colophony to heated glycerine, and continuing to heat and stir for some hours. It may also be prepared by dissolving 4 per cent. of caustic soda in glycerine, and adding thereto 16 per cent. powdered colophony; about 15 per cent. or more of either mixture may be incorporated with soap in the usual way.—W. L. C.

*Improvements in Lubricating Oils.* Jakob Seeger. Eng. Pat. 13,512, October 13, 1884.

TALLOW, oil of turpentine, and cod-liver oil are mixed, and added to a solution of potash soap in warm dilute alcohol; the whole is stirred and cooled to 90° F., and rape oil is added to the mass. No quantities of the ingredients are given, but special qualities are claimed for the lubricant so produced.—W. L. C.

*Improvements in the Preparation of Oils for Medicinal Purposes.* W. G. Hadley. Eng. Pat. 1399, January 31, 1885.

To cod-liver and castor oils the patentee adds caustic alkali to neutralise the oleic acid, and then mixes with this emulsion, sugar syrup, glycerin, and aromatic essences, in order to make them more palatable.

—W. L. C.

*An Improved Method or Process of Purifying Fat and Oil.* H. H. Lake. From J. P. A. Larson. Eng. Pat. 2100, February 14, 1885.

THE patentee renders fit for food various inferior fats, such as tallow and olive oil, by subjecting them to the successive action (1) of steam at 150-250° C., with or without a vacuum; (2) of a mixture of alumina salts and dilute sulphuric acid, at 100° C.; (3) of an alkaline carbonate; (4) of some weak oxidising agent at a low temperature, such as very dilute nitric acid, soluble chromates, etc.—W. L. C.

## XII.—PAINTS, VARNISHES, AND RESINS.

*Ultramarine-blue from Silica.* Fr. Knapp. Journ. Prakt. Chem. 31, 154.

THE author has failed to prepare ultramarine from silica without alumina.—A. G. G.

*The Umber Deposits at Ashburton.* R. J. Frecheville. Trans. Roy. Geol. Soc. (Cornwall), X. vii. 217.

THESE deposits occur at Ashburton, near Dartmoor, and occur closely associated with deposits of dolomitic limestone. By the alteration and decomposition of the latter the umber has been formed, and the change is indicated in the following analyses by Mr. J. J. Beringer. No. 1 is the analysis of a sample of unchanged limestone, No. 2 that of the umber in its natural state:—

No. 1.	Per cent.	No. 2.	Per cent.
Water (lost at 100° C.)	0.8	Water (lost at 100° C.)	65.0
Carbonate of lime	46.7	Combined water	4.8
Carbonate of magnesia	11.0	Lime	9.5
Silica	3.3	Silica	12.3
Carbonate of iron	2.6	Fe <sub>2</sub> O <sub>3</sub>	6.3
Carbonate of manganese	2.5	MnO <sub>2</sub>	10.9
Undetermined and loss	3.1	Undetermined and loss	1.0

The carbonates of lime and magnesia have doubtless been removed by the solvent action of water containing carbonic acid, thus giving rise to the formation of deposits of umber from twenty to thirty feet in thickness. The deposit is worked by removing the over burden, consisting of from three to four feet in thickness of loam, and then sinking large rectangular pits in the umber till the unchanged rock is reached. The timber supporting the sides is then removed, the pit filled up, and another commenced alongside. The umber obtained, after being stamped in the usual manner, is ground under edge-runners, and the liquid mud pumped up to tanks, where it remains until it settles sufficiently to be dug out.

The drying is then completed in a manner similar to that practised in the preparation of china clay. The umber is used for making the so-called silicate-oxide paints, as a colouring matter for the coarser kinds of cloth, and in the manufacture of brown paper. The output of umber from this deposit for the year 1883 was 2766 tons, the price of which delivered on rail at Ashburton averaged about 25s. per ton. Small deposits of umber have been found near Milton Abbot and at Verran, seven or eight miles from Truro, in both cases as a result of the decay of limestone rocks.—W. S.

## XIV.—AGRICULTURE, MANURES, Etc.

*Composition of Unwholesome Meadow Hay.* Morgen. Biol. Centr. 14, 90-91.

THE hay in question, when used as fodder, caused the bones of the animals to become brittle. Two samples were taken and examined; they were found to be very deficient in lime and phosphoric acid. Taking moisture at fifteen per cent.—

	CaO	P <sub>2</sub> O <sub>5</sub>	Albumen.
Sample 1 contained	0.37	0.20	8.3 per cent.
" 2	0.07	0.26	11.9

Sample 1 consisted almost entirely of inferior "acid" grasses and weeds, such as *aridus stricta*, *calluna vulgaris*, *corce panicata*, *potentilla*, *juncea* (rushes) and such like, with only two good grasses, *anthoxanthum odoratum* and *agrostis alba*, in very small quantities. Sample 2, with the larger amount of lime, etc., consisted mostly of marshy vegetation; but, nevertheless, with notable quantities of good grasses, such as *holcus lanatus*, *agrostis alba*, *lolium perenne*, etc. Thus it would seem that the amounts of lime and phosphoric acid present form a good indication of the wholesomeness or unwholesomeness of hay.—D. A. L.

*Removal of the Bitterness from Lupines.* F. Bente. Biol. Centr. 14, 91-92.

LUPINES (100lb.) are immersed for twenty-four hours in dilute hydrochloric acid (containing for 100lb. lupines, 2lb. of strong acid), then a saturated solution of calcium sulphite (2lb.) is stirred in, and after twenty-four hours the liquid is poured off. The lupines are washed by repeated soaking in fresh quantities of water. The seeds, after treatment, are somewhat bleached, are odorless, and destitute of bitter taste. They are eaten readily by sheep, horses, cows and pigs, and when dried may be kept for a long time without spoiling. The air-dried lupine, after treatment, contains 37.28 per cent. albumenoids, and 3.38 per cent. of fat. The process here described occasions a loss of about twenty per cent.; but apparently not including much nutritive matter.—D. A. L.

*Formation of Free Hydrochloric Acid in Plants.* W. Detmer. Biol. Centr. 14, 108-109.

THE author contends that the organic acids of plants are capable of decomposing metallic chlorides with the liberation of hydrochloric acid. And, as an example of this, he instances the fact that the addition of a trace of chloride promotes the action of diastase on starch, which he explains in the following manner:—The organic acids in the malt extract liberate hydrochloric acid, which favours diastatic action to greater extent than its equivalent of organic acids. If, however, citric acid, alone, and with chlorides, is added to malt extract, the activity of the diastase is greater in the first than in the second case, from which it is inferred that too much hydrochloric acid retards the diastatic action to a greater extent than its equivalent of organic acid. Definite experiments were now made to prove the decomposition of chlorides by organic acids; citric and oxalic acids were employed along with various chlorides. Methyl-aniline violet was used as indicator, inasmuch as it is much more readily affected by hydrochloric than by citric acid. (a) 15cc. distilled water, and (b) 15cc. distilled water containing 0.02grm. citric acid, (c) 0.72grm. potassium chloride, (d) 0.7grm. sodium chloride, (e) 0.02grm. citric acid and

0.7 grm. potassium chloride, (f) 0.02 grm. citric acid and 0.7 grm. sodium chloride. After remaining 18 hours at a temperature of 20-25 C. the solutions were tested with methyl-aniline violet; the colour in (a), (c) and (d) was not changed, in (b) it was slightly changed, whilst in (e) and (f) it was changed to blue, or to the same extent as it would be by very dilute hydrochloric acid. Oxalic acid behaves in a similar manner to citric acid.—D. A. L.

*Behaviour of Zinc Salts towards Plants and in the Soil.* A. Baumann. *Bied. Centr.* **14**, 117-126.

In order to investigate thoroughly the much-contested question as to injurious or harmless effect of zinc salts on vegetable life, the author has made a series of water-culture experiments to study the effect, and the limits of the effect, of soluble zinc salts on various plants; and a series of experiments with soils and zinc salts to discover both the effect on the plant and the chemical changes produced in the soil. For the water-culture experiments the solution contained calcium and potassium nitrates, dipotassium phosphate, magnesium sulphate, and iron phosphate. To these zinc sulphate was added in various proportions, so that the four solutions contained 10, 5, 1, and 0.1 milligrams of metallic zinc per litre respectively. Thirteen plants of various kinds were experimented on. Starting from the seeds, these plants were germinated in a similar manner, selected as nearly alike as possible, and cultivated in the above solution at first without zinc. Observations made, when the zinc sulphate was given to the plant, showed the effect to be more injurious than was anticipated. All the plants resisted the influence of the smallest quantity of zinc, and only one—the radish (*raphanus sativus*)—died in the 1 milligram per litre solution. The following resisted the 1 milligram solution, but succumbed to the 5 milligram solution. They are arranged in the order of their susceptibility: Meadow clover, kidney vetch (*anthyllis cubicularis*), spurry (*spergularia arvensis*), vetch (*vein sativa*), barley, oats, cabbage (*brassica oleracea*), mangold wurtzel (*beta vulgaris*), and buckwheat; whilst sainfoin is not affected by the 5 milligram solution, but dies in the 10 milligram solution. Finally, the 10 milligram solution kills all the plants; the clover in 16 days, barley in 30 days, vetch in 31 days, radish in 46 days, the sainfoin in 194 days. The other plants are intermediate in the order indicated above. The *coniferæ*, however (pine and fir), flourish even in the strongest zinc solution. Older plants perish sooner than the younger ones of the same kind. The action of the zinc always shows itself by a change in the colour of the leaves. The effect of zinc sulphate when applied to the soil is, however, quite different, and depends greatly on the character of the soil. To substantiate this statement the following plants—meadow cat's-tail grass (*phleum pratense*), oat grass (*avena arvenstratum*), rye grass, soft meadow grass (*holcus lanatus*), field pea, sweet pea, and cabbage (*brassica oleracea*)—were grown in two kinds of soil, one a chalk soil rich in humus, the other a sandy soil free from humus and poor in lime. The plants were sown in pots, and representatives of each sort were watered daily, some with distilled water, some with a solution of zinc sulphate containing 20 milligrams of zinc per litre, and some with a solution containing double that quantity. In the sandy soil for the first six weeks all the plants were well, and those receiving strongest zinc solution looked most vigorous than any of the other plants. After this period the zinc plants fell off, and ultimately died, the grasses resisting for the longest time. In the calcareous soil matters were different, and not only were the zinc plants not killed, but they even surpassed in development those not receiving the zinc. The cause of these phenomena is plain; the sandy soil did not contain the necessary constituents to make the zinc harmless and insoluble, whilst the humus soil, on the other hand, absorbed the zinc, setting free other valuable plant foods, such as potassium, sodium, and magnesium in a soluble form. This conclusion was confirmed by experiments, wherein various soils were treated with zinc solution, and the quantity of zinc retained determined. The zinc absorbing power is greatest in soils rich in humus; then follow

clayey and calcareous soils, then other soils according to their richness in alkaline earths and humus; finally comes poor sand soil, which has scarcely any retentive power at all for zinc. From direct experiments the author concludes that alumina has great zinc absorptive power without becoming soluble itself; zeolites also decompose zinc sulphate, whilst calcium and magnesium carbonates precipitate the whole of the zinc as carbonate. With regard to insoluble zinc salts, water cultivations with some of the plants mentioned above in solutions containing zinc carbonate or zinc sulphide, proved that these salts were equally as fatal as zinc sulphate, owing to the solubility of zinc carbonate in water containing carbonic anhydride, and to the fact that zinc sulphide under similar conditions is converted into carbonate. This solution does not take place in the presence of calcium carbonate, when it is present in proportions equal to or exceeding four of this salt to one of the zinc carbonate. For the sulphide the quantity required is somewhat less. Therefore, there is no solution of zinc likely to take place in the soil, any way not to any injurious extent, and the author's experiments prove, as well as those of previous investigators, that insoluble zinc salts in the soil are harmless to plants. If, however, a soil should contain considerable quantities of soluble zinc—as, for instance, near zinc mines and works—the author recommends the use of peat, heavy dressings of farmyard manure, and the application of clay, marl, or chalk. Certain zinc powders have been offered in the market for use on the soil; it is scarcely necessary to add that such an application is strongly deprecated. The poisonous action of the zinc on the vegetable organism evidently consists in a destruction of the chlorophyll colouring matter, inasmuch as neither the development of vegetation in the dark, nor the growth of plants containing no chlorophyll, is affected by zinc.—D. A. L.

*Manurial Value of Peat Waste and Concentrated Liquors from the Strontium Sugar Factories.* Mareker. *Bied. Centr.* **14**, 140.

THIS manure contains from 2.5 to 3.3 per cent. nitrogen, of which about 0.16 to 0.20 per cent. is derived from the peat, and is only of small value; the greater part comes from the roots in the form of nitrates, ammoniacal compounds, amides and amido-acid, and is of the same value as ammoniacal manures. The potash amounts to from 11.5 to 14 per cent., and as it is not accompanied by any of the other salts, which so frequently render the impure Stassfurt manures injurious, it forms an additional qualification to recommend the mixture of peat and waste liquor as a valuable manure.

—D. A. L.

*Amount of Nourishment and Alkaloids in Different Varieties of Lupines.* Dr. E. Flechsig and Dr. E. Tauber. *Die Landw. Versh.* **1883**, 431.

TWELVE varieties were grown under the same conditions of weather, manure, and soil; the seed was examined for proteins, fat, etc., and alkaloids, the straw for woody fibre, ash, etc. The most nitrogenous seeds were accompanied by the most nitrogenous straw, and the latter contains the largest proportion of ash. The figures are interesting, and should be consulted.—J. R.

*Feeding Experiment with Lupines.* Sachs. *Landw. Zeit.* **1884**, 441.

THE Lupines had been treated by a patent process to remove bitterness, and were found to increase the yield of milk from a cow, but neither to injure it nor affect the flavour of the butter. Horses eat sparingly, and pigs refuse them.—J. R.

*Manurial Value of Freshly-fallen Leaves of Trees.* Emmerling, Loges, and Emeis. *Bied. Centr.* **14**, 87-90.

FRESHLY-FALLEN leaves from—1. grey poplar; 2. white willow; 3. silver poplar; 4. hornbeam; 5. birch; 6.

sycamore; 7. alder; 8. oak; 9. beech—were found to contain—

	1.	2.	3.	4.

" " "	15.73	17.74	17.09	17.73
and in 100 parts of dry matter :—	15.35			

cent.; the first-mentioned leaves would therefore constitute an excellent fertiliser, even for a very impoverished soil. It is noteworthy that the beech humus beneath the beech tree, resting on grey-sand formation, contained three times more nitrogen than the freshly-fallen leaves, whilst the mineral matter of the leaves was more than double that of the humus. Apparently, therefore, the dense

To compare these with one another, and with various straws, the analytical results were calculated on the mean percentage of water, 17.5 per cent., and from these figures the manurial value was obtained, by multiplying the amount of nitrogen by 5, phosphoric acid by 2, and potash by 1; manurial units are thus obtained of the value of 10 pennings (slightly more than one penny) each.

Hence, the ashes of poplar and willow leaves contained 5 to 5.7 per cent. of valuable plant food; the ash from sycamore 4 per cent.; whilst the proportion of these constituents in the other ashes amounted to from 2 to 2.3 per

cent. network of surface roots of the beech tree are especially adapted for utilising the mineral matter set free by the decomposition of the freshly-fallen leaves, thus leaving the soil richer in nitrogen.—D. A. L.

*Peat as Manure.* Dr. Schriener-Triesdorf. Sächs. Landw. Zeit. 1884, 429.

THE author has for 10 years carried on experiments in wooden boxes sunk in the ground, each about 1 cub. metre capacity, filled with about 13 cwt. of red sandstone; half the boxes received an addition of 5 peat earth. With oats the results were:—

	PURE SAND.		SAND WITH 5 PEAT.	
	Seed.	Straw.	Seed.	Straw.
	gtn.	gtn.	gtn.	gtn.
Unmanured .....	8	27	71	170
Mineral Manure alone .....	14	53	91	277
Mineral Manure plus Nitrate of Soda .....	199	367	492	857
Mineral Manure plus Sulphate Ammonia .....	470	837	553	1073

The addition of peat yielded similar marked increase with barley, rye, buckwheat, peas, beans, potatoes, etc.—J. R.

*Manuring Experiments with Precipitated Phosphate of Lime.* Löffbecke-Marzhausen Landw. Zeit. u. Anz. 1884, 612.

IN agreement with previous experiments on light soils these experiments in 1882-83, with barley on a clayey

loam, and oats on a light soil, containing lime and humus, show that precipitated phosphate of lime, associated with nitrate of soda, is far superior to the former alone, or a mixture of it with superphosphate.—J. R.

*Influence of Light upon the Germination of Seeds.* A. Cieslar. *Naturforscher*, 1884, 156.

THE results showed that a few seeds (*viscous albina*) will not germinate without light; others (barley, etc.) germinate equally in darkness or light; some (*Poa nemoralis*, etc.) were assisted by light. Yellow light assisted germination, violet hindered it, white light caused a marked improvement.—J. R.

*Chemical Analysis of the Outer Wood and Heart Wood of Various Trees.* Dr. W. Daube. *Forstliche Blätter*, 20, 177.

IN trees the constituents separate into several concentric layers, vitality is confined to the outer wood, the inner wood seeming to take no further part in it. A sharp characteristic difference between the outer and inner wood is, however, not yet known, but the author sought to establish one, and selected trees of the following ages,—larch, 103; fir, 104; pine, 75; oak, 125; beech, 180. The relative amounts of oxygen, nitrogen, carbon, hydrogen, and ash were determined without establishing any essential difference, save in the pine, where the heart-wood contained 54% of carbon against 50% in the outer, and 39% oxygen against 43%. The author thinks this is due to the larger amount of resin in the heart-wood. The various mineral constituents were then determined, and showed potash always most abundant in the outer wood, phosphoric acid decidedly so; lime varies, also magnesia; ferric oxide the same, sulphuric acid larger in amount in the outer wood, silica and soda in but slight quantity.—J. R.

*Dissolved Wool.* Dr. Märcker. *Magd. Zeit.* 1884, 121.

WOOL intimately intermixed with quicklime, and moistened with water, will, after 2 to 3 months, furnish a capital compost for autumn dressing. Wool can also be treated in lead-lined boxes, with sulphuric acid. This procedure, though dearer, acts quickly, and there is no loss of ammonia.—J. R.

*Upon the Assimilability of Phosphoric Acid contained in Stones and Soil.* G. Lechartier. *Compt. Rend.* 98, 1058.

THE author has made experiments to show the direct assimilability of the phosphoric acid contained in stones freed from all organic matters.

The trial soils were composed partly of slate, partly of granite, the stones carefully washed, dried, powdered, and mixed, filled into flower-pots, and manured with a mineral manure composed of ammonium nitrate, calcium sulphate, and a potash salt, also one-half of the pots received phosphate, the other not; each pot was sown with five seeds of buckwheat, which together weighed 0.12-0.13 gm., and contained 0.0012 gm. phosphoric acid.

The table below gives the results:—

EMPLOYED.		Dry substance harvested.		Phosphoric acid harvested.
		Gram.	Gram.	
Blue-grey compact slate, with 0.267 phosphoric acid.	without phosphoric acid	5753	0.018	
	with " "	21885	0.257	
Red slate, with 0.108 phosphoric acid.	without " "	9.41	0.051	
	with " "	12.36	0.513	
Granite, with 0.120 phosphoric acid.	without " "	9.74	0.076	
	with " "	31.20	0.206	

The added phosphoric acid considerably increased the yield, but the plants were evidently able to take up an

important amount of phosphoric acid from the pure mineral.—J. R.

*Comparative Trials with Peat Compost and Nitrate of Soda on Beet.* Dr. L. Kuntze Spora. *Neue Zeits. f. Rübenzucker Ind.* 1884, 133.

LEYES from strontia-treated molasses were made into a compost by drying up with peat; the mixture, containing 2.5-3.3% nitrogen and 11.5-14% potash with good condition, was tried associated with Baker guano or superphosphate, against nitrate of soda with the same. With cereals no difference was produced. With beet good results were obtained in yield of roots and of sugar; and trials with various sorts of beet also showed that the compost with Baker guano gave a higher yield of crop and sugar than nitrate with Baker guano.—J. R.

*The Absorption of Atmospheric Nitrogen by Plants.* W. O. Atwater. *Amer. Chem. J.* 6, 565.

IN order to decide the question whether plants growing under normal conditions are able to absorb a considerable weight of free or combined nitrogen from the air, peas were grown in washed and ignited sand, moistened with solutions of nitrogenous and mineral matter of known strength. The concentration of the solution, the absolute quantity of solid matter, and the proportion of nitrogen with mineral matter was varied in different experiments. The plants grew outside in the air, but protected from dew and rain. The excess of nitrogen found in the plants at the end of the experiments over the quantity of nitrogen which was in the seed and the solutions, represents the quantity of nitrogen taken from the atmosphere. Different experiments yielded an excess of nitrogen, which rose in one case to 51%. The greatest excess was found, if the concentration of the solutions did not interfere with a good thriving of the plants, and provided the supply of mineral matter was more than sufficient. In such cases there was a gain of nitrogen amounting to 50%. The author does not state his opinion how uncombined nitrogen can be absorbed by the plant, but only refers to experiments made by Berthelot, which show that electricity of such a tension as prevails on the surface of the earth in the air surrounding the plant can cause the absorption of free nitrogen by means of dextrine and cellulose.—S. H.

## XV.—SUGARS, GUMS, STARCHES, Etc.

*Experiments with Various Sorts of Sugar Beets.* Dr. G. Liebscher. *Bied. Centr.* 13, 774.

CARRIED out on deep loam, with lewt. of superphosphate ploughed in in autumn, and lewt. nitrate of soda in spring worked in by a cultivator. Average results according to yield of sugar placed the varieties as follows, the best being first: Kl Wanzlebener, Knauer's Elektoral, Wendelsteiner, Dornburger, Knauer's Imperial, Vilmorin, Stoeblitzer, Benkenborfer.—J. R.

*The Part played by Animal Charcoal in Sugar Factories, specially as regards the Silicate of Lime.* H. Pellet and A. Galvalowski. *Bied. Centr.* 13, 711.

MANY factories have lately worked without animal charcoal, by careful special filtration; this in most cases has presented no difficulty, but in some the filters have soon been stopped up, and this according to the author is caused by the silica in the juice derived from the limestone employed, and specially from the coke used in burning the lime; for instance, a piece of original limestone contained 0.16 to 0.20 per cent. silica, and a piece of burnt lime 6½ per cent. A part of the silica dissolves in the juice, gradually separates during the evaporation, lining the pipes with a bad non-conductor, and the other part not so separated hinders the filtration. Examination of a three-kettle system gave 0.40 per cent. silicic acid in the deposits of the first, 23.40 per cent. silicic acid of the second, and 69.80 per cent. in deposits of the third. Juice thus containing silica, when filtered through charcoal, loses it, and on revivifying the charcoal used, the

latter is gradually made harder. The limestone should not be intermixed with the fuel, but be heated from the side.—J. R.

*Preservation of Dried, Washed, Pressed Sugar-beet Sections.* H. Hellriegel. *Bied. Centr.* **14**, 93-98.

SEVERAL series of experiments were instituted to investigate the subject suggested in the title. Various samples of pressed sugar-beet sections were taken. Samples were prepared as follows:—(1) dried slowly at 50°; (2) dried slowly at 100°, but not quite free from water; (3) samples which had been slowly dried were heated strongly and dried to excess; (4) fresh samples dried at first partially, then completely in current of air; (5) fresh samples heated strongly and dried to excess; (6) not sufficiently dried, remaining soft and containing 20 per cent. of water. To compare with these samples of clover and meadow hay, pea-straw, rape, and earth-nut meal, dried to a somewhat similar extent as the sugar-beet samples, were also experimented on. These samples were subjected to various varying conditions of temperature and moisture for different periods. From time to time observations were made as to the growth or non-growth of mildew, loss or gain in moisture, and of the proportions of dry matter. From which numerous observations, the author concludes that the sections are not remarkably hygroscopic, and, in fact, are less so than many of our ordinary feeding-stuffs, such as clover and meadow hay. The sections are also not very prone to decomposition, and did not become mildewy as readily as oilcake and hay. Moreover, after eight months' storing under most unfavourable circumstances, they suffered less loss in dry matter than rape and earth-nut meal, and clover and meadow hay.—D. A. L.

*Growth of Sugar-beet.* B. Corenwinder. *Bied. Centr.* **14**, 113-115.

SUGAR-BEET were grown on a soil somewhat poor in phosphoric acid, plots were arranged without and with different manures. The application of 600kilos. ammonium sulphate per hectare increased the yield per hectare from 33,440kilos. to 51,750kilos. The same quantity of ammonium sulphate, with 400kilos. superphosphate, gave a yield of 55,400kilos., whilst sowing 200kilos. of magnesium sulphate, in addition to the above quantities of the other manures, yielded 54,900 kilos., showing that the magnesium salt was superfluous. The composition of the roots from all plots was about the same, and the author remarks that the plant evidently assimilates definite amounts of mineral constituents without reference to the supplies in the soil. Cultivations of sugar-beet were made in washed and ignited sand with (1) all the necessary constituents, and (2) with lime excluded. The yield of roots in the first case was more than double the yield in the second, although the weight of leaves was in the reverse order, whilst without lime the percentage of sugar in the roots was lower, but the ash per cent. was greater than with lime. It is of interest to note that a remarkable effect withholding this ingredient has on the growth of the plant in spite of the very small percentage of lime (0.037 to 0.04) contained in normally-grown roots. The author remarks that water-culture only gives trustworthy results with water plants, and that for other plants purified sand should be used as the cultivating medium.—D. A. L.

*A Sugar and Betain from Cotton Cake.* H. Rittbansen and Others. *Bied. Centr.* **14**, 132-133.

THE sugar is obtained by extracting cotton cake with 80 to 85 per cent. alcohol. It crystallises in needles, reduces Fehling only after heating with acid, and its rotatory power is  $D_{20} = 104.5$ . This sugar is identical with the plus-sugar obtained from molasses by the strontium hydroxide process, also with Bohm's "gossypose," and Loiseux's "rafinose." Tollens does not recognise its identity with Berthelot's melitose, and therefore suggests the retention of the name raffinose. A betain, hydroxyquinoline, is obtained from the

mother-liquor from the sugar by precipitation with platonic chloride. Bohm has obtained quinidine platinochloride, by precipitation, from cotton seed.

—D. A. L.

*Composition of Starch-sugar Syrup, of Honey, and the Adulteration of the Latter.* J. Sieben. *Bied. Centr.* **14**, 134-137.

STARCH syrup, when fermented with yeast, yields less alcohol than pure dextrose, but more than corresponds to the dextrose present in the syrup, hence some other sugar must take part in the fermentation, even if only incompletely. The residue from pure dextrose, after fermentation, does not reduce Fehling's solution; but that from dextrose syrup reduces it strongly. From other determinations, the syrup is found to consist of: dextrose, 21.97 per cent.; maltose, 15.80; dextrin, 41.96; water, 20.10; ash, 0.30. The author has examined sixty samples of genuine honey. In very many cases saccharose was absent, in other cases it was present in small quantities, in some it reached four per cent. and in one eight per cent. Dextrose and levulose together compose about 68 to 78 per cent. of honey; the ratio they bear to one another, however, varies. The average composition of the sixty samples was:—Dextrose, 34.71 per cent.; levulose, 39.24; saccharose, 1.08; water, 19.98; non-saccharine matter, 5.02. The author heats the honey with hydrochloric acid, which destroys the levulose, with brown colouration, more readily than the dextrose, which can then be estimated alone. To detect adulteration of honey with starch syrup, the author proceeds as follows:—25grm. of honey are fermented for forty-eight hours with 12grm. of yeast free from starch and water, to make up 200cc.; aluminium hydroxide is then added, the solution made up to 250cc., and 200cc. of the filtrate are evaporated to 50cc. and examined in the polariscope. The presence of starch sugar will be indicated by dextro-rotation. When the residue from fermentation is heated with hydrochloric acid, the product should not reduce Fehling's solution, as honey contains no dextrin. The method mentioned above (heating with hydrochloric acid, etc.), and one wherein slight excess of Fehling's solution is used, and the filtrate examined after heating, are sometimes employed for detecting starch sugar in honey.—D. A. L.

*On the Occurrence of Leucine and Tyrosine in Beetroot Molasses.* E. O. von Lippmann. *Ber.* **17**, 2835.

SOME time ago the author observed the occurrence in the molasses of a monobasic acid,  $C_{11}H_{19}NO_4$ , identical with Schützenberger's glutamic acid (*Ann. de Chim.* v. 16, 289) and probably with Hattinger's pyroglutamic (*Wiener Monatshefte* 3, 228). The author concluded that the glutamic acid, as well as aspartic and other nitrogenous acids were formed by the action of alkalis on the albumen of the beetroot. It is true that the beetroot itself contains asparagine and glutamine, but other characteristic decomposition products of albumen are found in the molasses, and probably the greater part of the nitrogenous constituents consist of such compounds. The author now describes the separation and identification of leucine and tyrosine. A quantity of the ammoniacal alcoholic waste liquor from the calcium saccharate, which is frequently allowed to accumulate in works, was neutralised with sulphuric acid and allowed to stand, when a compact precipitate formed. The liquid was drawn off and evaporated to a small bulk. The residue was dissolved in hot water, neutralised with lead acetate, and filtered. The filtrate, after removal of excess of lead with sulphuretted hydrogen, was evaporated, and the thick residue thrown into strong alcohol. A gummy precipitate was formed, and was purified by repeated digestion with strong alcohol. It was found to consist chiefly of dextrin. The alcoholic solutions left a clear syrup on evaporation, which dissolved completely in hot water. Lead acetate was added until no further precipitate formed, and the filtrate was decolourised with animal charcoal. The syrup deposited crystals, which were removed. The mother-liquor was further concentrated, and after stand-

ing some weeks yielded a second crop of crystals. The first-formed crystals consisted of tyrosine, the second of a mixture of tyrosine and leucine, which were easily separated by alcohol. The two substances were identified by analysis, and by a careful study of their properties. The optical properties of the tyrosine and leucine were examined by Professor Landolt, and the identity of the compounds with those obtained from animal matters was established. Schulze and Bosshard obtained active tyrosine and leucine, the former levo-, the latter dextro-, by decomposing conglutine, prepared from the seeds of the lupin, with hydrochloric acid, but inactive compounds by decomposing conglutine with barium hydrate; but the active substances were obtained from beefroot by the action of lime or caustic alkalis. The author has observed the same decomposition products of the albuminates in the etiolated shoots of the beefroot as in those of other plants growing in the dark. The shoots were crushed and pressed, and the liquid was boiled, filtered and precipitated with alcohol. The precipitate contained asparagine, and from the filtrate, asparagine, tyrosine, leucine, glutamine acid and aspartic acid were isolated. A single observation showed that the tyrosine was dextro-, so that there are two optically isomeric tyrosines.—S. Y.

*Purification of Refuse Water from Sugar Factories.* Dr. A. Bodenbender. Braunsch. Landw. Zeit. 52, 16.

THESE waters contain much suspended matter, nitrogenous and non-nitrogenous substances, also various salts, such as chlorides, phosphates, etc. Decomposition sets in readily. The author proposes to filter off the suspended matter, and then to treat the water with sulphate of alumina, magnesia, or protoxide of iron, or else ordinary superphosphate, afterwards adding lime to a weak alkaline reaction. The clear water can be run off, whilst the deposit yields a valuable manure. This treatment is good even for irrigation purposes, as the irrigation fields, not being overloaded with decomposing organic matter, will be effective much longer. Such water can be used for household purposes, or be with safety discharged into a small water course.—J. R.

*Researches on Milk, Sugar, and Galactose.* W. H. Kent and B. Tollens. Ann. 227, 221.

THE authors prepare mucic acid by heating 100grm. coarsely-powdered milk sugar with 1200cc. nitric acid of sp. gr. 1.15 in a porcelain basin on the water-bath, until the volume is reduced to 150 or 200cc., or until the liquid has become thick. After cooling, 200cc. of water are added, and after standing some days, the mucic acid is filtered and washed with 500cc. of water. The yield is about 40grm. Milk sugar is converted by dilute hydrochloric or sulphuric acid into galactose and dextrose:

The yield of mucic acid from 100grm. galactose, treated as above, is 77.4 per cent. When 10grm. of galactose are heated with 20cc. of hydrochloric acid of sp. gr. 1.12 to 100° for 5 hours, levulinic and formic acids are formed. By heating 3grm. of mucic acid with 10grm. of water to from 175 to 180° for 8 hours, it is decomposed, probably into dehydromucic acid, pyromucic and other bodies.

—S. Y.

## XVI.—BREWING, WINES, SPIRITS, Etc.

*How Sulphur acts against the Oidium Fungoid.* E. Mach and Portele. Die Weinlaube, 1884, 349.

RECENT experiments confirm the previous conclusions of J. Moritz, that sulphur acts by formation of sulphurous acid, which formation is much assisted by elevation of temperature.—J. R.

*Comparison of Barleys of Various Countries.* L. Marx. Zeits. f. d. Ges. Brauwesen, 1884, 375.

THE author has examined over 400 barleys of the last 6 harvests of various countries, for the protein com-

pounds and phosphoric acid. The proteins vary from 9.60 to 12.76%; the phosphoric acid from 0.913% to 1.911%; Russia and Baden being highest, England and Austria lowest. No connection was found between the amounts of proteins and phosphoric acid; these both vary much, and whether a barley be rich in them can only be determined chemically, as a country will produce barley at one time rich and at another time poor in these constituents.—J. R.

*Production of Maltose.* L. Cuisinier. Chem. Centr. 15, 413.

DISTILLED water is best. Water containing calcium bicarbonate or gypsum must be freed from these; a water extract from green malt should be used. Directions are given for dissolving up the starch by use of water, malt extract, stirring and regulated temperature. Finally, the syrup is to be filtered and concentrated.—J. R.

*Plastering Wine.* J. Erdélyi. Die Weinlaube, 1884, 340.

AN experiment to show whether the colour and keeping power of wine is increased by plastering. The result was negative, and in author's opinion even injurious.

—J. R.

*The Influence of Grape Stones upon the Tannin of Red Wine.* Dr. J. Nessler. Bied. Centr. 13, 862.

RESULTS show that the skins which rise to the top, and the stones which fall to the bottom, should both be thoroughly stirred up in the wine some three or four times daily.—J. R.

*Correction of Acidities in Wine.* Dr. P. Wagner and Dr. F. Becker. Bied. Centr. 13, 862.

NUMEROUS experiments show that the addition of alcohol, neutral tartrate of potash, potassium carbonate or bicarbonate, powdered marble, chalk, or oyster shells, are, for various reasons, injurious, but chemically pure calcium carbonate may be used in proportion to the amount of free tartaric acid present.—J. R.

*Contributions to the Chemistry of Maltting and Manufacture of Spirits.* Prof. Behrend, of Hohenheim. Bied. Centr. 14, 51.

THE first part of this paper treats of the extraction of inorganic and organic matter by the "steeping water." Three kinds of barley were experimented on—Saxon, Bohemian, and Hungarian, and 1000 dried grains of each of these contained respectively 40.22, 35.82, and 33.44 grams. In the experiments ten litres of water were poured on 10 kilograms of barley contained in a suitable conical tin vessel provided with an outlet for water at the lower end. After 14 hours the first "steeping water" was run off and measured. The deficiency from 10 litres represented the quantity of water retained by the grains. It seems that the small grains retain slightly more water than the larger kinds. A second 10 litres of water were then added, and replaced after 24 hours by a third 10 litres. The third "steeping water" likewise remained 24 hours in contact with the barley, which was then fully steeped. Aliquot volumes of the three steeping waters were evaporated, dried at 110° to 115° C., weighed, burnt, and again weighed. The weights thus obtained gave total solids, and the inorganic and organic matter extracted. The water employed was exceptionally hard, and contained per litre 0.656grm. organic, and 0.354grm. inorganic matter. The results are tabulated in the original; they indicate that the first "steeping water" extracts the largest quantity of solid matter from the barley, whilst the third extracts the least, but nevertheless a considerable quantity. They, moreover, show that the first two "waters" extract more inorganic than organic matter, whereas the third "water" contains more organic than inorganic matter, and the total combined waters about equal amounts of each. And another point of special interest to the brewer is evident from these results—namely, that the smaller

grains yield more to the water than the large ones do, no matter from what standpoint the case is viewed; thus Saxon barley gives up 0.55 per cent. of its dry matter, Bohemian 0.63, Hungarian 0.79. The author gives a full explanation of these phenomena, attributing all to osmotic action. Owing to the large removal of nutritive matter by the "steeping water," prolonged steeping, especially in the case of small grain, should be avoided in practice.

In the second part of this paper the changes produced by germination in the nitrogenous matter of barley are investigated. In these experiments the Saxon and Hungarian barley, mentioned above, were employed. A preliminary experiment showed that the conversion of insoluble into soluble nitrogenous matter takes place very rapidly. In other experiments the grain was steeped for 36 hours, using two successive lots of water. It was then spread in layers about 2cm. deep to germinate. At various periodical stages carefully selected samples were taken, and total nitrogen, nitrogen soluble in water, and non-albumenoid nitrogen determined in them. All nitrogen determinations were made by Kjeldahl's method, which was found very satisfactory. The non-albumenoid solution was prepared by boiling the aqueous extract with ferric acetate, and filtering off the precipitated albumen. The results are tabulated below:—

CHANGES PRODUCED IN THE NITROGENOUS MATTER BY GERMINATION OF SAXON (LARGE-GRAIN) BARLEY.

STAGE.	PERIOD OF GERMINATION.	100 BARLEY GRAINS CONTAIN		PER CENT. NITROGEN IN THE DRY MATTER.					
		Grams. Dry Matter.	M grams. Nitrogen.	Total.	Soluble in Water.	Non-albumenoid.	ALBUMENOID.		
							Soluble.	Insoluble.	Total.
I.	Original Barley....	4.025	7.10	1.838	0.332	0.178	0.154	1.506	1.660
II.	Fully steeped. ....	3.871	7.04	1.841	0.212	0.167	0.045	1.599	1.644
III.	After 22 hours .....	3.811	69.2	1.844	0.217	0.159	0.056	1.599	1.655
IV.	After 62 hours.....	3.905	69.6	1.828	0.281	0.298	0.083	1.477	1.560
V.	After 86 hours.....	3.632	70.1	1.931	0.151	0.347	0.104	1.480	1.584
VI.	After 131 hours ....	3.430	69.8	2.035	1.045	0.189	0.556	0.990	1.546

Stage III., the root sprouts had appeared; stage IV., root sprouts were as long as the barley grain, stock sprout  $\frac{1}{2}$  that length; stage V., root sprouts were  $\frac{1}{2}$  and stock sprouts  $\frac{1}{2}$  the length of the barley grain; stage VI., was "slightly over-grown malt," with most root sprouts twice as long as a barley grain, some stock sprouts beginning to shoot.

made both before and after the experiments, with the results tabulated on p. 414, per 100 of dry matter.

The soluble nitrogenous matter was increased in all cases by the heating, especially with lupines and peas; but, whereas with the former the increase in the non-albumenoid nitrogen is greater than the increase in the amount of soluble albumen, with the latter the reverse is

Stages I., II., and III. were similar to those with the Saxon barley; as malt, stage IV. was "not ready";

the case, and the solution exceeds the decomposition of the albumenoids. Maize and dani are likewise affected to

a considerable extent, but not so much as the leguminous seeds; the potatoes had been dried at 110°, therefore, the albumen had been rendered insoluble, a state of things which was not much improved by the heating under pressure. The staleness or freshness of the potatoes does not appear to affect the results to any considerable extent. The results indicate that the albumenoid matter of the above materials is both dissolved and decomposed by steaming under pressure; moreover, the albumenoid matter in the different materials is not affected to the same extent. With regard to the solution, the solution of albumen precedes decomposition, a fact confirmed by other experiments, when steaming under pressure for a short time dissolved albumen; whereas, continuing the heating converted the albumen into amides. To test the

Valuing 1 kilo. of fat and albumenoids at 32.5 pfennigs, and 1 kilo. of non-nitrogenous nutritive matter at 6.5 pfennigs, the three would have the respective values, 9.88, 9.37, and 9.22 marks per 100 kilos.—D. A. L.

*Improvements in the Mode of and Apparatus for Cleansing Beer.* A. G. Southby, Jersey. Eng. Pat. 764, January 5, 1884.

THIS relates to improvements in the mode of and apparatus for cleansing beer, either in the fermenting vat or in casks and pontoons. In the first case the pulpy yeast is pumped from the surface of the beer, and by a force pump forced into filter bags or yeast presses, the liquid beer which drains away from these being either returned directly

† Freshly harvested.

effect of bulk of material, some experiments were conducted on a manufacturing scale; maize and dari were gradually heated in a Henze's pressure boiler, until pressure of steam indicated four atmospheres. The changes in the albumenoids were similar to those in the smaller experiments, but not so marked, owing to the shorter duration of the experiment—just over two hours. In practice it is, therefore, advisable not to prolong the period of heating with superheated steam, for the decomposition of the albumenoids, as well as fats, reduces the value of the spent product for cattle feeding; the yeast, however, thrives better with amides than with albumenoids as nitrogenous food.—D. A. L.

*Action of Sulphur on Wine, and Means for removing and keeping away Acetic and other Fungoids.* J. Nessler. Bied. Centr. 14, 135, 132.

WHEN flowers of sulphur are sprinkled over the fungoid termed *kabura*, on the surface of wine their development is stopped or retarded, but at the same time hydrogen sulphide is evolved, which gives a bad odour to the wine. The same gas is evolved when free sulphur is present in most or fermenting wine. The author recommends the use of sulphurous acid, which is efficient for destroying and keeping away the fungi, and is not accompanied by the disagreeable hydrogen sulphide. The author has a patent apparatus for the application of the sulphurous anhydride, which can also be used for its liquefaction.—D. A. L.

*Feeding Value of Brewers' Grains.* J. König. Bied. Centr. 14, 141.

THREE samples of brewers' grains had the following composition per cent:—

	I.	II.	III.
Water .....	12.61	6.26	9.66
Albumenoids .....	21.19	21.69	19.60
Fat .....	6.76	8.06	9.73

Woody fibre .....	17.12	15.00	17.62
Ash .....	8.46	4.67	4.04

to the vat or otherwise utilised. The suction pipe may be connected with the pipe leading from a parachute, or may dip down to the lowest part of a vessel suspended at the surface of the beer, the yeast being swept in by means of a revolving radial skimmer. When the beer is cleaned in casks or pontoons, the yeast trough or shoot or stillion into which the yeast falls from the casks, is made with a bottom sloping sufficiently for the yeast to run down into a well, from which it is pumped and forced into filter bags or yeast presses. The beer draining from these is returned to the cleansing casks.—W. D. B.

*Improvements in Treating Grain for Brewing and Analogous Purposes, and in Apparatus therefor.* E. R. Southby, London. Eng. Pat. 1269, January 11, 1884.

THE object of this invention is to prepare grain otherwise than by malting, that it may be ground up and mashed with malt as if malt alone were being worked. The treatment is advantageously applicable only to those grains—viz., barley, wheat, rye, and oats—the starch of which can without previous cooking be converted by the action of malt into sugar and dextrin. The grain, sufficiently moist to render the corns tough, is passed between rolls until the corns are flattened out and their structure disintegrated, without, however, their being reduced to powder. The crushed grain is kiln-dried at a temperature not exceeding 100°, until sufficiently desiccated to grind easily when passed through the malt rolls. The above processes are carried out by means of roller-mill and kiln described.—W. D. B.

*Improvements in the Treatment of Malt and other Grain.* A. Schnell Loebach Burgdorf, Switzerland. Eng. Pat. 7381, May 20, 1884.

THE object of this patent is the saving of time in the processes of steeping, germination, and drying in the manufacture of malt, and the mechanical appliances for carrying this into effect. A wheel or cylinder, the rim of which is provided with a number of cells, the sides of

which are perforated, revolves slowly, running on rollers. The grain to be malted is dropped into the cells from above, and a lid prevents the grain from dropping out during the rotation of the cylinder. The lower part of the apparatus dips into water so that the grain becomes moistened, and as the apparatus revolves slowly during its passage through the air germination takes place. The grain is finally dropped into a truck running into the interior of the cylinder by opening a door on the inside of the cell. The same apparatus may be used for drying the malt by passing a current of hot air through it during motion, and after the steeping tank has been drained off. The patentee claims (1) the arrangement as described for malting the grain; (2) the arrangement as described for drying the grain after the operation of malting; (3) the application of the apparatus for soaking, husking, washing, drying, and torrefying other grain besides malt.—C. C. H.

*Improvements in the Treatment of Alcoholic Spirits.*  
R. R. Tatlock, Glasgow. Eng. Pat. 8851, June 11, 1884.

To remove the harsh smell and taste particularly peculiar to new spirits, the patentee proposes to add thereto a small quantity of caustic soda, potash, or ammonia, and to neutralise the alkalis by a little acetic acid. The presence of the acid prevents the spirit from becoming yellow or discoloured. The alkali may be previously added to a small quantity of the spirit, or to the bulk without such previous admixture. Any salt having an alkaline reaction will serve the purpose, and any ordinary acid may be used in the place of the acetic acid, though not with the same advantage. The patentee claims (1) the process of treatment by means of caustic alkali; (2) the treatment by caustic alkali succeeded by the addition of an acid.—C. C. H.

## XVII.—PRESERVING FOOD, MEATS, Etc.

*Improvements in the Manufacture or Treatment of Cocoa.*  
W. L. Wise, London. From P. Lobeck, Germany. Eng. Pat. 8625, June 5, 1884.

The cocoa beans, either raw, roasted, shelled, ground, or otherwise prepared, are subjected for about thirty minutes to a temperature of 150° Centigrade and a pressure of from 5 to 6 atmospheres. The operation is effected in closed vessels, which may be of copper tinned on the inside. The following changes take place:—Firstly, the albumenoids present in the bean are converted into products soluble in water; and, secondly, the starch is changed into soluble dextrine and glucose. This conversion into soluble products probably extends to other constituents of the cocoa, which is thus rendered easily digestible, and capable of being made into a beverage ready for the table, by the simple addition of boiling water or milk. The inventor claims as the advantages of this method of treating the bean, that no alkaline carbonates are added (as is frequently the practice, with the view of rendering cocoa soluble), and that the aroma and taste peculiar to cocoa are exhibited in their greatest intensity and purity.—E. G. C.

*Method of Preserving Meat.* Cecil Russell, Tooting.  
From A. Losasso, Calcutta. Eng. Pat. 1534, February 4, 1885.

JOINTS of meat, or whole carcases, as the case may be, are placed in casks, or tanks, and covered with a cold, strong aqueous infusion of Mocha coffee. The vessels are then closed, and the meat is ready for storage or transport; thus preserved it will keep fresh for months, and when required for use it is removed from the casks or tanks and washed in cold water. One ounce of Mocha coffee may be allowed for each pint of water. This invention also applies to the preservation of game, fish, and other perishable articles of food.—E. G. C.

## XVIII.—SANITARY CHEMISTRY, DISINFECTANTS.

*Process and Apparatus for Deodorising the Fumes of Cement and other Kilns.* E. and A. Asby, Southampton and Grantham. Eng. Pat. 8212, May 26, 1884.

The contents of the kiln are first raised to a moderate heat, sufficient to drive off organic matter, accompanied by a small proportion only of carbonic anhydride. These fumes are passed through a retort or furnace chamber, containing coke or other fuel kept in a state of incandescence by an adequate supply of burning fuel. The fumes in passing through the incandescent fuel have their carbonic anhydride converted into carbonic oxide, which is burnt, with the other ingredients of the vapours or fumes. The hot gaseous products from the furnace chamber, and those direct from the kiln, may be conducted, on their way to the chimney or other exhausting apparatus, under suitable floors, so that the heat can be partly utilised for drying the slurry or other matter placed thereon, preparatory to its being treated in the kiln.—E. G. C.

*Hygienic or Sanitary Concrete for Paving and other Purposes.* J. Tottrell, Dublin. Eng. Pat. 8317, May 28, 1884.

POWERFUL disinfectants, such as carbolic acid, carbonates, sulphites, sulphates, bleaching powder, or other purifying, oxidising, and antiseptic substances, are mixed, either in a solid or liquid form, with the ordinary cements employed in paving roadways, and the floors, basements, foundations, walls, and the like.—E. G. C.

*An Improved Disinfectant.* J. Y. Johnson, London. From E. O. Beck, Paris. Eng. Pat. 14,864, November 14, 1884.

AIR or oxygen is caused, by suitable means, to pass through a liquid composed of water and spirit or essence of turpentine, in the proportion of, say, nine parts of the former to one of the latter. The liquid is maintained during the operation at the ordinary atmospheric temperature, and when sufficiently saturated with ozone, it can be used as a disinfectant, for washing wounds or sores, etc., etc.—E. G. C.

## XIX.—PAPER, PASTEBOARD, Etc.

*Improvements in the Method of and in Boilers or Apparatus for treating Wood Pulp and other Vegetable Fibre.* David Otto, Sweden. Eng. Pat. 11,651, August 26, 1884.

THIS invention relates to the treatment of wood or other vegetable fibre with solvent—for instance, solution of bisulphite—in boilers for the production of pulp, and consists, firstly, in the application of direct steam to the mixture of fibre and solvent, instead of heating the same by steam pipes; and, secondly, to an improved construction of cylindrical boiler with rounded ends rotating around its greater axis. The outer shell of the boiler is of steel, made in several distinct sections joined together by means of strong enclosing rings of sufficient width to lap far enough upon the two adjacent sections to be firmly secured to these by riveting, brazing, or welding. The inner shell is of lead—which need not be specially pure—about a quarter of an inch in thickness, applied in distinct lengths or sections joined when *in situ* by autogenous soldering. The lining thus formed is quite independent of the steel shell, and is prevented from crushing together by its own weight by means of internal lead-covered bracing, rings made of brass or some other metal having a higher coefficient of dilatation by heat than iron. Between the lead and steel there is a narrow space; thus the lead can expand and contract without injury; the steel shell affords the requisite strength to the whole structure, the lead alone coming in contact with the contents of the boiler. As air remains in the space between the lead and the steel, and, night, at high temperatures, expand sufficiently to crack the lead, a large number of orifices provided with stop-cocks, are made in the steel to serve the double purpose of per-

mitting egress of air and of pointing out the locality of minute cracks in the lead lining, which, if not looked to at once, would give the solution an opportunity to penetrate to the steel, and cause no small damage. Any escape of steam or solution from an orifice indicates damage to the lead in that locality. A sampling cock, of which the surfaces exposed to the solution are of lead, is fitted in a convenient position. Steam is directly introduced by pipes at each end, freely perforated. The extent of highly-heated surface is thus very small, and the inventor considers that it is this which enables him to produce a pulp, by the acid sulphate treatment, containing not more than one per cent. of calcium sulphate, whilst pulp from other boilers contains as much as 10-12 per cent. The solution of bisulphate best of 4.5 or 5 lb. with the disintegrated material should not occupy more than two-thirds of the boiler space in starting, as the condensation of steam is considerable. The temperature should not exceed about 150° C., each charge being kept in the boiler rotating slowly for 10 or 15 hours.

—W. D. B.

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

*Dicinchonine.* O. Hesse. Ann. 227, 153.

THE chief source of this alkaloid is the bark of cinchona, rosulenta and cinchona sucubra, especially the former, which contains cinchonidine, homocinchonidine, cinchonine, traces of quinamine and quinquinamine, and 0.2 to 0.3 per cent. of dicinchonine. The two first alkaloids are precipitated from a neutral solution of the sulphates by means of Rochelle salt; the solution is then saturated with ammonia and shaken with small quantities of ether, whereby cinchonine is for the most part separated. The alkaloids from the ethereal solution are dissolved in dilute acetic acid, and after neutralisation are subjected to fractional precipitation with potassium sulphocyanide. Dicinchonine sulphocyanide is precipitated, but the first and third fractions contain other bases. The salt is mixed with caustic soda and extracted with ether, the extract is washed with water and evaporated, and the residue is dissolved in alcohol and saturated with hydrochloric acid; dicinchonine hydrochloride crystallises from this solution on evaporation. The base is less easily obtained from quinoidine and from cinchona sucubra. The free base, which has the formula  $C_{25}H_{44}N_2O_2$ , dissolves easily in ether, acetone, alcohol, chloroform and benzene, less easily in water and petroleum-spirit; it is insoluble in caustic soda. Its alcoholic solution is alkaline, and has a bitter taste. It has the rotatory power  $(\alpha)_D = +63.6^\circ$ . The hydrochloride,  $C_{25}H_{44}N_2O_2 \cdot 2HCl$ , forms easily soluble prisms. The chloroplatinate,

occurs in orange flakes; the hydriodide forms compact crystals, readily soluble in water, but insoluble in saturated solutions of common salt or potassium iodide; the sulphocyanide is amorphous; the neutral oxalate is obtained in compact, easily-soluble prisms, when an ethereal solution of oxalic acid is added to an ethereal solution of the base. When heated to 140° to 160° for six hours with concentrated hydrochloric acid, and probably, also, with sulphuric acid diapoicinchonine is formed.—S. Y.

*Note on Brucine.* A. Hanssen. Ber. 17, 2849.

BRUCINE was boiled with chromic acid and dilute sulphuric acid. The liquid was poured into hot baryta water, filtered at once, and after removal of the excess of barium with carbon dioxide, the filtrate was evaporated. The acid was set free by dilute sulphuric acid, filtered and evaporated. It solidified to a glassy mass, insoluble in alcohol, chloroform and benzene. It contained no brucine. It was converted into the platinum double chloride, which formed gold-yellow scales. The composition was found by analysis to be  $C_{16}H_{20}N_2O_4 \cdot 5H_2O$ . A crystalline platinum double salt was also prepared from the product formed by the action of phosphoric chloride on brucine.—S. Y.

*The Efficient Matter in Senna-leaves.* R. Stockmann. Pharm. J. 3, 749.

THE author repeated Knibby's experiments, thinking that the cathartic acid,  $C_{10}H_{10}O_2 \cdot N_2S$ , discovered by the latter in senna-leaves, may represent rather a mixture than a uniform body. On preparing the acid, heating the extract or treating it with sulphuretted hydrogen was avoided. After purification, an acid was obtained which contained no trace of nitrogen or sulphur. If the solution of the acid be heated for a few minutes with a dilute mineral acid, it becomes turbid, depositing a brown amorphous precipitate, which has all the properties stated by Knibby for his cathartic acid. But this matter is not of a uniform composition; it can be subdivided by extraction with ether. The filtrate from the brown precipitate contains a sugary matter, which reduces Fehling's solution, but is not able to ferment. Stockmann thinks that cathartic acid belongs to that class of glycosides which can be decomposed by acids into sugar, and a whole series of other products.—S. H.

*Quinine Sulphate of Commerce, its Composition and Analysis.* W. F. Koppeschaar. Pharm. J. 3, 809.

QUININE sulphate of commerce contains, besides other alkaloids, nearly always cinchonidine, which cannot be removed by recrystallising. The best method to determine the percentage of quinine and cinchonidine is that recommended by Oudemans—viz., the precipitation of the sulphate solution with sodium tartrate, and after weighing, the polarisation of the tartrates, which contain nothing but quinine and cinchonidine. Whereas the angle of rotation of quinine tartrate is  $(\alpha)_D = -215.8^\circ$ , that of cinchonidine tartrate is  $(\alpha)_D = -131.3^\circ$ . The author thinks that the commercial quinine sulphate contains, besides quinine sulphate, a double compound of quinine and cinchonidine sulphate.—S. H.

*A New Apparatus for the Preparation of Solid Carbonic Acid.* B. Caillaet. Jour. de Phys. 4, 122.

THE apparatus, which is recommended to replace Thilorier's metal box, is constructed by Dueret, and consists of an ebullient cylinder, through the lid of which a thin tube conveys liquid carbonic acid up to near the bottom. The carbonic acid which is not condensed escapes through a tube fastened in the bottom, and projecting in the interior of the cylinder for more than half its height. It is preferable to cool the liquid carbonic acid by refrigerating means before allowing it to enter the cylinder.—S. H.

*Process for the Preparation of Thallin.* Dingl. Polyt. J. 256, 192.

FOR the preparation of tetrahydroparaquinanisol, named "Thallin," on account of the fine green colour which this base and its salts develop when treated with oxidising agents, the Badische Anilin- und Soda-Fabrik (Ger. Pat. 30,426, June 18, 1884) proceed as under:—4 kilos. of granulated zinc, 15 kilos. of hydrochloric acid of 1.14 sp. gr., and 1 kilo. of paraquinanisol hydrochloride are allowed to digest upon the water-bath for from eight to ten hours. The reaction is known to be complete when the zinc double salt of the new base, which is soluble with difficulty, begins to separate out. The zinc double salt is purified by recrystallisation from hot water, and the free base obtained therefrom by decomposition with an alkali. Thallin separates in the form of an oil, which solidifies on cooling to a hard, slightly yellow crystalline mass. Thallin is difficultly soluble in cold water, easily soluble in alcohol, ether, petroleum ether, and hot water. It melts at 42-43°, and boils at 282-283° (uncorrected). With organic and inorganic acids it combines to form salts soluble in water, of characteristic properties and crystallising well.—W. D. B.

*An Improved Method of Manufacturing Carbonic Acid under any Desired Pressure.* F. Raken. From H. Beins and J. F. Beins, Groningen. Eng. Pat. 4175, April 2, 1885.

BICARBONATE or sesquicarbonate of soda is mixed with ammonium or potassium alum, and water added. By

regulating the amount of this mixture by the capacity of the vessel to receive the carbonic acid liberated, the latter may be obtained under any desired pressure.

—W. D. B.

## XXI.—EXPLOSIVES, MATCHES, Etc.

*On Nitroglycerine.* Mathew Hay. *Monit. Secit.* 15, 424.

THE best proportions for preparing nitroglycerine are 10 parts of glycerine, 30 parts of fuming nitric acid, and 60 parts of strong sulphuric acid, which gives a yield of 234 per cent. on the glycerine. When pure it is a colourless oil, which is not decomposed on heating to 100° C.; 1 gram dissolves in about 500 ccs. of water, or 1 cc. of absolute alcohol. By caustic potash it is not decomposed according to the usually assumed equation:

but, on the contrary, the glycerine at the moment of its formation is oxidised by the nitrate with production of acetic, formic, and nitrous acids, approximately according to the equation:

Other alkalis act in a similar manner.—A. G. G.

*Improvements in Explosive Cartridges for Blasting and other Purposes.* G. G. M. Hardingham. From Thomas Woolhouse, Paris. Eng. Pat. 2443, January 25, 1884.

"This invention consists of an improved manufacture of cartridges for blasting, mining, and similar purposes, the same being in certain forms adapted for use with ordnance and other firearms. The principle embodied is further applicable to shells, military mines, and other appliances of a like explosive character." A glass vessel containing liquid ammonia is introduced into the interior of a cartridge of dynamite, gunpowder, or other explosive; by the shattering of this vessel at the moment of explosion the ammonia is volatilised, and has the twofold effect of quenching the flame and increasing the effective force. Liquid carbonic acid or other volatile non-inflammable liquid may be substituted for the ammonia. Or an inflammable liquid, as ether, alcohol, or benzoline may be employed. In place of glass, the containing vessel may be made of caoutchouc. Or the explosive may be mixed or saturated with the liquid; thus gun-cotton or tonite may be saturated with ammonia and alcohol. Or the containing vessel may be annular, the explosive being placed within the centre. In cases where it is desirable to dispense with the use of cartridges, the bore hole may be filled with loose powder, with vessels containing the liquid interspersed.—W. D. B.

*Improvements in Fuses for Shell Projectiles.* Thorsten Nordenfält. Eng. Pat. 3235, February 13, 1884.

MECHANICAL improvements, with the object of securing increased safety during carriage over rough roads, etc., and increased stability and efficiency.—W. D. B.

*Improvements in Explosive Compounds.* Henry Edward Newton. From Alfred Nobel. Eng. Pat. 5382, 1884.

WITH the object of diminishing the liability to explosion by concussion attendant upon their employment, nitro-cellulose, nitro-mannite, nitrated starch, picroates, and other analogous fibrous or pulverulent substances are moistened with a combustible liquid, in which a nitrate or other oxidising agent has been absorbed in quantity sufficient to ensure perfect combustion. Solid combustible material, such as paraffin, stearine, and naphthalene applied in the melted state, may also be employed. Preference is given to the use of glycerine, since when heated it possesses considerable solvent power for various nitrates; the nitro-cellulose or other explosive is saturated with a mixture of glycerine, and the nitrate heated to the lowest temperature requisite for complete

solution of the nitrate, and the whole allowed to cool, after which the explosive is ready for use. A good shell composition is stated to be yielded by mixing 1 part of gun-cotton with 2 parts of a solution consisting of equal weights of glycerine, zinc nitrate and cupric nitrate.

—W. D. B.

*Improvements in Machinery to be employed in the Manufacture of Lucifer Matches.* Thomas Allen, of Reading. Eng. Pat. 5507, March 26, 1884.

THIS invention consists in an automatic mechanism for the purpose of placing the splints between the laths of the dipping frame, the filling of the dipping frame having hitherto been effected by hand apparatus.—W. D. B.

*Improvements in the Manufacture of Gunpowder and other Explosive Compounds by the use of an Improved Material in the said Manufacture.* T. Nordenfält and V. A. Meurling. Eng. Pat. 6515, April 18, 1884.

COTTON or other similar fibre is rendered friable by being subjected to the action of hydrochloric acid, either in the state of gas or in solution, then pulverised and employed in place of the charcoal in gunpowder, or carbonised and the resulting charcoal employed for powder manufacture. Cotton reduced to powder by this means may also be employed in the preparation of gun-cotton.—W. D. B.

*Improvements in the Manufacture of Powder for Blasting and other analogous Purposes.* Camille Espir. Eng. Pat. 6548, 1884.

THE inventor claims the manufacture of a powder for blasting purposes, composed of 66 per cent. of unrefined nitrate of soda; 12 per cent. of refined and tritritated sulphur; 22 per cent. of fine sawdust from hard wood. If the compound be intended for artillery purposes, 10 per cent. of charcoal is added. For certain purposes the following composition is adopted:—66 per cent. of unrefined nitrate of soda; 8 per cent. of refined and tritritated sulphur; 21 per cent. of fine sawdust from hard wood; 5 per cent. of charcoal. The sulphur and sawdust are amalgamated by sieving, a solution in boiling water of the sodium nitrate poured upon the mixture, the whole well kneaded and dried by aid of steam.—W. D. B.

*Improvements in Detonating Signals for use on Railways and in Apparatus to be employed therewith.* E. D. Pass. From C. Lirand and E. Gaupillat, both of Paris. Eng. Pat. 7299, May 6, 1884.

THE improvements are confined to the mechanical construction and arrangement.—W. D. B.

*Improvements in the Manufacture of Explosives.* W. A. Barlow. From Adrien Gayon, of Paris. Eng. Pat. 9096, June 17, 1884.

IN carrying this invention into effect, 69 parts of powdered nitrate of potash are intimately mixed with 19 parts of flowers of sulphur, and 12 parts of ashes, rich in soda or potash, preferably obtained by burning dead leaves. One fifth part of tannin dissolved in 8 parts of water is introduced into the mixture, and the whole allowed to dry. The tannin solution is preferably obtained by making a decoction from chestnut, mangrove or oakwood.—W. D. B.

*Improvements in Machines for the Manufacture of Matches.* Sydney Pitt. From J. H. Mitchell, of Philadelphia, U.S.A. Eng. Pat. 11,686, August 27, 1884.

THE object of this invention is to provide a means for the continuous manufacture of matches, the splints being passed in the machine by a hopper, and the matches finally deposited in drying trays at the other end of the apparatus. By a picking-up mechanism, the splints, of length sufficient for two matches as usual, are delivered from a hopper, into which they are in the first instance

fed, on to an endless band which carries them forward through the machine for a short distance, when their upper surfaces meet a second endless band. The splints are carried between the surfaces of the two bands from this point until just before their final discharge from the machine. By suitable tightening rollers the tension of the belts is so adjusted that they hold the splints securely between them. Before sulphuring, the ends of the splints are warmed by means of steam heating channels, curved to conform to the travel of the belt, on either side of the machine. The sulphuring is effected by causing the ends of the splints to pass between two asbestos-covered rolls, in contact with one another, suspended freely so as to allow the passage of the splints between them. The lower roll revolves in a pan containing sulphur, the rotation being effected simply by the passage of the splints. The heading apparatus consists of a closed receptacle, containing the composition and a rotating spiral, by means of which the composition is discharged regularly upon a plate which is moved to and from the ends of the splints during their passage over it; this arrangement is adopted to imitate the operation of vertical hand-dipping, and to obtain an equal distribution of the heading composition. The main part of the heading apparatus can be readily detached should the composition take fire. On passing from the heading apparatus, the duplex band is made to take a rapidly reversed serpentine motion by passing around a series of pulleys. The object of this is to give the head a symmetrical form, not attainable if the belt travelled in a horizontal direction, and also to allow the composition to cool and stiffen. The splints are now discharged from the duplex band upon a cutting mechanism consisting of a pair of disc cutters rotating with their edges in contact. The shafts of each disc carry on either side a disc of rubber by which the splint is gripped and prevented from moving sidewise or upward whilst being cut. The now severed matches fall into trays carried upon an endless belt, the trays when filled being removed and laid away for the heads to thoroughly harden.

—W. D. B.

*Improvements in the Manufacture of Explosives and in the Treatment of Materials to be employed in the said Manufacture.* E. Luck and F. B. W. Roberts. Eng. Pat. 12,292, September 11, 1884.

This patent covers two distinct processes, one for refining sodium or potassium nitrate, the other for the preparation of a carbonaceous substance. According to the first, a quantity of plumbic nitrate equivalent to the sodium chloride present in the nitrate is added to the dissolved nitrate, which is then refined as usual. According to the second, wood or a carbohydrate is treated with nitric acid until the whole is reduced to a pasty pulp, the acid neutralised with sodium or potassium hydrate or carbonate, the whole evaporated to dryness, and the product used in the preparation of gunpowder to replace a part of the charcoal. Or the alkaline treatment may precede the application of nitric acid.—W. D. B.

*Improvements in the Manufacture of Blasting Powder from Nitrated Cellulose.* An Amendment of Specification 13,522, October 13, 1884. See J. Soc. Chem. Ind. iv. 243.

The claim for the hardening process is now struck out, the claim being now simply "a new method of manufacturing blasting powder, by sawing pieces of strongly pressed nitrated cellulose."—W. D. B.

*An Improved Coating for Explosive Compounds and Cartridges.* Michael Cock, Victoria. Eng. Pat. 14,561, October 30, 1884.

The cartridges or explosive compounds which it is desired to coat are warmed and dipped into melted sulphur, either alone or in admixture with other substances—*e.g.*, black lead or iron. The application of this invention is not confined to any particular kind of explosive, nor to the use of pure sulphur, or any particular mixture or compound of sulphur.—W. D. B.

*Improvements in Apparatus for Sulphuring and Phosphorising Friction Matches.* J. A. Elliot. From Edison Fitch, Quebec, Canada. Eng. Pat. 14,992, November 14, 1884.

This invention relates to a continuous apparatus for the manufacture of matches. The splints, in double lengths, are placed promiscuously in a hopper, one side of which can be agitated in order to shake the splints compactly together, thence received between two endless bands running parallel together for a portion of their length between guides provided with adjustable clamps, enabling the bands to hold the splints with sufficient firmness. The splints having been dried by passing over a furnace are ready for sulphuring. To effect this, the belt is canted over by appropriate guides, the splints brought into a vertical position, and their ends dipped alternately in a pan of sulphur kept melted by steam pipes. After sulphuring, the splints are permitted to return to their horizontal position, and brought over the pan containing the phosphorising compound; revolving, bevel-edged wheels transfer the heading composition to the splints, and also bring the ends of the splints in line. The heads are hardened by the application of a cold blast of air, and the splints finally cut in two by a rotary knife.—W. D. B.

## XXII.—GENERAL ANALYTICAL CHEMISTRY.

*A Red Colouration of Cyanide Solutions.* Louis Habell. Ber. 17, 2840.

SOME years ago, while preparing cyanogen compounds of selenium in Prof. Bansen's laboratory, the author observed a remarkable cherry-red colouration on warming a solution. A similar colouration has been repeatedly observed by the author in the decolourisation of ammoniacal copper solutions by addition of potassium cyanide. The same colouration was noticed in the separation and distillation of hydrocyanic acid from silver cyanide. The author also remarks that in testing for cyanides in presence of sulphur compounds by the Prussian blue reaction, a decinormal acid solution should be employed.

—S. Y.

*A New Thermo-regulator.* A. Fock. Ber. 18, 1124.

THE principle of the regulator is based on the fact that a bath of some volatile liquid like mineral oil, provided with a back-flow condenser, when heated to its boiling

point will remain at a constant temperature. The more volatile portions of the liquid are distilled off until the required temperature is reached, when by closing the

flow-off tap the condensing worm is brought into action and the liquid is maintained at this temperature without regulating the source of heat. The arrangement as shown in the diagram will be at once apparent. The thermo-regulator is recommended for melting-point determinations, and as the bath is opaque the difficulty occasioned thereby is overcome by adapting an electric signal to indicate the moment of melting, or by providing the bath with a mirror. This apparatus may also be used as an air-bath by closing the inner chamber with a cork.—J. B. C.

*Titration of Iron Ores.* Walther Hempel. Ber **18**, 1130.

THE analysis of iron ores offers considerable difficulties, since the gangue always contains a considerable quantity of iron insoluble in acid which cannot be determined except by a separate fusion, and the metal is present partly as ferric and partly as ferrous oxide. To obviate this the author proposes the following simple method: The finely-powdered ore (about 3grm.) is mixed in an agate mortar with pure sodium carbonate (4grm.) and pure calcium carbonate (2grm.), and ignited in an open platinum dish; by this means the iron is completely converted into ferric oxide, which can then be estimated by dissolving the mass in hydrochloric acid and titrating with stannous chloride. All iron ores are readily decomposed by this method.—A. G. G.

*A New Reagent for the Absorption of Oxygen.* O. Pfördten. Annalen, **225**, 112.

FOR absorbing oxygen the hydrochloric acid solution of chromous chloride is used, made by reducing a solution of chromic acid in hydrochloric acid with zinc and hydrochloric acid, and filtering the solution in an atmosphere of carbonic acid through asbestos, or glass wool, into a solution of sodium acetate. The precipitated chromium acetate is washed and dissolved in hydrochloric acid. Carbonic acid, sulphuretted hydrogen, and other gases which do not act on chromous chloride, can thus be freed from oxygen. The blue solution, as it becomes green by oxidation, can also serve as a sensitive indicator for oxygen. A special apparatus has been devised for this purpose.—S. H.

*On a New Method of Estimation of Manganese in Spiegeleisen, Ferromanganese, and the most Important Ores.* Wilhelm Kalmann and Alois Smolka. Monatsh. Chem. **6**, 65.

THE author heats 0.15 to 0.3grm. of the finely-powdered substance (it should not contain more than 0.15grm. of manganese) in a platinum crucible, first with a burner, and lastly with the blowpipe, whereby the manganese is converted into manganic-manganic oxide. About twenty times the weight of a mixture of two parts of fused borax, and three parts of sodium and potassium carbonates is fused and powdered, and added to the oxidised substance. The mixture is fused for fifteen or twenty minutes in the closed crucible, and afterwards for five minutes without the cover, the mass being stirred. The contents are then thrown into a measured quantity of a titrated solution of ferrous sulphate acidified with sulphuric acid. The excess of ferrous sulphate is estimated with permanganate. The manganese is calculated thus:—Weight of iron:  $x = 10 \times 56 : 6 \times 55$ . The author finds that, in the fused mass, for every six atoms of manganese there are 5 atoms of available oxygen. The results by this method differed very little from those obtained gravimetrically. With ferromanganese, rich in manganese, the determinations by the new method may vary 1 per cent. It is most suitable for substances in which the manganese is converted into  $Mn_2O_3$  by simple heating, and which contain at least 1 or 2 per cent. of that metal. The result may be 2 to 3 per cent. too low if the manganese is present as silicate.—S. Y.

*Estimation of Titanium in Iron and its Ores.* A. Ledebur. Chem. Zeit. **9**, 483.

THE ore to be analysed (2.5grm.) is treated with concentrated HCl evaporated to dryness on the water-bath, the residue heated with a little HCl, diluted with water, filtered and washed with cold water. The residue on the filter is dried, fused with sodium potassium carbonate, the fused mass moistened with water, treated with large excess of HCl and evaporated on the water-bath. To the residue concentrated HCl is added, heated gently for a time, diluted with cold water, filtered and washed with cold water. The two filtrates are united and contain all the titanic acid. It is advisable to test the silica residue by boiling with carbonate of soda solution, in which it should dissolve completely. The titanic acid solution is treated with sufficient sulphuric acid to convert the total chlorides present into sulphates, and evaporate down until all the HCl is given off and the  $H_2SO_4$  begins to fume. The solution is allowed to cool, diluted with water until all the crystallised salts are redissolved, sulphurous acid or  $NaHSO_3$  is added, and then gently heated to reduce the iron present. The solution is then neutralised with  $Na_2CO_3$  as far as possible, so that no permanent precipitate forms, and heated in a flask to boiling for two hours. The evaporated water is replaced from time to time, and small quantities of the bisulphite added. The titanic acid precipitates also phosphoric acid and some iron. Filter and wash with water. The precipitate is dried and fused with sodium potassium carbonate and treated with water, whereby the phosphoric acid is dissolved. The residue, consisting of titanic acid and iron, is treated with sulphuric acid, and submitted to the process of boiling and reduction by  $NaHSO_3$ , as before, to get rid of the iron. To determine titanium in iron 15grm. are dissolved in nitric acid, evaporated and strongly heated to destroy carbon compounds and to drive off  $HNO_3$ . The residue is dissolved in concentrated HCl, diluted with water and filtered. The residue on the filter after washing and drying is fused with  $Na_2CO_3$  and  $KNO_3$ , the silica separated by evaporating with HCl, and the process continued as above.—J. B. C.

*Separation of Zinc from the Group-metals.* W. Hampe. Chem. Zeit. **9**, 543.

BY converting zinc, iron, nickel, cobalt, manganese, and aluminium, into formates, and passing  $H_2S$  through the solution, ZnS precipitates completely. The precipitate is always free from Mn and Al, and also from Ni, Co and Fe, if the solution contain sufficient quantity of formic acid (at least 15-20cc. acid of 1.2 sp. gr. to 250-500cc. of liquid), and these metals are not present in excess. Fe comes down most readily in such cases, and traces of Ni and Co. In order to eliminate these metals, the filtered and washed precipitate is dissolved in  $HNO_3$ , saturated with  $NH_3$ , then formic acid added, and the solution reprecipitated with  $H_2S$ . In order that the ZnS may be easily filtered, the precipitation is done in a hot solution. The precipitate must be washed with  $H_2S$  water, containing formate of ammonia and formic acid. The quantitative tests of the method have been confined to the analysis of zinc blends. The ore is dissolved in nitric acid, saturated with  $H_2S$ , the precipitate dissolved in  $HNO_3$ , and reprecipitated. The two filtrates are united, saturated with ammonia, formic acid added until the precipitate redissolves, and the hot liquid precipitated with  $H_2S$ . The ZnS is then heated in a current of hydrogen, and weighed as metallic zinc.—J. B. C.

*Nickel Apparatus for Laboratory use.* F. Stolba. Chem. Zeit. **9**, 673.

NICKEL vessels are an excellent substitute for those made of iron or copper. When nickel basins are heated directly by the Bunsen lamp, the colourless flame should be used, as a deposition of soot produces brittleness of the metal. These basins may be used for boiling with caustic alkalis or their carbonates. Crucibles of nickel may be employed for fusing minerals or salts with caustic

or nitrates of the alkalis. Water-baths, spatulas, tongues, etc., of nickel are very serviceable. Nickel is attacked by acids even in dilute solutions, and also by acid salts. It withstands to a remarkable degree the action of strong  $\text{H}_2\text{SO}_4$ . Cerite may be decomposed with concentrated  $\text{H}_2\text{SO}_4$  in a nickel basin without any injurious effect. Minerals may be treated with fluor-spar and strong sulphuric acid. To what extent hydrofluoric acid affects nickel has not yet been determined. Lead or its oxide do not attack the metal. Platinum vessels, in which substances are to be decomposed by heating with  $\text{NH}_4\text{Cl}$ , may be advantageously replaced by nickel ones. Nickel triangles cannot be recommended, as they become brittle after a time. Nickel tripods and wire gauze are very useful and durable. The apparatus tested by the author was manufactured by Meitmann, of Iserlohn.

—J. B. C.

*On a Reaction of the Aldehydes.* Arthur Cahn. Ber. 17, 2938.

THE author has examined the action of various amido-compounds on aldehydes, and describes fully the compound formed by the action of equal molecules of benzaldehyde and para-amido dimethylaniline. The substances are mixed either directly or after dilution with alcohol. The product formed is para-benzylidene-amido-dimethylaniline,  $(\text{CH}_3)_2\text{N} - \text{N} - \text{C}_6\text{H}_4 - \text{N} = \text{CH} - \text{C}_6\text{H}_5$ . It forms light yellow scales or needles melting at  $93^\circ$ . It is but slightly soluble in cold alcohol, but dissolves readily in hot, hence it is easily purified. It is decomposed by strong acids with liberation of benzaldehyde. The hydrochloride,  $\text{C}_{13}\text{H}_{12}\text{N}_2 \cdot 2\text{HCl}$ , was prepared by passing dry hydrochloric acid gas into an ethereal solution of the base.—S. Y.

*Characteristic Reaction for Secondary Alcohols.* G. Chancel. Compt. Rend. 100, 601-605.

BY the action of nitric acid on the secondary alcohols, dinitro derivatives are formed. Methylbutylcarbinol with an equal volume of nitric acid of sp. gr. 1.35 gives an oil which, when mixed with alcoholic potash, forms a crystalline potassium dinitrobutane. Dinitrobutane gives on reduction normal butyric acid. Methylhexylcarbinol on similar treatment yields dinitrohexane, which forms by reduction normal caproic acid. To detect a secondary alcohol the following method is proposed: i.e., of the alcohol is treated with nitric acid, the solution poured into water shaken out with ether, and alcoholic potash added. If yellow prisms of the potash salt of the dinitrohydrocarbon form, a secondary alcohol is present.

—J. B. C.

## New Books.

A TREATISE ON PRACTICAL CHEMISTRY AND QUALITATIVE INORGANIC ANALYSIS. Adapted for Use in the Laboratories of Colleges and Schools. By FRANK CLOWES, D.Sc., London. Professor of Chemistry at the University College, Nottingham. Fourth Edition. London: J. and A. Churchill, 11, New Burlington Street. 1885.

THIS work, now in its 4th edition, is a small 8vo volume bound in black cloth, with frontispiece representing one of the Laboratory Benches of the University College of Nottingham. This frontispiece is used also in illustration of remarks contained in a chapter on laboratory fittings (Section VII.). Next follows the preface, in which the author states it as his aim throughout to give all necessary directions so fully and simply as to reduce to a minimum the assistance required from a teacher. He also claims to employ language both simple and intelligible, by avoiding the unnecessary use of scientific terms, and by explaining and paraphrasing in ordinary words any such terms when they are introduced for the first time. The table of contents contains references both to paragraphs and pages, and the subject matter

is divided into sections instead of chapters. Interspersed in the text are fifty-five wood-cuts, and numerous useful tables. The work terminates with a copious alphabetical index. The general plan and method of the work will be gleaned from the following abstract of the contents:—Section I. The Preparation and Use of Apparatus. Section II. Experiments Illustrating the Preparation and Properties of certain Gases and Liquids. Section III. Analytical Operations, Descriptions Illustrated by Experiments. Section IV. Analytical Reactions, subdivided into *Reactions for Metals and Reactions for Acid-Radicals, Organic Acid Radicals*. Section V. Analysis of Simple Substances containing one Metal and one Acid-Radical. Section VI. Full Analytical Course and Tables. Reactions and Detection of the Rarer Elements. Reactions of certain Organic Substances. Section VII. Laboratory Fittings, Apparatus, Chemicals and Reagents. A useful List of Apparatus for each Bench-locker is also given on a fly-leaf facing the first page of the text.

COMMERCIAL ORGANIC ANALYSIS. A Treatise on the Properties, Proximate Analytical Examinations, and Modes of Assaying the various Organic Chemicals and Products employed in the Arts, Manufactures, Medicine, etc., with Concise Methods for the Detection and Determination of their Impurities, Adulterations, and Products of Decomposition. By ALFRED H. ALLEN, F.I.C., F.C.S., Public Analyst for the West Riding of Yorkshire, the Northern Division of Derbyshire, and the Boroughs of Sheffield, Chesterfield, Doncaster, Wakefield, etc. Second Edition, revised and enlarged. Volume I. Introduction, Alcohols, Neutral Alcoholic Derivatives, Sugars, Starch and its Isomers, Vegetable Acids, etc. London: J. and A. Churchill, New Burlington Street. 1885.

OCTAVO volume, bound in cloth, containing preface, table of contents and 476 pages of subject matter, including an introduction covering two pages, and an alphabetical index covering ten. The work is illustrated with 10 wood engravings, and 1 sheet diagram representing the various starch granules, besides numerous excellent and useful tables. The following abstract of the leading divisions in the table of contents will furnish a correct idea of the subjects treated of in the text, and to some extent of the mode of treatment:—Introduction; Preliminary Examination of Organic Bodies; Specific Gravity; Observations of Changes of Physical State; Optical Properties; Ultimate or Elementary Analysis; Behaviour of Organic Bodies with Solvents; Behaviour of Organic Bodies with Reagents; Examination for Inorganic Matters. ALCOHOLS: Definition of an Alcohol; Methyl Alcohol; Ethyl Alcohol; Alcoholic or Fermented Liquors; Amyl Alcohol. NEUTRAL ALCOHOLIC DERIVATIVES: Ether; Compound Ethers; Aldehydes; Chloral; Chloroform. SUGARS: Constitution and Classification of Sugars; Relations of the Sugars to Polarised Light; Specific Gravity of Saccharine Solutions; Action of Strong Acids on Sugars; Action of Dilute Acids on Sugars; Inversion; Fermentation of Sugars; Action of Alkalis on Sugars; Reactions of the Sugars as Reducing Agents; Recognition of the principal kinds of Sugar; Cane Sugar; Sucrose; Malt Sugar; Maltose; Milk Sugar; Lactose; Glucoses. STARCH AND ITS ISOMERS: Tabular List of Isomers of Starch; Cellulose; Starch; Dextrin; Gums; Proximate Analysis of Plants; Composition of Cereals, etc. ACID DERIVATIVES OF ALCOHOLS AND VEGETABLE ACIDS: Reactions of Vegetable Acids with Reagents; Acetic Acid; Homologues of Acetic Acid; Lactic Acid; Oxalic Acid; Succinic Acid; Malic Acid; Tartaric Acid; Citric Acid; Errata; Index.

# Monthly Patent List.

## ENGLISH APPLICATIONS.

1855.

### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

- 6276 C. C. Carpenter, Westminster. Improvements in retort-lid fittings. May 22  
 6106 H. J. Haddan, London.—Communicated by J. W. Brightman, United States. Improvements in furnaces. Complete specification. May 27  
 7053 Maschinenbau-Gesellschaft (date J. S. Schwabe and Sohn, and P. Effertz, London. Improvements in machines for making ice, and engines wherein cold vapours, air, or gases are employed. June 9  
 7126 J. G. Lorrain, London. Improvements in chemical precipitation, and in the separation of matter mechanically suspended in liquids. June 11  
 7399 W. P. Thompson, Liverpool.—Communicated by F. C. Glaser, Germany. Improvements in or relating to apparatus applicable for the separation of suspended matters from water or other liquids, and for the removal of the resultant sediment. June 18

### II.—FUEL, GAS, AND LIGHT.

- 6303 G. F. Redfern, London.—Communicated by P. Prat, France. Improvements in apparatus for generating gases. May 22  
 6319 J. Taylor, A. Stewart, and C. Stewart, Glasgow. Burning tar, heavy oils, or other liquid fuels for heating purposes, applicable for steam-boilers and other similar purposes. May 29  
 6627 R. Wyllie, London. Improvements in the utilisation of the otherwise waste heat from steam-engines, boilers, and furnaces. June 1  
 6881 J. Y. Johnson, London.—Communicated by La Société Anonyme des Forges et Chantiers de la Méditerranée, France. Improvements in machinery or apparatus for manufacturing blocks of artificial fuel. June 5  
 6861 A. Gontard, Meckau, Saxony. Improvements in the purification of air or gases from solid or gaseous impurities contained therein, and apparatus therefor. June 8  
 6938 T. S. Landsay, London. Improvements in the means of generating fixed gases for illuminating, heating, and metallurgical purposes. June 8  
 7120 E. Entwistle and A. Pilkington, Blackpool. Improvements in apparatus or apparatuses to economise and effect a more efficient consumption of fuel, smoke, and noxious gases in open or closed grates or furnaces. June 18  
 7147 C. I. C. Bailey and S. C. Dean, Fulham. Improvements in making and utilising water and oil gas. June 18

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, ETC.

- 7079 J. Hardman, Manchester. Improvements in and in apparatus for obtaining carbolic acid and other tar acids from tar oils. June 10  
 7358 A. M. Chambers and T. Smith, London. Improvements in coke ovens and in methods of and apparatus for collecting and utilising the products of combustion from such coke ovens. June 16

### V.—TEXTILES: COTTON, WOOL, SILK, ETC.

- 6218 H. J. Haddan, London.—Communicated by E. Frémy, France. Improvements in the treatment of ramie and similar textile fibres, and apparatus therefor. May 21  
 6333 W. H. Thorpe and G. Pepper, Halifax. Improvements in machinery for drying silk, wool, cotton, and other fibre. May 23  
 6369 H. H. Lake, London.—Communicated by A. Sandron, Belgium. Improvements relating to the water-proofing and preservation of linen and other fabrics, ropes, hose, and other articles composed of vegetable substances. May 28  
 6393 C. D. Abel, London.—Communicated by J. O. Obermaier, Germany. Improvements in apparatus for treating fibres, yarns, and textile fabrics. May 29  
 6591 C. D. Abel, London.—Communicated by J. O. Obermaier, Germany. Improvements in apparatus for treating fibres for spinning. May 30  
 6816 S. W. Maquay, London.—Communicated by G. W. Hamilton, Australia. A wool-cleaning apparatus. June 5  
 6922 W. W. Hamilton, New York. Improvements in treating animal and vegetable fibres for textiles, cordage, and other uses. Complete specification. June 8  
 6923 W. W. Hamilton, New York. Improvements in treating animal and vegetable fibres for textiles, cordage, and other uses. Complete specification. June 8  
 7186 W. Jones and C. Kilpatrick, Manchester. Improvements in the treatment of the matters separated or precipitated from the water in which wool, silk, and other fibrous materials have been boiled, scoured, or washed along with soap or other material. June 12

### VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

- 6295 and 6296 J. Reffitt, London. Improvements in the means or apparatus employed for dyeing woollen, silk, and other woven or felted fabrics and yarns. May 22  
 6314 E. Taylor, Manchester. An improved method of purifying and decoloring the water in which silk and other fibrous materials have been boiled along with soap and the refuse, liquid, or dye in which silk and other fibrous materials have been cleaned or dyed, and recovering useful products from such water and refuse, liquid, or dye. May 23  
 6888 W. R. Lake, London.—Communicated by The Prag Spin-Loose, Manufacture and F. Storck, Austria. Improvements in apparatus for use in fixing the colour upon printed cotton fabrics and for washing the same. June 5  
 7187 J. C. Mewburn, London.—Communicated by G. Lombard et Cie, France. Improvements in the means or apparatus employed for purifying, bleaching, dyeing, or otherwise operating upon yarns or threads. June 12  
 7462 T. Nordenfett, London. Improvements in the manufacture of blood albumen. June 18

### VII.—ACIDS, ALKALIS, AND SALTS.

- 6127 C. A. Bartsch, London. Improvements in stills for concentrating sulphuric acid. Complete specification. May 19  
 6133 J. H. Johnson.—Communicated by Dr. F. von Heyden, Nachfolger, Germany. A new or improved process for the manufacture of naphthol-carbonic alkaline salts. Complete specification. May 19  
 6255 W. Black and W. L. Rennoldson, London. An improved process for the manufacture of hydrate of baryta and sulphide of sodium. June 21  
 6272 G. H. Bolton, Liverpool. Improvements in lids or covers for drums or packages for caustic alkalis or other material. May 22  
 6101 E. Hanisch and M. Schroeder, London. Obtaining sulphur from furnace gases. Complete specification. May 26  
 6105 E. Hanisch and M. Schroeder, London. Obtaining liquid anhydrous sulphurous acid from furnace and other gases. Complete specification. May 26  
 6345 A. Favier, Paris. Producing directly the nitrate of ammonia from the nitrate of soda. May 29  
 6614 H. Trecht, London. Improvements in obtaining carbonate of potash by the Leblanc process. June 1  
 6890 T. Terrell, London. Improvements in decomposing sulphate of iron and in the obtaining of sulphurous acid and red oxide of iron thereby. June 1  
 6715 E. W. Barnell and J. Simpson, Liverpool. Improvements in the extraction of sulphur from alkali-waste and other sulphides of calcium. June 3  
 6818 L. Pilkington, Liverpool. Improvements in the lids or covers for drums or other packages applicable for caustic alkalis. June 5  
 6866 T. Tynam, London. Improvements in the production of soluble phosphates of the alkalis in the manufacture of steel and iron. June 5  
 6867 T. Tynam, London. Improvements in the production of alkaline phosphates in the manufacture of iron or steel from phosphoric pig-iron. June 5  
 7134 P. Homer, London. Improvements in the manufacture of bicarbonate of potash. Complete specification. June 11  
 7136 E. F. Traesche, London. An improved method or process of producing hydrate or carbonate of strontium or of barium. June 11  
 7195 J. Mactear, Glasgow. Improvements in the manufacture of the alkaline earths and the hydrates of the same. June 12  
 7283 H. Oxlard and C. Oxlard, London. Improvements in apparatus for burning or calcining ores and minerals containing sulphur or arsenic, for the manufacture of sulphuric acid or arsenious acid, or white arsenic. June 15  
 7317 B. C. Molloy, London. Improvements in the manufacture of sulphuric acid. June 16  
 7355 H. H. Lake, London.—Communicated by A. Kayser, A. B. Young, and H. Williams, United States. An improved method or process for the manufacture of carbonate of soda or soda-ash. Complete specification. June 16

### VIII.—GLASS, POTTERY, AND EARTHENWARE.

- 6163 J. G. Sowerby, London. Improvements in the construction of moulds used in the manufacture of glassware. May 27  
 6340 J. V. Johnson, London.—Communicated by W. Hirsch, Germany. Improvements in the manufacture of decorated glass. May 28  
 6739 J. G. Sowerby, London. Improvements in moulds for moulding articles of glass or other ware. June 3  
 7240 J. Broadbent and J. M. Stokoe-on Trent. An improved pottery kiln or oven. June 15

### IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

- 6133 E. Cammish, London. Improvements in means and apparatus employed in the manufacture of bricks. May 19  
 6157 C. Schliekeyen, London. Improvements in apparatus for cutting bricks and tiles. May 19  
 6241 G. E. Smart, Tunbridge Wells. Improvements in tiles

or equivalent, and accessories applicable in the construction of walls or buildings, roofs, pavements, and the like. May 21  
6249 G. F. Redfern, London.—Communicated by Le Comte Bernard d'Abbadie, France. Improvements in tiles for walls, ceilings, partitions, &c.; also box plates, etc., for making the tiles. Complete specification. May 20  
6630 P. Maxwell-Lyte, London. Improvements in the manufacture of refractory bricks, furnaces, converters, crucibles, and other refractory apparatus, and cement. June 1  
6815 C. Kingsford, London. Improvements in drying or evaporating apparatus for use in the manufacture or treatment of cement and other materials. June 4  
6819 J. D. Denny, Newbridge, Roxburgh. An improvement in making bricks, faced bricks, and ornamented bricks for glazing or otherwise, also in the box-plates, etc., for making the said tiles. June 5  
7082 J. F. Ebner, London. Improvements in the composition of adhesive anti-rust waterproof material used and method of securing parquet flooring to stone, concrete, wood, metal, or other surfaces, applicable to other like purposes. June 10  
7106 A. Patrick, Glasgow. Improvements in making sewage pipes, glazed bricks, and other earthenware articles. June 11  
7118 C. A. Wilkes and W. Millar, London. An improved metallic compound for flooring, paving, and other purposes. Complete specification. June 9  
7289 W. Jay, London. Improvements in the manufacture of cement, and in apparatus for that purpose. June 12  
7391 G. M. Garrard, London. Improvements in presses for pressing tiles. June 16  
7338 H. R. Kewell, London. Improvements in fire-proof ceilings and floors. June 16

### X.—METALLURGY, MINING, ETC.

6214 J. R. Griffin, London. Improvements in method of and apparatus for reducing ores. Complete specification. May 19  
6138 E. Scott, London. An improved machine or apparatus for washing ore or similar materials. May 19  
6190 J. Noad, London. Improvements relating to the extraction of gold and other precious metals from ores and other substances or products containing such metals. May 20  
6205 G. Siddell, London. An improved mechanical appliance for working or operating on large forgings in iron or steel. May 20  
6211 J. McRobie, Glasgow. Producing steel of highest quality from the commonest pig-iron. May 21  
6220 J. G. Laurie, Glasgow. Improvements in and connected with moulds for casting steel or iron or compounds thereof. November 1881.—Previously included in No. 1151 of 1881.  
6317 G. M. Edwards, London. Improvements in machinery and appliances for treating, dressing, and cleaning iron and other mineral ores, and for other useful purposes. May 23  
6385 J. Riley, Glasgow. Improvements in admixing ferro-manganese or other substances with steel, and in apparatus therefor. May 26  
6429 W. R. Lake, London.—Communicated by C. J. Eames, United States. Improvements in the manufacture of iron sponge, iron, and steel, and in apparatus therefor. Complete specification. May 26  
6430 W. R. Lake, London.—Communicated by C. J. Eames, United States. Improvements in the manufacture of iron sponge, iron, and steel. Complete specification. May 26  
6481 W. R. Lake, London.—Communicated by C. J. Eames, U.S. Improvements in the manufacture of iron sponge, iron, and steel. Complete specification. May 26  
6633 F. Siemens, London. An improvement in the mode of working open hearth iron and steel furnaces, and in the construction of furnaces for that and other purposes. Complete specification. June 1  
6638 T. Hampton, London. Improvements in the manufacture of steel armour plates. June 1  
6663 J. S. Williams, London, United States. Improvements in the methods or means for constructing ordnance, and in apparatus or means employed therefor or therewith. June 2  
6664 J. S. Williams, Riverton, United States. Improvements in methods or means for moulding or treating metal and other materials, and in apparatus or means employed therein or therewith. June 2  
6674 A. E. Scott, London. An improved process for separating metals from their ores, especially refractory gold ores, munda, and sulphurous ores. June 2  
6711 W. R. Lake, London.—Communicated by B. Atha, United States. Improvements in the manufacture of metal ingots and apparatus therefor. June 2  
6718 B. D. Healey and B. H. Thwaite, Liverpool. Improvements in the application of gaseous fuel for smelting ores, and in furnace crucible and other plant therefor. June 3  
6729 W. P. Thompson, Liverpool.—Communicated by A. Kurzwehn and E. Bertrand, Austria. Improvements in or relating to the casting of iron or steel ingots. June 3  
6738 P. M. Justice, London.—Communicated by The Frue Vanning Machine Co., United States. Improvements in concentrating or washing apparatus for the treatment of ores or other materials. June 3  
6750 J. Deby and B. F. Fulton, London. Metallurgical process for the purification of metals, and for the production of metallic alloys. June 3  
6759 H. B. Fulton and J. Deby, London. Improvements in the treatment of copper precipitate, regulus, or ore, for removal therefrom of arsenic. June 3  
6753 J. Giers, London. Improvements in the manufacture of steel. June 5

6830 T. Williamson, Wistlaw. Improvements in regenerators and open-hearth furnaces. June 8  
6894 J. McCulloch, Glasgow. Improvements in preparing ores, oxides, or compounds of iron for smelting or reducing. June 8  
6930 A. Greiner and T. Erpf, Halifax. Improvements in the method of and apparatus for smelting iron. Complete specification. June 8  
6970 E. Fischer and J. Posnansky, London. A new or improved process for obtaining white lead direct from the ore. June 8  
6984 W. P. Thompson, Liverpool.—Communicated by E. H. Cowles and A. H. Cowles, United States. Improvements in smelting ores by an electric current, and in furnaces or apparatus therefor. June 9  
7008 E. Heath Oswald and W. R. Oswald, London. An improved method of the more efficient collection and retention of gas and other ores. June 9  
7009 T. May, London. Improvements in gas-producing furnaces for smelting metals, glass, brick-burning, and other purposes. June 9  
7011 H. J. Allison, London.—Communicated by The Compressed Steel Co., United States. Improvements in the manufacture of steel ingots. Complete specification. June 9  
7012 H. B. Lake, London.—Communicated by H. E. Calson, called Rognier, France. Improvements in the manufacture of steel. June 9  
7013 A. Ephraim, London. A new or improved process for iridising metal objects by electro means. June 10  
7093 M. J. E. Morris, London. Improvements in the treatment and concentration of sulphate of iron solution, more especially in the form of the plate refuse liquor. June 10  
7115 W. Heaton, Rotherham. An improved method of blasting in coal and other mines. June 11  
7130 C. H. McEuen, London. An improved process for the extraction of the precious metals from their ores. June 11  
7161 E. Hunt, Glasgow.—Communicated by M. T. Brown, United States. Improvements in precipitating copper from solutions containing sulphate of copper. June 12  
7179 J. H. Johnson, London.—Communicated by La Société Anonyme "Le Ferro Nickel", France. Improvements in the manufacture or treatment of iron and steel. June 12  
7231 R. G. Brook, Liverpool. New or improved apparatus for blowing molten copper. June 13  
7307 A. K. Huntington, London. A process for the production of aluminium. June 16  
7365 J. E. Stead, Middlesbrough. Improvements in the manufacture of iron and steel. June 17

### XI.—FATS, OILS, AND SOAP MANUFACTURE.

6270 S. Banner, Liverpool. Improvements in lubricants and in the manufacture thereof. May 22  
6195 T. F. Vasey, London. Extra-fine oils and fat from fish. May 28  
6322 C. P. Abel, London.—Communicated by L. Hugues, France. Improved apparatus for dissociating neutral fatty bodies by means of heat and for the direct production of fat acids and glycerine by the action of water at high pressure. May 29  
6407 J. H. Ashwell, Liverpool. Improvements in treating or utilising soap suds. June 2  
6752 J. Drury, London. Improvements in the method of purifying brown grease. June 3  
7154 P. Brintin, London. An improved manufacture of saponaceous material for washing purposes. June 18

### XII.—PAINTS, VARNISHES, AND RESINS.

6119 D. McCowan, Glasgow. Improvements in the manufacture of enamel paint. May 19  
6841 M. Schumann, London.—Communicated by H. Graf, Germany. An improved metallic paint. June 1  
7111 G. L. Wigg, M. Steele, and W. J. Wigg, Liverpool. Improvements in the manufacture of pigments. June 11  
7121 H. Melville and J. F. Whitney, Liverpool. Improvements in paints, coatings, or compositions for coating ships' bottoms or other submerged structures. June 11

### XIII.—TANNING, LEATHER, GLUE, AND SIZE.

7223 P. M. Justice, London.—Communicated by A. Sandron, Belgium. Improved means for waterproofing and preserving leather, cardboard, and similar materials. June 13

### XIV.—AGRICULTURE, MANURES, ETC.

6553 W. Grishaw, London. Improvements in treating and drying excreta and manufacturing the same into manure. May 27

### XV.—SUGAR, STARCH, GUM, ETC.

6135 J. H. Johnson, London.—Communicated by E. M. J. Baptiste, Etienne, France. Improvements in apparatus for the manufacture of loaf sugar. May 19  
7133 W. R. Lake, London.—Communicated by W. T. Jebb, United States. Improvements in the manufacture of starch. May 19  
6110 W. R. Lake, London.—Communicated by W. T. Jebb,

Improvements in the manufacture of grape sugar or glucose. May 19

6358 L. Lefranc, London. An improved process of extracting juices, syrups, and molasses in sugar manufactories, refineries, and the like. May 23

6132 W. R. Lake, London.—Communicated by F. O. Matthews, United States. Improvements in the manufacture of sugar and in apparatus therefor. Complete specification. May 26

6661 A. M. Clark, London.—Communicated by the Davenport Glucose Manufacturing Company, United States. Improvements in the manufacture of starch, glucose, and other starch products. Complete specification. June 2

7095 O. Korschelt, London.—Communicated by H. Soxhlet, Bavaria. Improvements in the manufacture of grape sugar. June 10

## XVI.—BREWING, WINES, SPIRITS, Etc.

6213 J. C. McWhirren, London.—Communicated by G. Nobeck and W. Gintl, Bohemia. Modes of treating and utilising certain waste products obtained in brewing and similar processes. May 21

6285 W. S. Sequire, London. Improvements in the manufacture of yeast. May 22

6193 J. Milne, Glasgow. Improvements in apparatus for drying malt, grain, seeds, and other analogous vegetable products. May 28

6194 H. C. Schacht and J. Hodson, London. Apparatus for effecting the turning of malt or other grain on the drying floors of kilns. Complete specification. June 1

6621 C. Rus Bonne, London. Improvements in apparatus for producing carbonic acid gas, and for utilising the same in raising malt liquors, and for other analogous purposes. Complete specification. June 1

7358 A. G. Salamon, London. Improvement in the treatment of brewers' waste, and in the preparation of compounds to be used for such purpose. June 17

## XVII.—FOOD PRESERVING, MEATS, Etc.

6215 C. L. Bachelier, London. An improved method of rendering incorruptible any organic, vegetable and animal substances, and preserving their nutritive and alimentary properties. May 26

6707 A. W. M. Leicester, London. A process for preserving fruits. June 2

7056 H. T. Johnson, Manchester. The preservation of food by means of air-tight vessels. June 10

## XVIII.—SANITARY CHEMISTRY, DISINFECTANTS, Etc.

6331 A. Howatson, London. Improvements in apparatus for separating solid impurities from water or other liquids. May 23

6114 A. Breuer, London. Improvements in the manufacture of porous bodies for filtering, or other purposes. May 26

6139 F. R. Conder, London. Improvements in the purification of water, which improvements are also applicable to other sanitary purposes. Complete specification. May 27

6387 W. Maenab, London. Improvements in apparatus for separating liquids from solid matters suspended therein. May 30

6643 T. Bradford, Manchester. Improved disinfecting apparatus. June 2

6833 H. Sanders, Wolverhampton. A vessel to contain certain chemicals, the fumes of which shall neutralise, condense, prevent, or deodorise the evaporation of the effluvia arising from night-soil placed in pans during their removal in waggon through the streets. June 5

6992 M. Hilton, Prestwich. The purification of sewage and sewage waters, bleachers', dyers', and printers' refuse water, and for the recovery, manufacture, and utilisation of products relating thereto. June 9

7230 E. W. Bickerton, London.—Communicated by A. E. W. Howe and W. R. Bickerton, Tasmania. An improved preparation for washing or cleansing, and disinfecting purposes. June 13

7173 H. M. Marty, London. Improvements in the method of using apparatus for disinfecting rags. June 15

7318 G. H. Ellis, London. A new or improved process for the economical production of a porous carbon for filtering, refining, decolorising, and deodorising liquors. Complete specification. June 16

7422 B. L. Ryder, London. Improvements in method and apparatus for desiccating vegetable and animal matter. Complete specification. June 16

7451 R. V. Tuson, London. Improvements in the manufacture of preparations to be used for the destruction of parasites on sheep and other animals, and similar purposes. June 18

## XIX.—PAPER, PASTEBOARD, Etc.

6829 R. C. Menzies, C. F. Cross, and E. J. Bevan, Liverpool. Improvements in the preparation of paper pulp from straw, esparto, wood, rags, and like fibrous substances. June 5

6810 R. C. Menzies, C. F. Cross, and E. J. Bevan, Liverpool. Improvements in the treatment of fibrous substances for the manufacture of paper pulp and textile fabrics. June 5

7156 H. H. Lake, London.—Communicated by J. Jordan, United States. Improvements in the treatment of paper-pulp, and in apparatus or machinery therefor. Complete specification. June 11

7158 H. H. Lake, London.—Communicated by A. D. Beaumier, France. Improvements in the manufacture of cardboard or pasteboard, and apparatus therefor. June 15

## XXI.—EXPLOSIVES, MATCHES, Etc.

6182 J. S. Williams, Riverton, United States. Improvements in methods or means of constructing and operating explosive projectiles, and in apparatus or means employed therefor or therewith. May 20

6183 J. S. Williams, Riverton, United States. Improvements in methods or means of constructing and operating explosive projectiles, and in apparatus or means employed therefor or therewith. May 20

6184 J. S. Williams, Riverton, United States. Improvements in methods or means of constructing and operating explosive projectiles, and in apparatus or means employed therefor or therewith. May 20

6185 J. S. Williams, Riverton, United States. Improvements in methods or means of constructing and operating explosive projectiles or receivers, and in apparatus or means employed therefor or therewith. May 20

6372 J. S. Williams, Riverton, United States. Improvements in methods or means of constructing and operating explosive projectiles or receivers, and in apparatus or means employed therefor or therewith. May 20

6517 W. Kennish, Halifax. Improvements in and relating to explosive projectiles. May 20

6633 T. G. Hart, Dartford, Kent. Improvements in explosives for use in firearms. June 8

6635 H. S. Mixin, London. Improvements relating to the manufacture of explosive compounds. June 8

7215 J. S. Williams, Riverton, United States. Improvements in methods or means of constructing and operating explosive projectiles, and in apparatus or means employed therefor or therewith. June 13

## ENGLISH PATENTS PUBLISHED.\*

APPLIED FOR DURING 1884 AND 1885.

### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

1884.

8661 E. Morris. Composition for preventing and removing incrustation in steam and other boilers. 21  
9173 G. P. Jacques. Incrustation composition to dissolve the crusts. 2d

1885.

4018 F. W. Gordon. Improvements in hot blast stoves. 6d

### II.—FUEL, GAS, AND LIGHT.

1884.

7340 A. Ponsard. Means and apparatus for the manufacture of gas for lighting purposes and for heating purposes. 6d  
8810 G. F. Orange. Apparatus for conserving and using the heat produced in furnaces. 6d

13225 B. F. Elderton. The treatment of coal gas, and apparatus for increasing its brilliancy for illuminating purposes. 6d

1885.

3776 A. H. Reed.—Communicated by G. E. Moore. The manufacture of hydrogen gas. 4d

### IV.—COLOURING MATTERS AND DYES.

1884.

8195 H. J. Hadden.—Communicated by the Farbenfabriken vormals F. Bayer & Co. Process for separating the alphanonitrophenol acid of the beta-naphthol from certain admixtures. 1d

9313 J. Eskine.—Communicated by the Farbenfabriken vormals F. Bayer & Co. The production of colouring matters suitable for dyeing and printing. 4d

9306 W. W. Grieves.—Communicated by the Farbenfabriken vormals F. Bayer & Co. Producing yellow colouring matter suitable for dyeing and printing. 2d

9576 E. Capitaine.—Communicated by Ewer and Pick. Producing sulphurous colours. 6d

10100 E. H. Newby.—Communicated by F. Thiebaut. The extraction from grapes or raisins of various substances, and the use of application of the same for colouring or other purposes. 4d

\*Any of these specifications may be obtained by post, by remitting the cost price, plus postage, to Mr. H. Rees & Co., Controller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 5d.	2d.
„ Above 5d., and not exceeding 1s. 6d.	3d.
„ „ 1s. 6d., „ „ 2s. 4d.	4d.
„ „ 2s. 4d., „ „ 3s. 4d.	5d.

11002 F. Gaess. The manufacture of red azo-dye-stuffs or colouring matters. 4d.  
11030 J. H. Johnson—Communicated by H. Caro. The preparation of purple colouring matters suitable for dyeing and printing. 4d.

## V.—TEXTILES, COTTON, WOOL, SILK, Etc.

1881.

10139 L. A. Groth—Communicated by H. Giesler. Apparatus for, and method of, chemically treating wool, cotton and other soft goods. 6d.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

1884.

9701 D. Dawson. A new method of fixing insoluble azo colours upon cotton and other vegetable fibre. 4d.  
9802 R. B. Lytle. Bleaching linen and cotton yarns, linen and cotton cloth, and other textile fabrics. 2d.  
10012 W. D. Thornton. Improvements in the method of and apparatus for dyeing. 6d.

## VII.—ACIDS, ALKALIS, AND SALTS.

1884.

8803 P. Jensen—Communicated by A. Kux. Apparatus for concentrating sulphuric acid. 6d.  
9107 E. F. Truesdel. Method of producing carbonate or oxide of strontium or of barium, and recovering bye-products therefrom. 4d.  
9158 E. Carey and H. Gaskell, jun.—Partly communicated by F. Hunter. Manufacture of sulphite of soda. 6d.  
9765 J. Murray—Communicated by H. Lefebvre. Decarbonating carbonate of strontia, and apparatus therefor. 6d.  
9768 W. L. Wise—Communicated by H. Grouven. Effecting the recovery of sulphur from soda waste. 4d.  
9807 W. H. Perry and J. O. Boulton. Apparatus for the manufacture of vinegar. 6d.  
10257 W. A. Hills. The manufacture of precipitated phosphate of alumina and the mixed precipitates of phosphate of alumina and sulphate of lime. 4d.  
10418 C. T. Richardson. The utilisation of certain waste products from the manufacture of soda and chlorine. 2d.  
1210 T. W. B. Munford and R. Moodie. Apparatus for the concentration of sulphuric acid, or for analogous purposes. 6d.

1885.

3893 J. J. Hood. The manufacture of chromates and bichromates. 4d.  
4175 F. J. B. Raken—Communicated by H. Beins and J. F. Beins. Method of manufacturing carbonic acid under any desired pressure. 2d.

## VIII.—GLASS, POTTERY, AND EARTHENWARE.

1884.

10786 C. D. Abel—Communicated by La Compagnie Générale du Verre et du Cristal Trempe. Manufacture of toughened optical glass articles, and apparatus therefor. 6d.

1885.

1033 G. W. Wilkinson. Gas kilns for burning glass, china, pottery-ware, and other such like articles. 6d.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

1881.

9357 S. de la Grange Williams and J. A. B. Bennett. Kilns for burning limestone, cement and bricks, and for other like purposes. 6d.

9857 H. M. Smith. Coating or surfacing bricks and tiles. 2d.  
10490 R. Stone. The manufacture of plaster from chalk, lime, gypsum, etc., and machinery and appliances therefor. 2d.

1885.

4154 W. E. Heys—Communicated by E. Ladewig. The manufacture of fire and waterproof boards or paper from asbestos. 4d.

## X.—METALLURGY, MINING, Etc.

1881.

10085 T. Bayley. The treatment and utilisation of the spent pickle after use for cleaning iron. 4d.  
10620 T. Froggatt. Stealing iron without welding or blistering. 4d.

10232 H. H. Lake—Communicated by T. Shaw. An improved alloy, chiefly designed for electrical conductors, and process of manufacturing the same. 4d.  
15027 F. J. King. The separation of ores and mineral products, and apparatus employed therein. 6d.

1885.

479 J. Lietzgy y Sardá. Improvements in the manufacture or treatment of iron and steel. 2d.  
1019 A. M. Clark—Communicated by D. Brennan and G. G. Young. Improvements in stone and ore crushers. 8d.  
1036 J. S. Booth. The construction of boiler and other furnaces. 4d.  
5003 W. Cochran. Moulds for cooling and discharging slag. 4d.

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

1881.

9672 A. Kind. Cooling apparatus for cooling oleine and other liquids. 6d.

## XIII.—TANNING, LEATHER, GLUE, AND SIZE.

1885.

4921 A. G. Brookes—Communicated by G. H. Maddock. Means or apparatus for brushing and cleaning or treating leather. 4d.

## XV.—SUGAR, STARCH, GUM, Etc.

1881.

10367 E. Langen. Purifying and clarifying sugar, and apparatus therefor. 6d.

## XVI.—BREWING, WINES, SPIRITS, Etc.

1881.

10109 W. A. How. Improvements in draught ale and other beverages, and in the means for effecting the same. 6d.  
10685 A. M. Clark—Communicated by E. L. J. Boniface. Method of converting the juice of the Jerusalem artichoke into levulose, and the application of the latter for obtaining various products by fermentation and distillation. 4d.

## XVII.—FOOD PRESERVING, MEATS, Etc.

1884.

10195 E. Capitaine—Communicated by R. Habermann. The treatment of the lupinus plant to adapt it for use as food for cattle. 4d.

## XVIII.—SANITARY CHEMISTRY, DISINFECTANTS, Etc.

1881.

10159 H. Porter and J. H. Porter. Apparatus or means for effecting the softening or purification of water, etc. 6d.  
10613 H. W. Lee—Communicated by T. Roberts. Method of separating solid and liquid fecal matters, and appliances for that purpose. 2d.

1885.

1580 A. B. Lorenz. Preventing water in reservoirs and pipes becoming stagnant and creating gases or becoming otherwise prejudicial to health. 4d.

4016 A. Engle. Destroying and utilising sewage in buildings, towns, and cities. 6d.

4307 W. H. Beck—Communicated by H. Wagner and A. Muller. Processes for treating sewage and other waste waters for obtaining the fats, fatty acids, and fibrous matter contained in the same, and in apparatus to be employed therewith. 6d.

## XIX.—PAPER, PASTEBOARD, Etc.

1881.

11087 J. Jameson. The preparation of safety paper affording protection against crasures or other alterations. 4d.

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

1881.

10167 J. G. Johnson—Communicated by F. von Heyden. Manufacture of salicylic acid, and of the homologues thereof. 4d.

## XXI.—EXPLOSIVES, MATCHES, Etc.

1884.

15047 C. W. Curtis. Improvements in the manufacture of explosives. 4d.

# THE JOURNAL OF THE Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES

No. 7.—VOL. IV.

JULY 29, 1885.

Non-Members 20/- per annum; Members  
21/- per Set; Single Copies 2 6.

## The Society of Chemical Industry.

### Past Presidents:

Sir H. E. Roscoe, Ph.D., LL.D., F.R.S.  
Sir Frederick Abel, C.B., D.C.L., F.R.S.  
Walter Weldon, F.R.S.  
Dr. W. H. Perkin, F.R.S.

### COUNCIL

President: E. K. Muspratt.

#### Vice-Presidents:

Sir F. A. Abel, D.C.L., F.R.S.	Dr. Peter Griess, F.R.S.
Sir I. Lowthian Bell, Bart., F.R.S.	Dr. W. H. Perkin, F.R.S.
Alexander M. Chance.	John Spiller.
Prof. James Dewar, F.R.S.	E. C. C. Stanford.
James Duncan.	J. C. Stevenson, M.P.
David Gamble.	Walter Weldon, F.R.S.

#### Ordinary Members of the Council:

R. Forbes Carpenter.	Dr. S. A. Sadler.
Henry Donlon.	Sir Bernhard Samuelson,
Dr. John Evans, F.R.S.	Bart., M.P.
Ivan Levinstein.	Sir Chas. Tennant, Bart.,
Dr. R. Messel.	M.P.
B. E. R. Newlands.	Prof. W. A. Tilden, F.R.S.
Thomas Royle.	John Williams.

With the Chairmen and Secretaries of Local Sections.

#### Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, E.

#### Honorary Foreign Secretary:

Ludwig Mond, 28, Park Crescent, Portland Place, W.

#### General Secretary:

Charles G. Cresswell, Palace Chambers, 9, Bridge Street, Westminster.

## THE JOURNAL.

### Publication Committee:

#### The President.

Sir F. A. Abel, F.R.S.  
Joseph Bernays, M.I.C.E.  
W. Lant Carpenter.  
Prof. Frank Clowes, D.Sc.  
George E. Davis.  
Prof. Dewar, F.R.S.  
Prof. Chas. Graham, D.Sc.  
Peter Griess, Ph.D., F.R.S.  
D. B. Hewitt, M.D.  
David Howard.  
Prof. A. K. Huntington.  
F. Hurter, Ph.D.

Editor: Watson Smith, The Owens College, Manchester.

ASSISTED BY THE FOLLOWING STAFF OF

#### Abstractors:

G. H. Beckett.  
D. Bendix.  
E. J. Bevan.  
W. Dalrymple Borland.  
C. Claus.  
E. G. Clayton.  
Julius B. Cohen, Ph.D.  
C. F. Cross.  
A. R. Davis.  
A. G. Green.  
S. Hamburger, Ph.D.  
J. J. Hummel.  
C. C. Hutchinsonso.  
D. E. Jones.  
Herbert Jones.

W. E. Kay.  
A. J. King, B.Sc.  
D. A. Louis.  
F. Machenhauer.  
Wm. Macnab, Jnn.  
W. G. McMillan.  
J. M. H. Mnaro, D.Sc.  
H. R. Procter.  
H. A. Tadmacher.  
F. W. Renant.  
Samuel Rideal.  
James Taylor, B.Sc.  
F. L. Teed, D.Sc.  
Alex. Watt.  
Sydney Young, D.Sc.

## NOTICE.

Notice is hereby given that the resolution, embodied in the Report of Council to the Annual General Meeting, 1881, which forbids the publication of communications other than those read before the Society or its Sections, is now rescinded. Communications bearing upon Technical Chemistry can now be sent to the General Secretary, and, if they be approved by the Publication Committee, will be inserted in the Journal.

### LIST OF MEMBERS ELECTED, JULY 7th, 1885.

C. A. Bolton, 40, Carlton Street, Nottingham, chemist.  
C. H. Clifton, Royal Oak Brewery, Stockport, brewer.  
F. G. Cotes, Rawson Street, New Basford, Nottingham, pharmacist.  
E. Francis, Rock Villas, Parkside, Nottingham, lecturer on chemistry.  
J. Goddard, 1, Clipstone Avenue, Nottingham, ironfounder.  
Evan R. Harris, Luckwell House, Bedminster, Bristol, iron-works manufacturer.  
Adolph Hess, Oil Works, Leeds, chemical manufacturer.  
G. F. Horner, Old Basford, Nottingham, bleacher.  
G. T. Lewis, 231, South Front Street, Philadelphia, U.S.A., white lead manufacturer.  
L. A. Lewis, 12, Crescent Place, Mornington Crescent, N.W., assistant analyst.  
Sydney Lupton, M.A., The Harehills, near Leeds.  
W. H. Parker, 177, Alfreton Road, Nottingham, pharmacist.  
Beatus Petersen, 69, Nyhavn, Copenhagen, manager chemical works.  
C. T. Richardson, Monkton Lodge, Jarro-w-on-Tyne, alkali manufacturer.  
John Thom, Birkacre, Chorley, Lancashire, calico printer.

### LIST OF MEMBERS ELECTED JULY 23rd, 1885.

John Abbott, Braemar House, Lancaster Gate, Hyde Park, W., chemical manufacturer.  
W. H. Aykroyd, Oakwood Villas, Toller Lane, Manningham, Bradford, dyeing chemist.  
Oliphant A. Brown, Lennoxmill, Lennoxtown, N.B., print-works manager.  
H. Jeff. Dodd, 195, Queen's Road, Dalston, N., chemist.  
J. Emerson Dawson, 3, Great Queen Street, Westminster, S.W., M.I. Inst. C.E.  
Anthony Edge, Readville, Mass., U.S.A., chemist.  
E. H. Grimwade, Mildmay Chambers, 82, Bishopsgate Street, E.C., wholesale druggist.  
Wm. Hammersey, Tar Works, Beckton, E., tar distiller.  
Lieut.-Col. Sir James McGarel Hogz, Bart., K.C.B., M.P., 17, Grosvenor Gardens, London, S.W., chairman Metropolitan Board of Works.  
F. Knipfler, Starch Works, Wandsworth, S.W., starch manufacturer.  
W. W. L. Lishman, 36, Washington Street, Gillington, Bradford, Yorks., dyeing chemist.  
V. L. Lovibond, The Hermitage, North End, Fulham, S.W., brewer.  
J. G. Flowerdew Lowson, Balthayock, Perthshire, N.B., paper maker.  
Wm. Metcalf, Stanhill House, Oswaldtwistle, near Accrington, tar distiller.  
Jno. Morrison, P.O. Box 74, North Adams, Mass., U.S.A., colour maker.  
Arthur H. Newton, Belsize Court, Hampstead, N.W., colour manufacturer.  
Gustav Quaes, Home Park Mills, King's Langley, Herts., paper maker and stainer.  
J. S. Knoch, Walton Chemical Works, Chesterfield, manu-facturing chemist.

J. Isaac Smith, 1, Norman Villas, Bath Road, Hounslow, sanitary inspector.  
 G. R. Underwood, Mass. Institute of Technology, Boston, Mass., U.S.A., assistant professor industrial chemistry.  
 T. Holt, Warrington, Harpenden, Herts., analytical chemist.  
 Rowland Williams, 9, Albert Square, Manchester, analytical and consulting chemist.  
 T. Howell Williams, 10, Ascham Street, Kentish Town, N.W., manufacturing chemist.  
 David W. R. Wilson, Sinderby, Thirsk, Yorkshire, pharmacist.  
 J. W. Wyatt, Nash Mills, Hemel Hempstead, Herts., civil engineer.

#### CHANGES OF ADDRESS.

John Farrow (l/o Clayton), Helme House, Sandwich Road, Elmwood Park, Eecles.  
 E. T. Brewis, 111, Great Brunswick Street, Dublin.  
 H. Brown (l/o Cumberland Market), Royal Oak Brewery, Stockport.  
 G. L. Cabot (l/o Boston), Readville, Mass., until October 31st, then c/o Chas. Almy, junr., Esq., 1, Brewster Place, Cambridge, Mass., U.S.A.  
 Jno. Cliff (l/o Wellington Street), Nesbitt Hall, Fulmer, Leeds.  
 H. P. Cooper (l/o Rectory Road), 15, Haringey Road, Hornsey, N.  
 H. R. Edmunds (l/o Brooklyn), 337, East 27th Street, New York, U.S.A.  
 W. N. Evans (l/o Bristol), 9, St. Bride's Avenue, Fleet Street, E.C.  
 F. J. Greenway (l/o Wilkinson Street), 378, Ecclesall Road, Sheffield.  
 T. Farmer Hall (l/o Leatherhead), Dunster House, Mark Lane, E.C.  
 Ellwood Holmes (l/o Manchester), Welburn, Jessmond, Newcastle-on-Tyne.  
 Asa Lees (l/o Fulham), 75, Duncombe Road, Upper Holloway, N.  
 G. H. Lloyd (l/o Edgbaston), Maney House, Sutton Coldfield, near Birmingham.  
 A. S. Lodge (l/o Rouen), Spring Side, Prestwich, near Manchester.  
 John Lyle (l/o Streatham), 37, Mincing Lane, E.C.  
 F. W. Paul, Hallside Steelworks, Newton, by Glasgow.  
 W. L. Remondson (l/o South Shields), St. Bede Chemical Works, East Jarrow.  
 F. Rosicki (l/o Manchester), 13, Fasanen Strasse, Frankfurt-a-M.  
 W. Johnston Saint (l/o Munich), 11, Queen's Road, Aberdeen.  
 Fred. Smith (l/o Chelsea), West Parade, Sutton on Hull.  
 J. E. Stoddart (l/o Cornwall Street), 60, Robertson Street, Glasgow.  
 W. S. Squire (l/o Regent's Park), Clarendon House, St. John's Wood Park, N.W.  
 F. P. Stiker (l/o Oswego), 633, Ellicott Street, Buffalo, N.Y., U.S.A.  
 Andrew Taylor (l/o South Clerk Street), 11, Lutton Place, Edinburgh.  
 Sir Chas. Tennant, Bart., M.P., 35, Grosvenor Square, W., and The Glen, Perthshire, N.B.  
 T. E. Vasey, 11, Corn Exchange Chambers, Mark Lane, E.C., and 6, South Parade, Leeds.

#### Death.

Jas. Higgin, l/o The Hollies, Timperley, Cheshire.

#### PROCEEDINGS OF THE FOURTH ANNUAL GENERAL MEETING,

*Held at the City Guilds of London Central Institute, South Kensington, on Tuesday, July 7th, 1885.*

DR. W. H. PERKIN, F.R.S., took the chair at eleven o'clock, and was supported by Mr. E. K. Muspratt (President elect), Mr. Walter Weldon, F.R.S.; Mr. J. C. Stevenson, M.P.; Sir Frederick Abel, C.B., D.C.L., F.R.S., and by representatives of the leading chemical firms throughout the United Kingdom. The minutes of the last Annual Meeting, held in Newcastle-upon-Tyne, were read and confirmed.

The SECRETARY read the following Report of the Council:—

#### REPORT OF THE COUNCIL.

Four years have passed since the inaugural meeting of the Society of Chemical Industry, and it is not possible to bring forward a better proof of the success which has attended the Society in its efforts to

advance all branches of applied chemistry, than the 2000 names now upon its register. Since the last Annual Meeting at Newcastle, 345 new members have been elected, and 60 have been removed by various causes. The Council has to regret the death of 14 members, of whom the following demand special mention:—Dr. August Voelcker, so well known for his important contributions to the chemistry of agriculture; Sidney Gilechrist Thomas, whose name is identified with the basic process of steel-making; G. W. Wigner, founder and president of the Society of Public Analysts; Dr. Adrian Blaikie, Inspector of Alkali Works for the Tyne District; and Geo. H. Herbert, an enthusiastic supporter of the Society from the outset, and one of the principal merchants of Tyneside.

Two new sections have been established this year—one at Nottingham, under the chairmanship of Professor Clowes; and one for the West of England and South Wales, over which Professor Ramsay, of Bristol, has been elected to preside. The papers and discussions during the past session have reached a total of seventy-one, to which Birmingham has contributed three, Glasgow fifteen, Liverpool six, London seventeen, Manchester thirteen, Newcastle sixteen, and Nottingham one. The Bristol and South Wales Section is only just formed. It has not yet held any meetings.

The Council has felt it desirable that every endeavour should be made to keep the Journal from becoming unnecessarily voluminous, both for the sake of the readers and from motives of economy. A sub-committee has been accordingly formed which has power to reduce shorthand notes of discussions, and it will also be within the province of this sub-committee to induce the authors of papers to make these papers as concise as possible before they are printed in the Journal. In fine, all communications for the Journal will be submitted to this committee in MS.; and in view of this arrangement the Council would, under exceptional circumstances, permit papers other than those read before the Sections, to appear in the Journal under the head of "Communications." In September last five numbers (February to June inclusive) of the first volume were reprinted, at a cost of £128, in response to a generally expressed wish. To this extra expense, and to the general cost of the Journal, must be ascribed a deficit as between receipts and expenditure in 1884 of £167, as will be seen from the Treasurer's report. There will be no reprinting this year; and a substantial increase in the number of members leads the Council to hope that there will be a small surplus.

At the end of last year the Executive Council of the International Inventions Exhibition invited the Society to assist in preparing a representative exhibit showing the progress of applied chemistry during the last quarter of a century. A committee was formed with Mr. Ludwig Mond as honorary secretary, and members were invited to contribute. Twenty-seven responded favourably to the invitation, and a fine collection of chemical products and models, the result of their liberality, now forms the Society's collective exhibit.

Soon afterwards, at the instance of Sir Frederick Abel, the Executive Council of the Exhibition courteously resolved to grant season tickets to the Society's members at half-price, and under the terms of this arrangement 150 season tickets have been sold.

In conclusion, the Council would urge members to use their best endeavours to induce all those who are engaged in industrial chemistry, or whose business involves chemical engineering, to join the Society. The Council places reliance upon the usefulness of the

account of this industry, and the relationships which have been found to exist between the colour of the compounds and the chemical constitution, it is possible with more or less certainty to predict the colour a compound will have before it is produced, and the means which can be used to modify it.

It will be impossible for me to give you but a very brief sketch of the history of this industry in the time at my disposal: anything like a complete account would fill volumes. On account of this I shall not be able to refer except casually to the coal-tar industry itself, the development of which is nearly entirely due to the one under consideration. Nor can I give a consecutive account of the coal-tar colours themselves, because the discovery of new series of colouring matters, and the progress of old ones, necessarily produce overlapping as it were, and renders such a course difficult and confusing. I therefore propose to take them according to the groups we now know them to belong to. I will therefore commence with that which contains the first colouring matter connected with this industry—i.e., the *mauveine* and *safranine* group of compounds.

As I already mentioned, the coal-tar colour industry dates from 1856, the discovery of the aniline purple or mauve dye being made during the Easter vacation of that year, and the patent for its production taken out on the 26th of the following August. From the accounts I have already given elsewhere, I have mentioned how the discovery of this colouring matter was made during the prosecution of scientific research, which had for its object the artificial production of quinine, a subject which of late has very much occupied the attention of chemists, though it has not as yet been accomplished.

When commencing this industry, which was looked upon by many with considerable doubt as to its practicability, the difficulties encountered were very numerous on account of its unique character, but few of the processes having their representatives in other industries, the products were also very valuable, so that great care had to be employed with them. Moreover, the success of the product tinctorially had not been proved on the large scale, so that it was necessary rarely to proceed tentatively and not launch out too rapidly.

Aniline, as is well known, was at this period a rare body, originally obtained from indigo by Unverdorben in 1826; for its production from benzene we are first indebted to the discovery of nitrobenzene in 1834 by Mitscherlich, and then to Zinin, who found that this substance when submitted to certain reducing agents produced a base which was eventually identified as aniline. It was not long before the date of this industry that a method of producing this base from nitrobenzene, with greater ease than by the process of Zinin, was discovered; and it is to Béchamp we are indebted for this, who found that the reduction might be easily accomplished by means of iron filings and acetic acid. Had this discovery not been made, aniline could not have been produced sufficiently cheap to be used for the production of colouring matters. And it is interesting to note that this process of Béchamp, slightly modified, is the one used to-day for the production not only of this base, but its homologues and analogous compounds.

It was not long before the difficulties of producing nitrobenzene were to a great extent overcome. Messrs. Simpson, Maule & Nicholson also began to experiment on the production of nitrobenzene, and after a time were able to produce it at a sufficiently low cost to be able to supply us with part of our requirements. I mention this in passing because it was the starting point of the history of the connection of this firm

with artificial production of colouring matter, which they carried on so successfully afterwards.

After the mauve was discovered it was necessary to teach dyers how to use it. Being an organic base, it is opposite in properties to the vegetable colouring matter, and therefore the ordinary methods of application were not generally useful, and much time had to be spent in dyehouses and printworks in the early days of this product in reference to this subject, and at that time the question of fastness to light, soap, and bleaching liquor was much insisted on. Fortunately for the future of the coal-tar colour industry, although the mauve would not resist bleaching liquor well, it proved to be a very fast colour—the fastest purple yet produced, I believe—and thus its introduction became rapid. After this the love of brilliancy of colour which it had induced caused less attention to be given to the subject of fastness. I quite think that had this, the first coal-tar colouring matter, yielded colours as fugitive as some which have since been used, this industry would probably have been, to say the least, much delayed in its progress; so that it will be seen the mauve had to bear all the burdens of the difficulties incident on the inauguration of this industry, the future products being free from these impediments. The importance of this colouring matter after its success was established was quickly recognised in France, and its manufacture commenced there. This soon resulted in its importation into this country irrespective of patent rights. As, however, the foreign manufacturer employed responsible agents in this country, the law was without difficulty put into operation successfully—unfortunately, however, only to teach Continental manufacturers the lesson not to employ responsible agents in this country any longer, but, by means of correspondence or travellers to deal directly with the consumers, and this *modus operandi* (practically, though perhaps not theoretically) enabled them to ignore the existence of patents, and import their products freely into this country. On this point I shall have to speak again further on. The mauve was first employed in silk dyeing in London, Messrs. Thomas Keith & Sons, of Bethnal Green, being the first to use it. The second application was calico printing, Messrs. James Black & Co., of Glasgow, being the first to employ it largely for this purpose. It afterwards was extended to other trades.

With reference to the chemical history of this dye, although it had been submitted to analysis very soon after its discovery, its formula, or rather the formula of its principal constituent "*mauveine*," was not established until some time after it had become a commercial product, and was prepared in a crystalline condition. It was then shown to have the composition  $C_{27}H_{21}N_3$  (Proc. R. S. xiii. 170).

It was found to be a very powerful base, decomposing ammonia salts with evolution of ammonia, and combining with carbonic acid to form a carbonate. Its ordinary salts are produced by its combination with one molecule of a mono-basic acid, its hydrochloride having the formula  $C_{27}H_{21}N_4HCl$ .

In concentrated sulphuric acid mauveine dissolves with a dirty green colour, changing to blue on slight dilution, and back to purple when thoroughly diluted; this is a distinctive reaction of this class of colouring matters. Further researches have shown (*J. Chem. Soc.* xxxv. 717-732) that in the ordinary commercial product, besides mauveine, there are two other compounds, one possessing a redder shade of colour, the other being remarkable for its great solubility in alcohol. This latter from analysis appears to have the formula  $C_{24}H_{20}N_4$ .

The first product, or mauveine, is evidently a derivative of paratoluidine and aniline. The second of ortho-

toluidine and aniline, and the third of pure aniline. This has been called pseudo-mauveine. It might perhaps be better called pheno-mauveine.

When boiled with aniline mauveine yields an indigo-blue product, difficultly soluble in alcohol. This change takes place without formation of ammonia, and shows how different mauveine is in its character to rosaniline.

Runge found that aniline, when treated with dilute chloride of lime, yielded a blue or violet coloured solution, which soon underwent change. Some experiments on this, made in 1868 (*J. Chem. Soc.* xxii, 25-27), showed that the product which I named "Runge's blue," was a peculiar compound, the salt of an organic base, which itself dissolved in alcohol with a reddish brown colour, the salts being blue. It is quite different from mauveine, and of no practical value; but what is interesting is that when exposed to heat, as by boiling a solution of one of its salts, it decomposes with formation of mauveine.

A beautiful colouring matter was obtained from mauveine by treating it with ethyl iodide. It gives shades of colour of a very red purple tint, and it was therefore called *dahlia*. It was mostly used in calico delaine and other kinds of printing, but being costly, the production was never very large. This substance is a mono-ethyl derivative of mauveine, and all attempts to further ethylate this compound have proved fruitless. In properties it appears to be more like an ammonium compound than a displacement product.

#### Safranines.

In the preparation of mauveine, a colouring matter was obtained from the liquors, from which it was precipitated, yielding beautiful crimson-red shades of colour on silk. The amount produced in this was so small, however, that we were not able to introduce it as a dye. But it was found that it could be produced by the oxidation of the mauve dye itself, and was then manufactured under the name of "aniline pink," but afterwards "safranine." This substance is evidently closely related to mauveine, as it gives the characteristic reaction with sulphuric acid I have already referred to.

The preparation of this from the mauve dye was too costly to allow of its being brought into general use. However, new processes have been since discovered, by which this or other colouring matters of its class can be produced cheaply.

The first of these processes consisted in passing nitrous acid into commercial aniline, heating the mixture with arsenic acid, and then extracting the colouring matter produced. Hofmann examined this, and showed that it had the formula  $C_{21}H_{20}N_4$  (*Ber.* vi, 526, 1872).

The examination of the product which was obtained by oxidising the mauve dye, I found to have the composition,  $C_{20}H_{18}N_4$  (*J. Chem. Soc.* xxxv, 731), results which correspond with analyses published by Dale and Schorlemmer (*J. Chem. Soc.* xxxv, 682) obtained from the examination of a similar product. This substance, I also found, was associated with that examined by Hofmann in a product prepared by Messrs. Guinon & Co., of Lyons.

Methods of a more synthetical nature have since then been discovered. O. Witt found that safranine could be obtained from orthoazotoluene and hydrochloride of toluene at  $150-200^\circ$  (*Ber.* 10, 874, 1877). He then found that by oxidising a mixture of one part of paraphenylenediamine, and two parts of aniline, on the application of heat a safranine could be obtained which has the formula,  $C_{18}H_{16}N_4$ , and which is called phenosafranine.

The formation of this colouring matter by this and

other processes has been studied by Nietzki (*Ber.* 16, 464). He finds that the aniline in the reaction, in which paraphenylenediamine takes part, may be substituted by other primary monamines, or a mixture of these with dimethylaniline, and thus a large number of these dyes can be obtained.

Phenosafranine is now produced very largely, and in a pure crystallised condition, and is a very useful dyeing agent.

If we assume that all the safranines are strictly homologous compounds, the formula that Nietzki gives for phenosafranine would make the formula of that examined by Hofmann, and that examined by myself and Dale and Schorlemmer, to be incorrect, and that they should contain two hydrogens more than are assigned to them. This I cannot think is possible from all the analytical results we obtained.

The constitution of mauveine has not yet been established, and I have still experiments on this subject in hand. This may also be said of safranine, I think, although Nietzki has proposed a formula for it, in which nitrogen occupies a similar position to the methane-carbon in the rosaniline series.

#### Triphenylmethane Derivatives.

We must now go back again to the early days of this industry to consider the next class of compounds—viz., triphenylmethane derivatives.

The industrial success of the mauve dye caused aniline to become a very favourite body to experiment with, and the result was that in 1859 the discovery of that important colouring matter first known as fuchsine or magenta took place. Hofmann had observed in his experiments on the action of carbon tetrachloride on aniline in 1858, the formation of a red colouring matter, which consisted of this substance as a secondary product of the reaction, but it was M. Verguin who first discovered a process for the transformation of aniline into a red colouring matter of tinctorial value. The discovery of this compound marks a most important fresh departure in the history of coal-tar colours. As I mentioned, the mauve had paved the way for future colouring matters, and this new substance, which could be applied to fabrics by the same methods as the mauve, was most eagerly sought after owing to the brilliancy of its colour, and probably its manufacture was one of the most successful financially of all the aniline colours.

M. Verguin's process, which consisted in treating commercial aniline with tin tetrachloride, was soon superseded by better processes. The number of patents taken out for the production of this dye was very large, and all imaginable products were claimed as capable of producing it from aniline. The two most important, however, were those in which mercury nitrate and arsenic acid were used. The first of these processes, with which I had some experience, required much care to regulate the reaction and prevent deflagration. The next process with arsenic acid, known as Medlock's, was by far the best, and was employed very extensively until the last few years, the use of nitrobenzene as the oxidising agent being now mostly used in the place of arsenic acid.

The manufacture of magenta, which at this period was often called roseine, was carried on chiefly in this country by Messrs. Simpson, Maule & Nicholson, by the arsenic acid process. Mr. E. C. Nicholson and Dr. A. P. Price, of this firm, worked out the process with great success, and were the first to produce this colouring matter in a pure state. The beautiful display of the crystallised acetate, shown at the Exhibition of 1862, illustrated this fully.

It was with products supplied by Mr. Nicholson that Dr. Hofmann made his first researches on this

colouring matter. He changed its name from roseine to *rosaniline*, and found that the base, when in combination with acids, had the formula  $C_{20}H_{11}N_3$ .

The important observation of Nicholson, and the critical experiments of Hofmann, on the necessity of using, not pure aniline, but a mixture of aniline and toluidine for the production of this substance, was made about this period.\*

The next important step in this industry was the use of rosaniline itself as a source of new colouring matters. For this we are indebted to the experiments of two French chemists—viz., MM. Girard and Delaire, who discovered that rosaniline salts, when heated with aniline, gave violet and blue colouring matters, which they called *Violet Imperial* and *Bleu de Lyon*. It is, however, to Mr. Nicholson and the credit of producing these bodies, in a practically pure state, belongs. This especially refers to the blue, the product known as opal blue, used by Dr. Hofmann in his investigations on the subject, being of great purity. Dr. Hofmann showed that these products were phenylated rosanilines, as is now well known, ammonia being given off in the reaction. And I may mention in passing that the manufacture of these blues is now carried on to such a large extent that the ammonia produced in this reaction is collected for the production of its sulphate or other salt.

One of the difficulties in the way of the new blue was its insolubility in water. Mr. Nicholson, however (in 1862), probably thinking of the method used to render indigo soluble, experimented upon the action of sulphuric acid on this compound, and he found that it was possible to obtain sulphonic acids from it. One of these, the sodium salt of which is known as "Nicholson's" or "alkali blue," is the monosulphonic acid, which is itself insoluble in water, but forms soluble salts, which can be applied to the goods, and then decomposed by acids. This compound has had much to do with the successful introduction of this colouring matter. The other product known as soluble blue is the sodium salt of trisulphonic acid.

In the early part of 1864 the *Hofmann violets* were introduced. These, as is well known, are the ethylated rosanilines produced by acting upon rosaniline with ethyl iodide. These colouring matters are more brilliant, though much more fugitive than mauveine; but by this time the desire for permanency was giving way very much to that of brilliancy; and these colouring matters were quickly taken up by dyers and calico printers.

About this time some colouring matters derived from phenol were introduced, and which, curiously, are found to belong to the class of substances now under consideration. These were brought forward by Messrs. Guinon, Marnas & Bonnet, of Lyons. The first product was aurin, prepared from phenol by means of oxalic and sulphuric acid (Kolbe and Schmitt's process). The next was *péonine*, obtained by acting upon aurin with ammonia. The third was *aculine*, prepared by heating aurin with aniline. This last was a blue dye, which has since been shown to consist chiefly of triphenylrosaniline.

Purple and violet derivatives were also obtained from rosaniline by a process of my own, in which brominated turpentine was employed. These were known as *Britannia violets*, and were much used.

Other coloured derivatives were also discovered; for example, by the action of aldehyde and sulphuric acid, a blue product was obtained, which, when treated with sodium hyposulphite or sulphuretted

hydrogen water, yielded the well-known *aldehyde green*.

On examining the action of acetylchloride on Britannia violet, I obtained a peculiar green, which was used principally by calico printers, and very considerable quantities of acetylchloride were prepared for this purpose. The process was not published. This green was of a blue shade, and was obtained in a crystallised condition in combination with picric acid. The crystals had a golden metallic reflection.

Soon after this it was noticed that a green compound was produced in the preparation of the Hofmann violets, though generally only in small quantities. It was afterwards found that by making rosaniline react with an excess of methyl iodide that it could be produced practically. It was called *iodine green*; but the product now manufactured is a chloride. This colouring matter gave good candle-light greens. One of its peculiarities is that when heated it is converted into violet methyl-roosaniline, with loss of methyl-chloride.

A new method of producing rosaniline violet was proposed by Lauth, and patented by MM. Porrier and Chappat, in June, 1866. The process consisted in taking aniline, in which hydrogen had been replaced by an alcohol radical, and oxidising this instead of first preparing rosaniline, and then replacing the hydrogen in the colouring matter by the radical. The product proposed for this purpose was methyl-aniline.

Owing to the improved method of methylating aniline, which, I believe, was first proposed by Messrs. Girard and Delaire (*Bull. Chem. Soc.* [2], vii. 360), this process has become a very important one, and large quantities of dimethyl-aniline are now used, the oxidation being effected by copper salts. The product, according to the researches of Otto Fischer, consists chiefly of pentamethylpararosaniline.

The most important advance in the production of green colouring matters of the triphenyl-methane series was the discovery of the *Benzaldehyde, Victoria or Malachite green*.

In 1877, Otto Fischer, whilst investigating the condensation products of tertiary aromatic bases (*Ber.* x. 1625), obtained by the action of benzaldehyde on dimethyl-aniline in presence of chloride of zinc, a colourless base of the formula  $C_{23}H_{26}N_2$ , the salts of which, when exposed to the air, rapidly oxidised to a fine blue-green dyestuff, which, he thought, would prove to be of complicated constitution. A little later (*Ber.* xi. 950) he showed that by treating this colourless base with some of the ordinary oxidising agents, this green could be more easily produced, and that it stood to the colourless compound in the same way as rosaniline does to leucaniline. Emil and Otto Fischer afterwards say (*Ber.* xii. 796) that the first experiments for the production of this green were made by the Badische Anilin- und Soda-Fabrik, in March, 1878. About this time Oscar Doebner (*Ber.* xi. 950) found that a green colouring matter was produced by heating benzaldehyde with benzyl trichloride and zinc chloride. This product has been found to be identical with that of Fischer's. This green colouring matter is now largely made from benzaldehyde, as this process is found to be the best. A similar compound is also prepared from diethyl-aniline, and is known as brilliant green. It is a beautifully crystalline body. It is rather curious that this produces shades of colour somewhat yellower than the green from dimethyl-aniline, whereas, being of a higher molecular weight, we should have expected it to be bluer.

The principal difficulty which had to be contended with in the production of these colouring matters was the need of a supply of benzaldehyde. The usual

\* In my original patent it was shown that colouring matters could be obtained, not only from aniline, but also from toluidine, xyline and cumidine—these bases, as usually prepared at that date from the hydrocarbons obtained by fractioning coal-tar naphtha, not being pure, but mixtures.

method of obtaining it from bitter almonds, which was the only one in use, was quite out of the question, so that other sources had to be looked for. The Badische Anilin- und Soda-Fabrik, however, successfully overcame this difficulty. At first they experimented with the process of Lauth and Grimaux, which consists in the oxidation of benzyl-chloride, with an aqueous solution of lead nitrate; the product made by this process, however, was too dear. But they found that the decomposition of benzylidene-dichloride, by means of water, as observed by Cahours (*Ann. Chem. Suppl.* 2, 306) and Limpricht (*Ann. Chem.* 139, 316) gave them a means of producing this compound practically, the reaction being as follows:—

This process, which they have successfully employed since March, 1878, consists in the preparation of benzylidene dichloride from pure toluene, and in the subsequent treatment of this chlorinated body with milk of lime, at 100° C.

I have stated that the group of colouring matters under consideration are called triphenylmethane derivatives, and to show how this has been proved to be the case, I must now refer very briefly to some of the theoretical work which has led to this knowledge. The most important of this refers to rosaniline. I have already drawn attention to the work of Hofmann, which gave us the first knowledge of the composition of this colouring matter, and the further information that it contained hydrogen, which could be displaced by phenyl and alcohol radicals; but as to the matter of constitution, I think the experiments of Caro and Wanklyn were the first, as they showed the relation which existed between rosaniline and aurin, or rosolic acid, and, in fact, they produced rosolic acid from rosaniline; but it is to the beautiful researches of Emil and Otto Fischer that we are indebted for a clear knowledge of the constitution of this class of colouring matter.

But to clear the ground before proceeding further, I must remind you that ordinary commercial rosaniline, or magenta, prepared from aniline and toluidines, is a mixture of colouring matters. This was first known by Mr. Nicholson, who found that for the production of the finest blues it was necessary to purify the base and separate one of these before phenylating; but it is only of later years that the difference between these bodies has been carefully studied and explained. The base examined by Hofmann contained  $\text{C}_{20}$ , and is the chief constituent of commercial rosaniline. The other contains  $\text{C}_{19}$ , and is now called pararosaniline, because it is produced from aniline and paratoluidine. Similarly, in commercial aurin, two compounds are found, one containing  $\text{C}_{20}$ , now called rosolic acid, and one containing  $\text{C}_{19}$ , now called aurin; and these latter can be produced from the corresponding rosanilines; and Dale and Schorlemmer have also shown that aurin can be also converted into pararosaniline, by the action of ammonia (*J. Chem. Soc.* xxxii. 121).

Emil and Otto Fischer, however, by submitting the leuco compound of commercial rosaniline to the diazo reaction, obtained the hydrocarbon  $\text{C}_{26}\text{H}_{18}$ , and from rosaniline prepared from paratoluidine and aniline the hydrocarbon  $\text{C}_{19}\text{H}_{16}$ .

And this latter hydrocarbon was found to be identical with Kekule's triphenylmethane—

On nitrating this hydrocarbon, they obtained a

trinitro derivative, which, when reduced, gave the tri-amido body,

which is paraleucaniline, and by carefully heating its hydrochloride to 150–160°, it was converted into pararosaniline.

Also they found that by oxidising trinitrotriphenylmethane they obtained trinitrotriphenylcarbinol, and this when reduced gave pararosaniline direct.

From these results the constitution of the base is evidently—

The salts—the hydrochloride, for example—being

Similar results were obtained from the hydrocarbon from rosaniline; it is tolyldiphenylmethane:—

The rosolic acid and aurin corresponding to the rosanilines are constituted in an analogous manner:—

From these results we see the beautiful relationships of the various colouring matters of this series to each other, and by it obtain information which is of practical value, as well as theoretical. The following formulae of a few of these products further illustrate this:—

Hofmann, I worked with it for some time, but my results were never published, because, owing to the erroneous formula given for it by Dumas and Laurent, which was accepted, my results would not fit in; nevertheless the information obtained afterwards proved of great value to me, although at the time the labour spent appeared to be lost labour, showing the value of research even when not successful. The formula of this hydrocarbon was not established until 1862, when it was studied by Dr. Anderson. This was only six years before the discovery of Graebe and Liebermann, and, had not the formula of anthracene been established before these chemists commenced their work, the relationship of alizarin to it would not have been discovered, and up to this day it is possible that this artificial alizarin industry would not have been in existence. Researches like that of Dr. Anderson I have often heard spoken of slightly, because they don't bear much on their surface; but who knows what such work may lead to? Earnest workers cannot be too much encouraged.

As anthracene was not a commercial product, it was necessary to experiment on its production before alizarin could be manufactured, and not only on the best methods of getting it, but also to get a rough idea of how much could be produced, because unless the hydrocarbon could be obtained in large quantities, artificial alizarin could not compete with madder. In our works at Greenford Green we commenced by distilling pitch; but afterwards tar distillers were induced to try to separate it from the last runnings of their stills by cooling and then filtering off the crystalline products which separated out, and in fact visits were paid to most of the tar distillers of the United Kingdom, others being corresponded with on the subject, and the result was that in a short time such quantities came in that the distillation of pitch was abandoned. And although much doubt and anxiety prevailed at first as to the possibility of getting a sufficient supply of this raw material two or three years since, there were about 1000 tons of commercial anthracene (about 30 per cent.) produced in excess of the requirements, the annual production in the United Kingdom being estimated at about 6000 tons 30 per cent., or nearly 2000 tons pure anthracene.

Although the colouring matter obtained from anthraquinone or dichloranthracene was at first simply considered as alizarin more or less pure, yet on investigating the matter it was soon found that it contained other colouring matter. To this I drew attention in 1870 (*J. Chem. Soc.* xxiii. 143, footnote), and in 1872 gave the analysis of a product which I named anthrapurpurin, followed by a more extended account a year afterwards (*J. Chem. Soc.* xxv. 659, and xxvi. 425). This was called anthrapurpurin; because it is an anthracene derivative having the formula of purpurin, with which it is isomeric. In the latter paper I also referred to another colouring matter dyeing alumina mordants of an orange colour (*J. Chem. Soc.* xxvi. 423). It was also shown that anthrafluoric acid when fused with alkali gave a colouring matter behaving with mordants in the same way (*J. Chem. Soc.* xxvi. 20), and this has proved to be the same body. This latter reaction was afterwards more fully studied by Schunck and Roemer, and the colouring matter produced by it was shown also to have the formula of purpurin; they therefore called it flavopurpurin (*Ber. ix.* 678), so that the colouring matters formed have proved to be three in number—alizarin, anthrapurpurin, and flavopurpurin, all of which are valuable dyes, whereas in madder root there is only alizarin and purpurin, the latter being of but secondary value. This can now also be

produced from anthracene. The researches which have been made on the subject of the conditions under which these different colouring matters are formed, have led to the discovery of methods for their separate production, so that in artificial alizarin, which name commercially embraces all these colouring matters, both mixed and separate, we have more than a simple replacer of madder root, and as these colouring matters just referred to can be applied with the same mordants, varieties of styles of work can be produced by the calico printer and dyer which before were unknown. Anthrapurpurin is, I believe, of as great importance as alizarin itself, and used with it increases its brilliancy, and alone gives very brilliant scarlet shades.

Artificial alizarin was first produced commercially in this country by my firm at Greenford Green in 1869, when 1 ton was produced; in 1870, 40 tons were made, in 1871, 220 tons, and so on increasingly. It was not produced on the Continent until 1871, when, according to Graebe and Liebermann, 125-150 tons were made. These weights do not apply to dry colour, but to paste.

I cannot go into any lengthened account of the chemistry of this industry here; its development, however, has kept pace with theoretical investigations, in some cases it may be said to have forestalled it. For example, in the old methods of working, more anthrapurpurin than alizarin was produced; the conditions required to modify this were found out by experiment. According to all our previous knowledge as to the introduction of hydroxyl into a body by the fusion of its sulphonic acid with alkali, a monosulphonic acid should give a monohydroxyl compound, and a disulphonic acid a dihydroxyl compound. Therefore to produce alizarin, which is a dihydroxyl compound, an anthraquinone disulphonic acid was thought to be the proper thing to use. By experience this was gradually found to be incorrect, a monosulphonic acid being required to produce alizarin, a disulphonic giving anthra or flavopurpurin, the colouring matter not being due to the primary but to a secondary reaction, as was afterwards shown by research—the mono and dioxanthraquinones (the latter known as anthraflavic and isanthraflavic acids) being the first products of the reaction, and then undergoing oxidation by the caustic alkali employed, yielding the corresponding colouring matter, a portion of the products, however, being at the same time reduced back to anthraquinone.

A very important improvement preventing this loss by reduction was discovered by J. J. Koch, who found it might be avoided by the use of a small quantity of potassium chlorate with the alkali used in the fusion.

The amount of caustic soda used in this industry is very large, and at the Badische Anilin- und Soda-Fabrik,—and, I believe, elsewhere—it is made on the spot; and I must say the cleanly way in which alkali is made in the above works contrasts very favourably with what I have seen in some of the alkali works in this country.

Like rosaniline, alizarin has now become a material for preparing other colouring matters. Of these there are two in use—viz., nitroalizarin, which gives orange-yellow shades with alumina mordants, and alizarin blue, a remarkable compound prepared from nitroalizarin by treating it with sulphuric acid and glycerol. This gives shades of colour like indigo. When first discovered, considerable difficulty was found in its application on account of its insolubility; it has since been found to form a soluble compound with sodium bisulphite, and by this means its application has become much easier. The constitution of

the colouring matter derived from anthracene may be represented as follows :—

Those colouring matters under the name of artificial alizarin are the most important of the coal-tar colours, their money value amounting to more than a third of the entire value of all the colours produced in this industry, and at present the price of artificial alizarin compared tinctorially is not more than one-fourth of that which madder or garancine ordinarily were before their production. There are now three works producing it in this country, but the bulk of that used still comes from Germany.

#### Phthalines.

The discovery of this class of bodies dates back to 1871, and was the result of the investigation of Baeyer. He found that phenols unite with a number of polybasic acids and with aldehydes, with separation of water when the mixture is heated alone, or with glycerol and sulphuric acid, the compounds formed not being ethers. Those produced when phthalic anhydride is employed, and which embrace those of practical value, are called phthalines. The first of these discovered by Baeyer was *gallein* (Ber. iv. 457), produced by heating pyrogallol with phthalic anhydride; its formula is  $\text{C}_{20}\text{H}_{11}\text{O}_5$ ; by reduction it loses the elements of water and combines with hydrogen forming *cevadine*. These colouring matters, which for a long time remained unnoticed, are now being extensively used.

Later, in 1871, Baeyer discovered *resophthalin*, or *fluorescein* (Ber. iv. 555). This substance, which is remarkable for its yellowish green fluorescence, dyes silk and wool yellow, but does not combine with mordants, and is not a very useful dyeing agent. But it was discovered by Caro in 1874, the subject being afterwards worked out jointly with Baeyer, that fluorescein when brominated yielded that beautiful dyestuff now called *eosine*; this was introduced into the market in July, 1874. Other substitution products were then studied, and the iodine product was found to give bluer shades of red than the bromine. One of the most beautiful colours of this series is the dichlorotetraiodofluorescein, in the preparation of which dichlorophthalic anhydride is used. It is called *phloxine*. The methylic ether of eosine

and its nitro derivative also have become commercial articles. These bodies are now manufactured in a practically pure condition. Their structure has been made out by research to be as follows :—

Eosine. Tetrabromofluorescein (Potassium Salt).

Tetraiodofluorescein (Potassium Salt).

Phloxine. Dichlorotetraiodofluorescein (Potassium Salt).

The introduction of these colouring matters had a great influence on the manufacture of phthalic acid. This acid, it will be remembered, was proposed a good many years since as a source for the production of benzoic acid, which was largely in demand for the manufacture of aniline blues, phthalic acid when carefully treated with lime yielding calcium benzoic. But as phthalic acid was required to be produced in an extensive way, new experiments had to be made on the subject. The difficulties connected with this were surmounted by the Badische Anilin- und Soda-Fabrik, who are now the chief manufacturers of this body and its anhydride, which is the substance required; when freshly prepared it is one of the most beautiful products one can see.

Dichlorophthalic acid is now also manufactured for the preparation of the bluish shades of fluorescein derivatives already referred to. But this is not all; it was not only necessary to produce this anhydride in quantity, but it was necessary also to produce *resorcinol*. This substance was originally prepared from galbanum by fusing it with potash, or by distilling brazilin, etc., both technically impractical processes. It was afterwards produced by fusing various halogen derivatives of phenol and benzene sulphonic acid with alkali; these also were not practical processes. It was, however, eventually found that it could be produced by fusing metabenzendisulphonic acid with potash, the original observation being made by Gallein; and by this process this product, which was a rare compound, is now manufactured and has become a common one, being produced in very large quantities.

#### Indigo Series.

Indigo is too well known a substance for me to make any remarks in reference to its history as a colouring matter, and with reference to the chemical side of the question I suppose few substances have

had more work bestowed upon them than this body, so that I must confine any few remarks to its artificial formation. There is one point of interest, however, connected with indigo, and that is that it was the original source of aniline, this base being discovered in the products of its destructive distillation by Unverdorben, in 1826, as already mentioned.

Notwithstanding the large amount of work which has been bestowed upon this colouring matter, its constitution has only been lately arrived at, and for this, and the methods of its artificial formation, we are indebted to the beautiful and laborious researches of Baeyer. The first process for its artificial production was patented by Baeyer in March, 1880. The process consists in preparing orthonitropropionic acid and acting upon it in presence of an alkali, with a reducing agent, such as grape sugar, xanthate of sodium, etc.

This process renders the application of artificial alizarin very easy to calico printing, because the products can be applied to the fabric and the reaction then completed, and thus the indigo is formed and fixed in the fibre, and this process is in use in some of the printworks of Mulhouse, where there is a continued though small demand for orthonitropropionic acid. Other processes have been discovered by Baeyer for the formation of indigo; he has found that it can easily be formed from orthonitrobenzaldehyde by condensation with bodies containing  $CH_3CO$  group, such as acetone.

Hitherto this artificial formation of indigo has not met with much practical success. This does not arise from difficulties in its manufacture, but in its cost compared with natural indigo, which is a very cheap dyestuff.

So far as it has been manufactured, however, the possibility of this has been entirely dependent upon scientific research disconnected with its study. To prepare nitropropionic acid it is necessary to begin with cinnamic acid as a raw material. This acid, until 1877, was only obtained from certain balsams, and was a very costly material. It was then discovered that it could be produced with comparative ease by the action of acetic anhydride and an acetate on benzaldehyde (*Journ. Chem. Soc.* xxxi. 428). Caro afterwards found that this process might be simplified by heating a mixture of benzylidene dichloride with sodium acetate, and it is by this process that it is now prepared.

The constitution of indigo Baeyer represents as follows:—

Several derivatives have been made which are interesting dyes, such as methyl indigo, tetrachlor indigo, etc.

#### Azo Compounds.

The commencement of the history of the azo colours in an industrial sense has little to do with the theoretical side of the question, the early products being the offspring of empirical observations, and in no way connected with the theory of the azo compounds, a condition of things very different from that now existing. Time will not allow me to enter into the beautiful work of Griess, much of which will be found in the "Philosophical Transactions" for 1864.

The first definite compound of this class, shown to possess dyeing powers, was a substance discovered by Prof. Church and myself, known first as nitrosophthalene, then as azodinaphthylamine, but now called amidoazonaphthalene. This substance, how-

ever, was of no practical value, because its salts, which are violet, cannot exist except in the presence of a certain amount of free acid. This substance has since been found of value in the preparation of the Magdala Red.

The first substance of this class sent into the market was the phenylic analogue of amidoazonaphthalene—viz., amidoazobenzene, which was discovered by Mène. It was introduced by Nicholson, who prepared it by a process which has not been published. It was afterwards patented by Dale and Caro, in 1863. This is a yellow dye, but did not demand success, because of its volatility. It has, however, since become useful for the manufacture of induline.

The first really successful azo colour was Manchester or Bismarck brown (tri-amidoazobenzene), which is produced by the action of nitrous acid on metadiamido-benzene.

The next important step took place in 1876, by the discovery of chrysoidine, by Caro and Witt. Independently, this product is prepared by the action of diazobenzene on metadiamido-benzene.

About this time the subject began to be worked out on a scientific basis, and since then the number of diazo dyes produced is marvellous, and it will be useless for me to do more than to refer to one or two of the most important. About this period also the value of the sulpho group began to be realised, and this has greatly added to the value of these dyes.

The first use of the sulpho group in relation to azo colours was in connection with amidoazonaphthalene, patented by myself in 1863.

During the early history of the coal-tar colours, innumerable experiments were made with naphthalene derivatives to produce colouring matters, but no results of any value were obtained; the experiments were mostly made with naphthylamine. The first colouring matter that was obtained from it that was of value was Martins' yellow a dinitronaphthol. After this came the Magdala red, which was not much used. The principal development of the coal-tar colours of late years has, however, been in connection with diazo reaction. In these reactions naphthol is much used, and this product, which a few years ago was unknown, is now manufactured by tons by fusing naphthalene sulphonic acid with alkali, and is produced at a few pence per pound. Most of the azo colours produced from benzene derivatives are of a yellow or brown colour, but, by taken products of a higher molecular weight, colours of different shades of red are produced. The one which has commanded the greatest success is the scarlet, first known as Meister's scarlet, produced by the action of diazoxylene chloride on the disulphonic acid of  $\beta$ -naphthol; its constitution may be represented thus:—

And in the formation of bluer shades, diazocumene chloride is used. The cumidine used is now made from xylidene, by the beautiful reaction of Hofmann's, in which an alcohol radical associated with the nitrogen leaves that element, and enters into the hydrocarbon radical. These scarlets have had a very injurious influence on the cochineal market, and have in many cases displaced cochineal.

If  $\alpha$ -diazonaphthalene chloride be used instead of the xylene or cumene compounds, the colours known as Bordeaux is produced. Then, again, where derivatives of  $\alpha$ -naphthol are used, different results are also obtained, so that great varieties of products can be produced. The preparation of these azo colours is a matter of much simplicity, the colouring matter being precipitated in bringing the products together, and, moreover, they can be produced in almost theoretical quantities; hence they are remarkably

cheap dyeing agents. The following are the formulæ of some of these azo dyes:—

From which it will be seen that the colour changes from yellow to red and claret by the increase of the molecular weight of the radicals introduced, and also by the relative position occupied by the groups, etc.

#### Quinoline Compounds.

Products of the quinoline series have of late been claiming attention in relation to colouring matters. It will perhaps be remembered that, in the early days of the coal-tar colour industry, a beautiful blue colour belonging to this series, discovered by Greville Williams (*Chem. News*, Oct. 11, 1860, 219), was introduced. This substance was called cyanine. Its employment as a dye for silk at first produced quite a sensation, on account of the beauty of the colour; but unfortunately it was too fugitive to be of any practical value. Recent researches have shown that chrysianiline is also to be regarded as a body of the quinoline class. Alizarin blue, and also the beautiful yellow dye obtained from acetanilide by Fischer, and known as flavanilin, are found also to belong to this class of substances.

Other colouring matters which have since been prepared from quinoline direct might be referred to did time permit. The peculiar green which is produced by the condensation of tetramethyldiphenylketone with quinoline is of interest, because the introduction of this quinoline has a very different influence on the resulting colouring matter to that of groups containing amidogen—in fact, it appears to act more like phenyl, as the green is very analogous to benzaldehyde green.

There is a very interesting new manufacture growing out of the coal-tar colour industry, and that is, the preparation of derivatives of quinoline as substitutes for quinine. I have mentioned that much work has of late been directed to the study of quinine itself, and although the artificial formation of this substance has not yet been discovered, new bodies have been obtained during these investigations which are thought to possess valuable medical properties. This is rather a remarkable development from this industry, seeing that it was owing to experiments made on the artificial formation of quinine that it owes its foundation.

There is another peculiar colouring matter I have not yet referred to—peculiar, as it contains sulphur. I refer to methylene blue, a very valuable dye, the constitution of which has been so well worked out by Berthel. I feel I must be content with this slight reference to it.

As I have shown, the coal-tar colour industry originated in this country, where for some time it was solely carried on. The second impulse was from France in the discovery of magenta and its blue and purple phenyl derivatives, which were soon brought

to a state of great purity in this country. The Hofmann violets were then discovered and produced also in this country, several other colours being perfected and largely used. By this time the manufacture of coal-tar colouring matter had made some progress in Germany and Switzerland; crude products in a cheap form were first made, but improvements soon followed. The subject of these colouring matters was taken up with great earnestness in the German laboratories so much so that it was stated at one time that this industry was acting injuriously to science, as it had diverted an undue amount of attention from other subjects. Time has, however, proved the groundlessness of this statement. This laboratory work, as well as research work generally, fitted a number of highly-trained chemists to enter the colour works, where they soon improved the processes, and thus they were able to produce products of a quality to compete with those of English manufacture, which had, owing to their purity, given superior and more reliable shades of colour in the hands of the dyer; and the result of the application of this scientific labour to this industry is that Germany produces products of the highest class and at the lowest price. The fact that Germany is now the head-quarters of this industry, raises the important question, Why has England allowed this state of things to come about? All the raw materials are produced in this country, both the products from coal and the other chemicals required, and, as we have seen, the industry originated and was first carried on here, and, in addition, we are the greatest consumers of the colouring matters. This fact is well worth considering, and it is many-sided. In my opinion, the Patent Laws, and the difficulty of preventing infringements from abroad, was one cause which may have prevented this country from maintaining its first position.

When speaking of the early history of the first coal-tar colour mauveine, I referred to this class of infringement and how it was first met by the proceedings taken against the agents employed in this country, and that this course was so far successful, but only pointed out how easily the law could be evaded if foreign manufacturers gave up responsible agents and sold direct to the consumers. Having no duties on such articles, no assistance could be obtained at the Customs, and the colouring matters were generally declared under the name of vegetable dyes or extracts, so that it was impossible to stop them entering the country, and even when found, owing to the onus of proof of their being manufactured by the patentee's process laying with the patentee, an almost insurmountable difficulty was raised, as in most cases no traces of the products used in the preparation were left in the colouring matter. The only other proceedings which could be instituted were against the consumer; here again the difficulties were practically insuperable.

In most cases the consumers were using the patentee's products to some extent, and it was impossible to know to what extent, in fact, without going into the many details connected with this point, it may be assumed that in most cases proceeding against a consumer of this kind of article is detrimental and practically useless.

The result of this infringement, by importation from abroad, is that a patentee had to compete against all other manufacturers with the exception of his own countrymen.

There can be but little doubt that this state of things has had much to do with preventing the development of this industry, and crippling enterprise in this country, as it prevented manufacturers even from working under royalties, there being no security whatever except in name. Again, the fact that a

foreigner could take a patent in this country, manufacture in his own country, and send the product here, was a great source of loss and mischief to our trade. The new patent laws may probably alter this, but still the difficulty of importation in defiance of patent rights still remains.

There is another matter which tells much against this country—namely, that we are not able to export colour to foreign countries upon the same conditions as foreign manufacturers can into this, because we are met with import duties which handicap us to a prohibitive extent, whereas the foreign manufacturer, being protected in his own country, may maintain his prices there and sell at a lower price in this country; but what is still more injurious, he may dispose of surplus production in this country at or even below cost price. The injurious effect of such a course upon our market can be easily understood by business men, and I need not go into it here. These are matters our manufacturers have to contend with, and cannot help themselves; there is, however, one matter in which they are undoubtedly at fault.

We find that in Germany the manufacturer understands the value of well-trained chemists, and sympathises with them; they also realise the value of theoretical chemistry—this is a condition of things we don't find in this country.

Unless I am mistaken, the coal-tar colour industry has acted as the great stimulus to the development of general chemical industries of Germany, and these, by starting with so much scientific aid as they have called to their assistance, have made an amount of progress during the last 25 years which is most remarkable. Up to that time England had been the seat of most of the large chemical industries, and the success which we have had appears to me to have produced a feeling of false security, and more attention has been paid by the heads of firms to the markets than to the chemistry of their manufactures.

I believe that 30 years ago there were very few chemists employed in chemical works, either in this country or on the Continent. Now there are very few without them; but in this country they are far less numerous and much less efficient than in Germany, and for this our manufacturers are to a great extent responsible. I am told that at some of our large chemical centres, the chemists, or so-called chemists, are sometimes paid not more than could be earned by a bricklayer. If such openings are put by manufacturers before young men, their parents are not likely to give them an expensive scientific training. If they get any they are not likely to continue it longer than enough to do analysis very imperfectly, say by studying for about nine months. An ordinary tradesman would not be considered efficient unless he passed a much larger apprenticeship than this, but I know teachers complain that it is difficult to get students who are to be works chemists to stay longer than this. The result is that when really efficient men are wanted, they are not to be found, and they have to be got from abroad. In my address to the Chemical Society last year, I referred to the past neglect of research at our chemical schools, so that I need not speak further on that aspect of the subject here, though it is an important one in relation to our industries.

There is no chasm, as we have already seen, between pure and applied chemistry, they do not even stand side by side, but are linked together, so that a technical chemist needs to be a thorough chemist, and unless we employ such men we must be at a great disadvantage in relation to foreign manufacturers.

This brings me to a subject which has occupied much attention of late, but I fear is much misunderstood by the public generally. I refer to the teaching

required by technical men, or technical education. The general idea is that it should be carried out in what may be called its narrow sense. That is to say, that it should be in relation to the existing manufactures and the present methods employed in them. Whereas there can be no doubt it will be of small service unless it is carried out on a very broad and scientific basis. As it is, the processes which are *publicly* known and taught, are more or less antiquated, simply because improvements are naturally kept secret as long as possible, and therefore to spend a large amount of time in studying details of old processes would manifestly be a great waste of power, and I am glad to find that this view of the matter is held by some of our leading chemical manufacturers. Our chemical industries are now undergoing such rapid and radical changes, owing to the advances in scientific discovery, that this cannot be too much borne in mind. To train a young man as a technical chemist, I consider, requires first that he should have a thorough knowledge of chemical science and know how to use it by conducting research, that he should have a general knowledge of those sciences which are connected with it, such as physics, and of those subjects required by all manufacturers, such as engineering mechanics, etc., and also study the way chemical operations are carried out on the large scale, not in one branch of manufacture only, but in many.

With men in our works so trained, and of course possessing the suitable natural qualifications, we might expect to see our chemical industries make good progress and keep well to the front, but such a course of study could not be gone through in twelve months, nor would men so qualified be content to receive the remuneration for their services which is now given.

The proposed course for technical chemists at the Central Institute of the City and Guilds of London Institute is to occupy three years; the students having already devoted one year to elementary chemistry, this makes four years of study, and this is hardly sufficient. It is to be hoped that those who are to be principals, or to take responsible positions in works, will avail themselves of the opportunities afforded by this Institute or get some similar course elsewhere, so that we may have efficient men in this country to advance our chemical industries, and also that the value of such chemists may be appreciated in this country.

The employment of well-trained chemists in Germany, and the division of labour which results from this, has no doubt been one of the chief causes of the great success not only in the colour, but in other chemical industries. In this country it not unfrequently happens that an inventor, or the head of a firm, feels that no one can do the work he is connected with like himself, which is probably quite true, but at the same time he forgets that one person is not able to attend to the details of a number of processes adequately from sheer want of time and strength; if, however, properly qualified men can be set over them, although they may be slower and less capable than himself, yet having less divided minds and more time they are able to work out the details under his direction with much more success than he could alone, as well as see things from other points of view, and thus greater perfection will be attained. I think this is a matter deserving of careful attention on the part of our manufacturers.

I have now given a very brief, and therefore a very imperfect outline of the history of the coal-tar colour industry, an industry to which none other can be compared for its rapid progress. I have drawn your attention to the fact that it is the offspring of scientific research, that in return, as I before stated, it has

in many cases given a fresh impulse to research by giving the chemist new products, and also by opening up new subjects of theoretical interest for consideration, and from the fruits thus resulting again reaping further benefit. This linking together of industrial and theoretical chemistry has undoubtedly been the great cause of its wonderful development. We now have not only all the colours of the rainbow, but we have also the more sombre, but often not less useful, colours, and, moreover, there are also great varieties of products of similar colour possessing different properties which fit them for special uses. This industry is also one of no mean dimensions. I have not been able to get any very recent statistical information on this subject, but notwithstanding the great reduction of prices of the products of late years, yet owing to the extended development it has undergone, the value of the annual output has probably increased and not declined, and from what information I have on the subject I should say it is perhaps not less than £3,500,000.

In my remarks I have also been led to refer to some of the points connected with the migration of this industry from this country to Germany, and the probable influence our patent laws had upon this, to the matter of technical education, and the employment of high-class chemists in chemical works. This latter subject is undoubtedly of great importance, and requires the earnest consideration of our manufacturers. If it is found profitable to employ chemists of this class on the Continent, surely it should be found equally profitable to employ them here. In conclusion, I am happy to say there are signs of the coal-tar colour industry returning to our country, in part at any rate, especially in relation to alizarin, for which there are now three large works in existence, and the production of other colouring matters is also increasing.

Mr. J. C. STEVENSON, M.P., in proposing a vote of thanks, said that they were fortunate in having a president who had all along been identified with the very important industry, the progress of which had just been described. Having himself given his attention to the more simple department of inorganic chemistry, he admitted his incompetence to fully appreciate, much less criticise, the amount of research thus laid bare, but at any rate he could admire the facility with which the president manipulated the complex formulæ of the substances described. Nothing could more clearly illustrate, on the one hand, chemical science in its marvellous interconnection with chemical industry and, on the other hand, the important position which in the future these new industries must take in their Society. Coal tar, once adjudged little better than a refuse and only fit for daubing palings, now appeared as the source of a host of beautiful colours—colours so bright as to shock that modern æstheticism which demanded to be clothed in the hues of faded leaves. But even these were doubtless well within the powers of their president to produce. At Avignon there was a monument to the man who benefited his countrymen by the introduction of the madder root as a staple industry in the Department. What a memento was this monument of a vanished industry displaced by the process which the President had described. At the same time, they must remember that chemistry was not as yet independent of organic materials for these colours—the product of the vegetable life of the primeval forests. Whether chemistry would ever make coke and water into sugar was problematical, but at all events, up to the present, it had only succeeded in extracting and developing from organic bodies principles already existent in those bodies.

He was glad to note that these modern chemical industries were still in some sort dependent on their older brethren for reagents, and that they still required caustic soda and hydrochloric acid. On these older industries the remarks of the president had a bearing, though in them there might not be so much scope for science as there was in the special branch chosen by the president; nevertheless, he was free to confess that in the past too much reliance had been placed on our natural advantages of cheap fuel and machinery, and too little upon science. Manufactories might be more orderly, and the British workman had yet to learn the value of tidiness. He moved that a hearty vote of thanks be given to the President for his most able address.

Mr. E. K. MESSPRATT, in seconding the motion, was glad to hear Dr. Perkin state that the removal of the aniline industries to Germany was due, in his opinion, to two causes—(1) The effect of our patent law, and (2) the want of technical education in this country. He himself mainly ascribed it to the second cause, but in a somewhat wider sense; and so far as patents were concerned, the evils arose not from any defect in the law of patents, but from the absence of a uniform and international patent law. Technical schools were of undoubted value, but if children were not well educated in primary and intermediate schools they would never grow up to be successful competitors with the Germans. Long before technical schools were established the German universities afforded scientific education in abundance, and one of the reasons why they had been so successful in applying science to their industries was that many of them were educated as purely scientific chemists. We ought not to lose sight of this fact, but should train our rising generation to think and investigate for themselves, thus becoming efficient chemists rather than mere testing machines.

Mr. WALTER WELDON, F.R.S., asked Mr. Stevenson to somewhat enlarge the scope of his motion so as to convey to Dr. Perkin a vote of thanks not only for his address but also for his great services as President. During the past session some ten or twelve council meetings and twenty or thirty committee meetings had been held, and Dr. Perkin had attended all those meetings, and had given the most careful attention to every item of business which had come before them. In fact he had torn himself away from his beloved research to attend to the business of the Society as devotedly as a merchant in the City attends to the business by which he gains his livelihood.

Mr. STEVENSON then put the motion in the amended form, which was carried unanimously.

The PRESIDENT then briefly replied.

The scrutineers then presented their report on the results of the voting for ordinary members of Council, as follows:—

The scrutineers reported that they examined 205 ballot lists, of which five were invalid. The result of their examination of the valid votes given shows that the following have been elected ordinary members of Council:—

R. Forbes Carpenter.  
Henry Doulton.  
Dr. John Evans, F.R.S.  
Ivan Lewinstein.  
Dr. R. Messel.  
B. E. K. Newlands.  
Thos. Royle.

Dr. S. A. Sadler.  
Sir Bernhardt Samuelson,  
Bart., M.P.  
Sir Charles Tennant, Bart.,  
M.P.  
Prof. W. A. Tilden, F.R.S.  
John Williams.

(Signed) J. ROBBINS,  
GEO. WARD.

The PRESIDENT declared the above duly elected, together with the following:—

*President:* Mr. E. K. Muspratt.

*Vice-Presidents:*

Sir F. A. Abel, C.B., D.C.L.,  
F.R.S.  
Sir J. Louthian Bell, Bart.,  
F.R.S.  
Alexander M. Chanee,  
Prof. James Dewar, F.R.S.  
James Duncan.

David Gamble.  
Dr. Peter Griess, F.R.S.  
Dr. W. H. Perkin, F.R.S.  
John Spiller.  
E. C. Stanford.  
J. C. Stevenson, M.P.  
Walter Veldon, F.R.S.

*Treasurer:* E. Rider Cook.

*Foreign Secretary:* Ludwig Mond.

Mr. DAVID HOWARD proposed the reappointment of Messrs. Theobald Brothers as auditors, saying the complexity of the accounts was so great that it was desirable that professional auditors should be appointed.

Mr. WILLIAM CROWDER seconded the motion, which was carried unanimously.

#### NEXT PLACE OF MEETING.

Mr. MUSPRATT proposed that the next Annual Meeting be held at Liverpool, which he might describe, with Widnes, as being the birthplace of the Society. On behalf of the Section, he could assure the members that they would have a cordial welcome.

Dr. HEWITT seconded the motion, which was carried unanimously.

Mr. MUSPRATT then took the chair.

Mr. F. SIEMENS' paper was then read.

#### ON HEATING REGENERATIVE GAS FURNACES BY RADIATION FROM FLAME, AND ON PRODUCERS TO SUPPLY GAS SPECIALLY SUITABLE FOR THAT PURPOSE, AND FOR THE RECOVERY OF BYE-PRODUCTS.

BY MR. FREDERICK SIEMENS.

IN tracing the action within a flame from the moment the gases unite until the heat has been fully abstracted from the products of combustion, the flame will be found to pass through various successive periods materially differing from one another; of these there are two which require quite different development and treatment. The first is the period of active combustion, the essentially chemical process by which the heat is produced. The second period is after combustion has been completed, when the products of combustion alone have to be dealt with, which still contain a great portion of the heat produced during the first period. The conditions of the flame during these two periods are so entirely different, that it is quite reasonable that they should be separately and differently treated, and should not be considered as one, as has been hitherto invariably the case. Whilst chemical action is proceeding, the flame ought to be allowed clear space within which to burn; it should not be interfered with by surfaces of any kind, and it should be allowed freely to emit its radiant heat; whereas the products of combustion having very little power of radiation, and not injuring surfaces upon which they impinge, should be brought into contact with the surfaces to be heated, for the purpose of abstracting their remaining heat.

As is well known, combustion is interrupted when flame meets solid surfaces, whilst the solid surfaces themselves also suffer—not so much from the heat as from the mechanical action of the flame; to explain these circumstances various theories have been proposed, as well as to account for the fact that flame has great power of radiation in its first stage and little in its second. It is agreed in all these theories that the gases in combustion forming the flame are intensely excited, and that the molecules of gas are rotating around one another, or are otherwise in

violent agitation. According to the electrical theory, which is the one accepted by the author, a flame consists of small but innumerable lightning flashes, and it is at once evident that when a solid body is brought into such a flame it obstructs the action of the flame by arresting the motion of the particles of gas which strike on it, as well as by its attraction and adhesion; the molecules of the gas being resisted in their motion, combustion cannot continue, at least in those parts nearest to the opposing surfaces. As a result, smoke is produced, enveloping the obstructing surfaces; and radiation cannot act because of its inability to penetrate the cloud of smoke in which the flame is enveloped. Then, as regards the action of the flame on any surface, it is quite natural to expect that if flame is composed of innumerable flashes of lightning, no surface or body exposed to it can long withstand its action. The flame in its first stage being composed of innumerable lightning explosions, and carrying free carbon, accounts also for its radiant power. In the second stage of the flame, as no chemical action is going on, and there is no free carbon to emit heat by its incandescence, the carbon being converted into invisible  $\text{CO}_2$ , it is quite natural that there should be little radiant action.

A flame radiates much better than a solid body. The reason of this is that each particle of carbon raised to incandescence within the flame acts as a centre of radiation, and emits its light and heat in every direction, whilst a solid body simply radiates from its surface. Thus, in the flat-flame burner the edge radiates out nearly as much light as the face, and would radiate out quite as much, only that owing to its narrowness some of the incandescent carbon particles come in the way of the light radiating from those behind them; whilst the Argand burner serves as an illustration of a hollow flame, the light radiating outwards, not only from the outer surface, but from the inner surface through the flame itself, and heat and light obey the same law in this respect. If the area of a flame is doubled, it radiates four times as much as originally; whilst a solid body, if doubled in area, radiates only twice as much as before. A volume of flame applied for heating by radiation cannot therefore be made too large from an economical point of view, because the radiation from a body of flame increases, not according to its outer surface, but in proportion to its volume.

From a careful consideration of the various circumstances thus set forth, connected with the production and action of flame, the author has designed a furnace, now well known as the radiation furnace, a short description of which in some of its applications will be given later on.

In order to employ radiation in the most profitable manner, a gas, rich in hydrocarbons, should be used, for the production of which special forms of gas producers may be adopted with advantage. Of these there are two so far employed. One of these was described by the late Sir William Siemens in his paper, "On the Use of Coal-gas as a Fuel," read before this Society on the 29th June, 1881. A diagram (Fig. 1) of this producer is placed before the meeting, and it may be shortly described as consisting of a cylindrical chamber truncated towards the bottom, which is filled with coal through a large hopper at the top; this chamber is formed of an iron casing A, covered on the interior with a lining of refractory material B, and in this lining passages C are arranged all round for the exit of the gases. A large opening at the bottom admits of the withdrawal of ashes and clinkers that may be found in the combustion of the fuel, and a blast of air—which by preference should be heated—is directed into the very heart of the mass of fuel.

The result is a very high temperature in the centre of the mass, one of the essential conditions for the total conversion of coal into combustible gas being a maximum degree of heat at one portion of the process, and no heat is lost at that point, which loss would

Fig. 2 is a section of the modified gas producer arranged for this purpose, with the addition of the curtain wall A, which comes down to the level of the fuel at B, or may extend a little below it, dividing the gas producer into two compartments so as nearly

FIG. 1.

interfere with the due conversion of carbonic acid into carbonic oxide. At the same time, water, which is admitted by a continual streamlet near the bottom, is evaporated by the residual heat of the fire and clinkers which is thus utilised, and currents of steam are directed or drawn into the apparatus, passing through the zone of highest temperature towards the centre of the mass. They there become converted by contact with the incandescent fuel into carbonic oxide, and hydrogen (free from nitrogen), which add greatly to the calorific effect of the gas produced.

The modified form of Siemens' old-type producer, which is also employed for the purpose of enriching the gases by transforming the heavy hydrocarbons, that would otherwise form tar on condensation, is described in a paper read by the author's principal assistant, Mr. Head, before the Iron and Steel Institute, in May last, and published in the *Journal of the Institute*, Part I of the volume for 1885. The gas producer is divided into two compartments, one of which receives the hydrocarbons—the volatile constituents of the coal,—and the other the carbonic oxide formed by the decomposition of its solid carbonaceous matter. The proposed separation may be conveniently carried out by means of a curtain wall placed over the fuel, and by providing for the hydrocarbon constituents a separate outlet from the chamber thus formed,

to separate the zone B, where carbonic oxide is mostly

FIG. 2.

produced, from the zone C, where hydrocarbons are

given off. At the bottom is a grating E, open for removal of ash or clinkers, and for admission of air. When increased action is desired, air may also be admitted to the body of the fuel by one or more nozzles F, formed in the brickwork, the supply current to each being maintained by a steam injector G. The nozzle and injector are so situated and directed as to provide against blowing flame or gases down through the grating E.

The hydrocarbon gases which collect in the chamber C, are led away by channels J, which heat the hydrocarbon products from the zone C, and direct them on to the incandescent fuel in the zone B, whereby they are further heated and converted into permanent gases. The curtain wall A need not absolutely separate the chambers B and C from each other, for if a small proportion of the volatile gases should leak into the carbonic oxide compartment, as in doing so they would come into contact with incandescent fuel, the desired effect would thus be ensured.

That gases may be enriched by converting the hydrocarbons into permanent gases, was determined for the late Sir William Siemens in the following manner. A certain quantity of gas was collected in a graduated receiver from one of the Siemens old-type gas producers; this gas was taken immediately above the fire through one of the stoking holes, and was found, on cooling to atmospheric temperature, to be reduced in bulk from 120cc. to about 85cc., the

two open-hearth steel-melting furnaces, the result was a saving amounting to 28½ per cent. in weight of coal in favour of the latter, the same quality of coal being used in each case, and the furnaces being erected to the same plans, and doing the same work. Recently a block of four gas producers of the Siemens old-type have been altered by the addition of a curtain wall provided with channels J as above described, in which similar results have been obtained. By making the curtain wall A solid, instead of with channels J, as shown in the diagram, the two chambers B and C will be divided from each other so that the hydrocarbons liberated from the fuel may be led away by a pipe D for treatment for ammonia and tar, while the gases resulting from its complete decomposition will be led away separately to the furnace.

In some works it may be found convenient, after treatment of the hydrocarbon gases for tar and ammonia, to utilise some of them for illuminating purposes. Owing to the inferior description of fuel usually employed in gas producers, as compared with that used at gasworks, the illuminating power of the hydrocarbon gases may not be found equal to the standard of the gas supplied by gasworks; but larger or additional burners can be used, and by this means manufacturers may almost entirely save their gas bills. Taking each burner as consuming 7 cubic feet per hour, even a hundred such burners, lighted for

FIG. 3.

apparatus being at the same time much coated with tar. The receiver having been cleansed with spirits of wine and washed with water, another sample of gas from the same producer was taken, with this difference, that on its way to the receiver it was passed through a combustion tube, which was heated by a spirit lamp. The same volume being collected as before, the weight of gas taken would be somewhat less than on the previous occasion, and had the gas on cooling to atmospheric temperature been reduced to the same bulk as previously without deposit of tar, the result would have been considered satisfactory; but a better result was obtained, for the loss in bulk was only about 20cc., the receiver being comparatively free from tar. It is to be regretted that time would not allow of analyses of the gas obtained under these conditions to be made, but gas made from Staffordshire coal, in the Siemens old-type gas producer, has been found to contain less than 35 per cent. of combustible elements when working at its best; whereas, gas made from the same coal in one of the Siemens modified gas producers, described above, where the desired conditions for conversion of tar into permanent gases are present, has been found to contain 48 per cent. of combustible elements.

At a works where the Siemens old-type and new-type gas producers were tested comparatively upon

twelve hours each day, would not consume all the hydrocarbons liberated from a ton of coal. Moreover, the quality of the illuminating gas could be improved by adding a little cannel coal to the fuel charged in the gas producers, or in some of them, during the time that the gas is required to be used for illuminating purposes, and this will afford an alternative method to the employment of larger burners, or a greater number of smaller ones.

The gases not required for illuminating purposes should be returned to the main gas flue supplying the furnaces. Indeed, it is not desirable to use gases consisting mainly of carbonic oxide and nitrogen in regenerative gas furnaces, where the new method of heating by radiation is adopted, for which, as has been explained, gases rich in hydrocarbons are better.

In designing the regenerative gas furnace, in which radiant heat is to work to the best advantage, it is necessary that the gas and air ports shall open at some distance below the roof of the heating chamber, and at some distance also from the side walls, so that the inflowing gas and air may have unobstructed space after ignition for entering into combustion, and for the free development of the flame; for the same and other reasons the flame is kept as much as possible out of contact with the material on the furnace bed,

and when these are crucibles, ingots, blooms, or packets of iron, they should be so placed that the radiant heat may play freely upon and about them.

The diagrams give sectional views of the furnace as now constructed for various purposes. A is the roof, B are the working doors, C the bed of the furnace upon which the materials are melted or heated, D and E are one of the pair of regenerators, and D' and E' the other pair, between which should be placed

FIG. 4.

the pockets used for arresting the dust from the waste gases, as shown in Figs. 5 and 6. The gas and air are alternately brought into the heating chamber by the ports F, G and F', G', therein forming the flame which traverses it from end to end, as shown in Figs. 3 and 4, or sweeps round it in a semi-circular or horse-shoe form, as shown in Figs. 5 and 6. Where there are working doors, the flame should pass above

K, so that it shall only commence at the entrance of the gas and air into the furnace chamber, and the combustion may be extended throughout the furnace,

FIG. 6.

the flame in this case taking a semi-circular or horse shoe course.

FIG. 5.

their level; in this way the men will not be inconvenienced while watching operations inside the furnace; but, as already mentioned, the main object to be secured is to avoid contact of the flame with the materials under treatment, or with the walls of the furnace.

As shown in Figs. 3 and 4, which represent an open-hearth steel-melting furnace, the air inlet may be arranged above the gas inlet, thus forming two parallel horizontal ports for the delivery of the gas and air in broad streams into the furnace chamber, the inflowing air overlapping the gas. In cases where there is a great length of travel for the flame, such as represented in Figs. 5 and 6, the ignition is retarded by extending the horizontal wall, or tongue

This new system of applying heat within the modified regenerative gas furnace has now been employed for a sufficiently long period to establish the economy of the method, as well in regard to the fuel used as to the material of which the furnace is constructed, and that treated on its hearth. One of the latest and most interesting applications has been to the open-hearth steel-melting furnace. At the Landore Works, the furnaces which were altered nearly eighteen months ago are still at work—a result entirely unprecedented in this class of furnace, which, as is well known, is worked at the very highest temperatures employed in the arts. But besides the longevity of the furnaces, they are found to work more uniformly, whilst the yield is larger, owing to

there being less oxidation of the metal, as is proved by more ore being used per ton of pig iron, in order to decarburise it to the same extent. The furnaces work much more uniformly, and with great economy as regards consumption of fuel. Various other steel works throughout the country, and several glass works, are now modifying their furnaces so as to obtain the benefits offered by this new method of heating.

Another important application is to forge, mill, and puddling furnaces, as, owing to the absence of contact between the flame and the materials with which the furnace is charged, a great reduction in the loss of metal which has hitherto occurred through oxidation will be effected.

In steel re-heating furnaces, contact of the flame with the ingots produces red-shortness in the metal, exhibiting itself in fissures, particularly at the corners of the ingots or blooms, when these are subjected to treatment either under the hammers or in the rolls. The removal of the injured portions involves a stoppage of the operations, resulting in waste, not only of material but of time also, and occasionally rendering the blooms entirely useless for the purposes intended. In the radiation furnace this cause of loss no longer exists, while there is also a saving due to non-oxidation of the metal.

In iron re-heating furnaces the saving in waste of metal will be much more considerable than in furnaces for the re-heating of steel, owing to the higher temperature at which they are worked, and the metal will weld much more easily, as it is heated out of contact with flame. These furnaces should be made as long and wide as convenient, in order to obtain as much room for the development of the flame as possible, and for placing the ingots, blooms or packets sufficiently far apart to allow the radiant heat to reach them on all sides.

As regards puddling, it might be advantageous to erect a furnace containing a number of pans, which could either be placed in two rows, the men working at each face of the furnace, or the men could work on a semi-circular face by constructing the furnace of a horse-shoe form. The side of each pan should be separated from the next by a partition containing air in circulation, or by a water channel.

In the same manner, a furnace heated by radiation from flame may be constructed of such size and productive capacity, that it may serve for heating all the metal for a mill or forge, or, at any rate, two or three such furnaces should suffice for the output of several hundred tons of metal per day, the only consideration being the convenient location of the furnaces with regard to the position of the mills and hammers.

In heating furnaces constructed and worked, as hitherto, by contact of flame with the metal to be heated, the furnaces must necessarily be made as small as possible; for the flame under such conditions parts with its useful heat in a run of a few feet, after which the sooner it leaves the furnace the better. But when heating by radiation is adopted the conditions will be quite changed, for the flame not being brought into contact with surrounding objects (including the metal to be heated), will be kept at a uniform temperature throughout its course, radiating all the time the maximum heat required for the charge in the furnace; and when combustion has ceased, the hot gases will be deprived of their remaining heat through contact in the regenerators. It will perhaps be difficult for those accustomed to heat metal by contact with flame, to realise the possibility of effecting the same object better, more quickly and more efficiently by means of radiation; but to overcome the difficulty it is only necessary to associate heating by radiation exclusively with the

regenerative gas furnace, in which both air and gas are raised to a high temperature before combustion, as without such initial heating a flame of high temperature, and one therefore capable of radiating intense heat, could not be obtained.

Bearing in mind that contact of flame with the metal to be heated is avoided, there is no reason why a heating furnace should not hold at the same time piles, blooms, or ingots in various stages of heating, from cold metal to metal which is ready for the hammers or mills. Each individual bloom, pile, or ingot will, under such conditions, take up from the heat radiated by the flame, only the amount which it is susceptible of receiving without interfering with its neighbour; but the blooms, piles or ingots must be placed sufficiently far apart to allow the radiant heat to reach them from all sides. In such an application it would be advisable to arrange the blooms or packets in the furnace, so as to form gradations of heated metal, in order that a cold bloom or packet, on being introduced into the furnace, may not be placed next that which is hottest at the time.

The new method of heating by radiation from flame, thus offers the solution to an objection which has sometimes been made against the regenerative gas furnace on the ground of its great cost, which has certainly limited its application for heating furnaces at iron and steel works in this country; but, when a few, or perhaps one furnace only, will be built for a mill, the capital expenditure on furnaces, even with separate boiler settings, should compare favourably with the cost of the old grate furnaces and boilers. Moreover, they will offer the advantages of saving in fuel, in wear and tear, and in metal.

Manufacturers who think that the suggestion which has been made is in advance of the times, and who might doubt the possibility of obtaining a flame of such a considerable length as would be required for a furnace to heat 100 or 200 tons of metal per day, will be pleased to learn that the problem has been already solved by the author in connection with the manufacture of glass. There exist many furnaces of the dimensions now foreshadowed for heating iron and steel, some of which have a run of flame of upwards of 40 feet; and one of them, measuring 42 feet by 16 feet 6 in. inside dimensions, holds 130 tons of glass, is capable of producing 24 tons of glass per day, or at the rate of a ton of glass per hour, the consumption of fuel being about 18 cwt. per ton.

These furnaces hold at the same time freshly charged (cold) batch and refined glass, the charging of batch and the gathering of refined glass being continuously carried on in same chamber.

On the present occasion it is not necessary to refer to details of the glass furnaces constructed respectively on the old and new principles, which the author has erected; but it may be well to state that the advantages of the new system are quite maintained. Thus fewer pot breakages occur, the loss by waste glass continues to diminish, and fewer repairs are required; moreover, a superior quality of glass is produced from a cheaper composition than hitherto employed. The gross results are that the new furnaces last six times as long, and melt more than nine times the quantity of material that they did previously to their reconstruction. The flame being kept away from the working holes, the glass-blowers work more at their ease, turn out a better product, and are able to reheat their glass in the furnace without tarnishing it.

With these advantages, and others of a minor character, a glass-blower is able to produce 50 per cent. more goods without much greater exertion. In another furnace in which lamp glass chimneys are

made, a more refractory material is employed than hitherto, and the glass produced is whiter and of better quality, whilst open instead of closed pots can be used for the production of superior qualities of glass, whereby a great saving in pots and fuel is effected.

Another most important application for the greater extension and improvement of which trials are now being made, is to the heating of boilers by means of gas; but in order to obtain the greatest benefit from this method of firing, it is necessary that there should be use for the gas made in the producers by night as well as by day. If flame is allowed to touch the sides of a boiler there is of necessity smoke produced on its inside surfaces, and the radiant heat of the flame not being able to penetrate such an atmosphere of smoke, the water in the boiler cannot get the advantage of it. It will readily be perceived how great a quenching effect the metal of the boiler has upon a flame, when it is remembered that the temperature of steam—which is, of course, that of the boiler—is only  $311^{\circ}\text{F.}$ , even at 60lb. pressure, whilst that of the gaseous flame in contact with it is about  $2000^{\circ}\text{F.}$  In this application the principle has been followed of allowing the active flame to have free space for its development, and for the radiation of its heat within the length of the tube, and not allowing it to touch the sides until after complete combustion has been effected, when the products of combustion may be brought into direct contact with solid bodies. The way in which this is arranged is shown by the diagram Fig. 7, and by means of the little working model exhibited. The illuminating gas with which this model is supplied is deteriorated by partial combustion before reaching the flame outlet, so

varies from twenty-five to thirty per cent. These results refer to ordinary horizontal flued boilers, to which only this method of heating has been so far applied; but a vertical boiler is being constructed by the author specially designed for the application of radiant heat, from which it is expected that even better results will be obtained.

Another valuable application which has been suggested by Professor Armstrong, F.R.S., is to the manufacture of coke in the ordinary beehive oven. A furnace for this purpose would be very similar in construction to the glass-melting furnace of horse-shoe form, shown in Figs. 5 and 6, the flame radiating heat of a very intense character upon the coal to be carbonised, the gases being drawn away below the bed of the furnace by means of an exhaust, in the usual manner. In order to prevent the flame being drawn down by the action of the exhaust, small coal (mixed, perhaps, with tar) should be charged on the top of the mass of coal to be carbonised, so that on heat being applied it would bind the upper surface, forming a skin impermeable to the passage of gases. The gases withdrawn from the bottom of the furnace may be led away for the removal of bye-products, and then re-delivered to produce the heat required for carbonisation, and also utilised for other purposes.

There must be several applications of the radiation furnace to the chemical industries, which should offer important advantages. In some cases gas has been used with the sole object of avoiding the introduction of ashes or dust into the furnace; but where contact of the flame is not necessary as regards the chemical operations performed, the utilisation of the heat by radiation first within the heating

FIG. 7.

that it may be taken in that condition as not better than producer gas. If the flame was allowed to play along the tube in the ordinary way, it would very soon strike against the upper surface, producing smoke and soot, but by the arrangement of deflector rings inserted in the tube, the gas is not allowed to touch the surface of the tube until after complete combustion has been effected; and it will be noticed that by this means the flame has no discolouring effect on the tube. By this arrangement perfect combustion is produced, and there is no smoke. But besides this, a boiler fired in this manner lasts longer, because the flame being out of contact with the plates, these are not worn away so readily, boilers being more rapidly destroyed through direct contact with the flame than from almost any other cause. As the remaining heat of the products of combustion come into direct contact with the sides or flues of the boiler and its regenerators, it is completely utilised, and the maximum of heating effect is thus ensured.

Thus, in various applications that have been made, a saving in fuel has been effected which

chamber, and by contact afterwards with extended surfaces, will be a great step in advance of the mere application of gaseous fuel. It is hoped, therefore, that this paper will prove of interest to the members of this Society, and that it will lead to an interesting discussion.

On the motion of Mr. MUSPRATT, seconded by Mr. CROWDER, a vote of thanks was unanimously accorded to Mr. Siemens for his paper, and it was resolved to defer discussion upon it until the paper had appeared in the Society's Journal.

On the motion of Mr. TYRER, seconded by Mr. CROWDER, a vote of thanks to the authorities of the City and Guilds Institute for the use of their rooms was carried by acclamation, and the proceedings terminated.

#### THE ANNUAL DINNER.

The annual dinner of the members of the Society of Chemical Industry was held in the Freemason's Tavern, Great Queen Street, on Tuesday evening.

About 130 members and friends were present. The chair was occupied by the President (Dr. W. H. Perkin, F.R.S.), who was supported by Sir F. A. Abel, Mr. E. K. Muspratt (the President-elect), Sir J. McGarel Hogg, Mr. Walter Weldon, Professors Hugo Müller and Odling, Mr. David Howard, Mr. Ludwig Mond, Mr. E. Rider Cook, Professors Armstrong, Tilden, Meldola and others.

The first toast proposed was the usual loyal one. Mr. E. Rider Cook then proposed "The Houses of Parliament," responded to by Sir J. MacGarel Hogg, M.P. (Chairman of the Metropolitan Board of Works). "The Learned Societies" was the next toast, proposed by Mr. Ludwig Mond, and acknowledged by Dr. Hugo Müller, F.R.S. (President of the Chemical Society), and Dr. W. Odling, F.R.S. (President of the Institute of Chemistry). "The Society of Chemical Industry," was now proposed by Mr. Walter Weldon, F.R.S., and replied to by Mr. E. K. Muspratt. "The President" was the next toast, proposed by Sir F. A. Abel, C.B., F.R.S., and responded to by Dr. W. H. Perkin, F.R.S. Mr. David Howard then proposed "Our Guests," a toast which was suitably replied to by Dr. Löwenherz. The toasting was finally concluded by the President proposing "The Officers of the Society," which was responded to by Mr. Watson Smith and Mr. Tyrer. Interspersed with the toasts were several vocal and instrumental pieces, ably rendered by Messrs. A. Zimmermann, Max Schrattenholz, and F. J. M. Page.

#### THE EXCURSIONS.

##### MESSRS. ORLANDO JONES & CO.'S STARCH WORKS.

The first visit was on Wednesday morning to the starch works of Messrs. Orlando Jones, of Wandsworth. Divided into four parties, one of which was conducted by the head of the firm, the remainder by various other gentlemen, the company was led over the works, and the details of the manufacture of starch from rice were explained in a most interesting manner. The operation in this extensive and well-conducted factory, which probably excited most attention as being of a chemical nature, is that in which the gluten is dissolved and separated from the ground grain by treatment with dilute caustic soda solution. By a process of deposition and decantation the husk fibre and starch are separated. After working up into white masses the starch is cut into cubical blocks, and dried to a certain extent, when after packing in paper and placing in a drying chamber for three or four weeks, the starch is found with an apparently crystalline appearance, adding greatly to the beauty of the commercial article. The alkaline solution of the dissolved gluten, it is stated, is run off as waste, no use having been found for it. The fibre however is partly used in the moist state for cattle-food, whilst a portion is, after drying, submitted to a special treatment, and is then utilised by paper-makers for giving body to paper. A special product, which consists of a form of "wheaten flour," is prepared in these works. The bran which has been separated from the flour is finely ground and then restored to the latter, and in this lies the peculiarity of the preparation. A saccharine preparation is also manufactured from maize, after cleaning and crushing the grain.

##### MESSRS. JOYNSON & CO.'S PAPER MILLS

at St. Mary Cray were next visited, and here a luncheon was most kindly provided for the visitors. In these noted paper-mills were seen the several processes in their different stages, from the sorting of the rags, and the bleaching, to the manufacturing from

the pulp of the finest brands of paper. Since only assorted rags are used, it is needless to say that only paper of the better and very best classes is made by Messrs. Joynton & Co.

#### THE BECKTON GAS AND CHEMICAL WORKS

were visited on Thursday morning, July 9th. A large party of about 400 were conveyed by the "Glenrosa," the finest boat of the London Steamship Company, from All Hallows Pier to the landing stage of the Beckton Gas Works, where the visitors were received by Mr. Trewby, the principal engineer. In these admirably conducted works the visitors were conveyed from one principal point of interest to the other by rail. The Beckton Gas and Chemical Works form the central station of ten other gas-works, carbonising about 1,500,000 tons of coal annually. It required no great perception, though it did some practical knowledge of the subject, to observe that the latest and best improvements in the arts of gas-making and tar-distilling are employed by this, the first, and we believe still the only, gas-company in the country supplying at once illuminating gas, pure coal-tar products, and dye stuffs. In the gas works, the firing of the retorts with gas was an interesting feature, as also the mechanical and automatic apparatus for charging the coal into the retorts. In the tar distillery was seen to advantage the admirable system of setting the tar-stills referred to in Dr. Lunge's work on Coal-tar, *loc. cit.* pages 97, 98, and 99 (Fig. 4), so that the red-hot cinders never appear outside the stills, but are wheeled away under the same by a subterranean arched passage, thus avoiding possibilities of fire or explosions. An interesting process for moulding naphthalene into corrugated sticks, for enriching illuminating gas by means of the well-known Albo-carbon lamp, was also witnessed in operation. The apparatus used somewhat resembles that by which a certain class of candles is made. The rectification of benzene, toluene, and xylene, is conducted in a well-appointed special department, and the fractionation is performed in a dephlegmating column. Sulphate of ammonia is manufactured in comparatively vast quantity in these works, the sulphuric acid used being prepared on the spot in extensive vitriol chambers. The chambers are supplied with sulphurous acid from pyrites burnt in the ordinary pyrites burners, and from spent oxide saturated with sulphur (from the oxide purifiers) burnt in shell-kilns.

#### THE PUMPING STATION AT CROSSNESS AND DISINFECTANT FACTORY OF THE METROPOLITAN BOARD OF WORKS

was the next point of interest. At this station and factory an experimental process is being carried out for disinfecting London sewage. It was explained to the visitors by Mr. Dibdin, principal chemist to the Metropolitan Board of Works.

Manganate of soda is made, brought into dilute solution, acidified, and the acidified permanganate liquor well agitated with the sewage pumped up by gigantic pumping engines, working, despite the enormous amount of power expended, with wondrous silence. The water is afterwards returned, when disinfected, to the Thames at suitable periods of the tide.

#### THE NEW TILBURY DOCKS,

next visited, were interesting chiefly on account of the enormous scale on which the excavations and works generally are being carried on, as well as on account of the peculiar nature of the strata exposed in course of excavating. Mud deposits and peat bogs

appear to have covered this neighbourhood at one time, and deposited in these now, at a depth of some forty feet below the normal surface, are still abundantly to be found in an excellent state of preservation, trunks and branches of trees, as well as occasionally animal remains. The inspection of these extensive docks by the visitors was greatly assisted by the subdivision of the party into groups, each headed by an engineer, who explained the operations in progress. The weather throughout the day was most propitious, and this event had much to do in making the excursion such an enjoyable one. As the steamer neared All Hallows Pier on the return journey, Mr. J. C. Stevenson, M.P., in a few well-chosen and kindly sentences, proposed a vote of thanks to the Local Secretary of the London Section, Mr. Tyrer, for the most effective way in which he had carried out the numerous and multi-form arrangements necessary in organising such a meeting, and thus contributing so largely to achieve a result so eminently successful. The vote, responded to most heartily, was then acknowledged in a few words by Mr. Tyrer.

#### THE CONVERSAZIONE AND RECEPTION.

On Wednesday, at half-past eight, the presidents of the Chemical Society, the Institute of Chemistry, and the Society of Chemical Industry held a reception in the galleries of the Royal Institute of Painters in Water Colours, Piccadilly, W., where in the course of the evening about 1000 ladies and gentlemen assembled. The conversazione, amid surroundings so charming to the eye as well as to the ear, may be pronounced a brilliant success. An admirably-arranged programme of instrumental and vocal music, under the direction of Miss Adelaide Thomas, was carried out to perfection, with the assistance of Miss Mary Thomas, Miss Riley (violin), Mons. Albert (violinello), Mr. Tapley (vocalist), and Mr. Marshall (accompanist). Conspicuous in this programme was the beautiful trio in D Minor by Mendelssohn for pianoforte, violin and violinello, which was exceedingly well performed by Miss Adelaide Thomas, Miss Lucy Riley, and Mons. Albert.

MEETINGS, Session 1885—First Monday in each month (unless otherwise indicated).

Notices of papers and communications for the meetings to be sent to the Local Secretary.

Meeting held June 1, 1885.

#### NOTE ON PROFESSOR LEONHARD WEBER'S PHOTOMETER.

BY BOVERTON REDWOOD, F.C.S., F.I.C.

This instrument consists essentially of two tubes attached at right angles, in the form of the letter T,

in such a manner that, while one is supported in a horizontal position, the other can be placed horizontally, or at any required angle. At the junction of the two tubes is a reflecting prism, by means of which, in combination with a diaphragm, the field of vision of an observer looking into an eye-piece, which forms one end of the movable tube, is divided vertically into two equal portions. One-half of the field is illuminated by the light passing through the movable tube, and the other half by light passing through the fixed tube. The source of the light passing through the fixed tube is a small lamp burning petroleum spirit. This lamp furnishes the standard light, and a scale is attached to enable the observer to measure accurately the height of the flame. Inside the fixed tube, between the petroleum lamp and the reflecting prism, is a frame, carrying in a vertical position a circular plate of opal glass, and travelling along the tube, from end to end, by means of a rack and pinion. At one end of the movable tube (the other end being furnished, as described, with an eye-piece) is a holder, in which a rectangular plate of opal glass (or, if desired, two or more of such plates) is placed. The petroleum spirit lamp having been lighted, and the flame adjusted to the height of two centimeters, the light to be measured is placed at a convenient distance

from the rectangular glass plate (usually 1 meter), and the eye of the observer being applied to the eye-piece, the travelling opal glass plate is moved by means of the milled head of the pinion until the two halves of the field of view are equally illuminated. The position of the travelling opal glass plate is then read off on the graduated scale attached to the fixed tube, and the illuminating power calculated by means of the table of values supplied with the apparatus. It is obvious that the travelling opal glass plate, being illuminated by the petroleum lamp, becomes itself, to some extent, a source of light; and the amount of illumination of one-half of the field, therefore, depends partly upon the proximity of this plate. If it is found that the light to be measured is so powerful that the standard side of the field is not equally brightly lighted, even when the travelling plate is brought as closely as possible to the reflecting prism, at the junction of the two tubes, the light may, of course, be removed to a greater distance, or a second opal glass plate may be inserted in the holder. Under ordinary circumstances both tubes of the photometer are in the same horizontal plane; but if it is desired to measure the illuminating power of angular rays, the movable tube, which is fitted with an arc divided into degrees, may be placed at any desired angle. The apparatus is also applicable to the measurement of diffused light.

The formula for calculating the illuminating power (B) of a flame from the readings obtained with the instrument, is:  $B = k \cdot C \cdot \frac{R^2}{r^2} (a + bl)$  normal (standard) candles.

In this formula the factor  $k=1$  for such lights as are of the same colour as the standard light,  $C$  is the constant of the rectangular opal glass plate,  $R$  is the distance of the centre of the light to be tested from the rectangular plate, and  $r$  the distance of the standard light from the circular travelling opal plate,  $a$  and  $b$  are constants relating to the standard light, and  $l$  the length of the flame of the standard light,  $a$  and  $b$  have the respective values of  $-0.88$  and  $+0.94$ , and are so calculated that when  $l=2$  (the normal height of the flame being 2cc.)  $a + bl = 1$ . Accordingly, when the height of the standard flame is maintained at 2cm., the expression  $(a + bl)$  may be omitted from the formula. Moreover, when the standard flame is maintained between 1.9 and 2.1cm., the expression  $(a + bl)$  may still be omitted, and the result corrected by subtracting or adding as much per cent. as  $l$  is tenth millimeters longer or shorter than 2cc. With each apparatus the values of the opal plates are furnished; but in the printed description of the apparatus Professor Weber describes how these values may be experimentally verified.

The photometer is remarkably portable and compact (it packs into a box 2 1/2 in. by 1 1/2 in. by 6 in.), and it requires for its use no specially prepared dark room.

The principle of bringing the light passing through two tubes into a divided field of vision for comparison, has long been adopted in the construction of chromometers for liquids; but the writer believes that the credit of applying it for the measurement of light belongs to Professor Weber.

The writer is not in a position to express any confident opinion as to the merits of the instrument; but he hopes at a future date to give the results of his experience in its use. Opinions, however, frequently differ so widely in regard to photometric appliances that the experience of an individual appears to be of comparatively small value, and the writer's object in making this brief communication is to direct attention to Professor Weber's invention, in the hope that others engaged in photometric work may be induced to give the apparatus a trial. In the meantime the writer may mention that he saw the instrument in use in the laboratory of the Normal Aichlungs Kommission, in Berlin, and was informed that the results obtained with it compared very favourably with those furnished by the ordinary photometer.

#### DISCUSSION.

Messrs. F. W. HARTLEY, W. DIEBEN, and Dr. P. F. FRANKLAND criticised the details of construction of Professor Weber's photometer, and specially complained that operators were left with arbitrary standards, even more than in the older forms of photometer.

Mr. REDWOOD pointed out that he had claimed nothing as yet for the instrument; but he should feel it incumbent upon him to give the benefit of his investigations in a future communication.

#### ON THE SOLUBILITY OF NITRIC OXIDE IN SULPHURIC ACID.

BY G. LUNGE.

IN some recent communications to the Chemical Society I have mentioned the analytical operation

performed by means of the "nitrometer," described by myself sometime ago. Mr. A. H. Allen has lately described a number of new and highly interesting applications of this apparatus.\* In this paper he has mentioned a few circumstances which he considers as drawbacks, to be avoided by special means. One of these is the formation of a persistent mercurial froth, which delays the reading. Allen mentions a way of avoiding this delay, but I do not think it even desirable to do so, as a certain time should elapse after shaking the apparatus, both to give time for the temperature of the gas to be equalised with that of the surrounding air, and for allowing all the acid to run down from the sides of the measuring tube. The froth sometimes observed at the top of the acid, which is far more troublesome, is easily avoided by a sparing use of grease in the glass tap, and when employing vaseline-I have never been troubled at all with such froth.

It seems a more serious objection that Allen believes sulphuric acid to have a notable solvent power for nitric oxide; hence he recommends the acid to be diluted below that point where this solvent action becomes appreciable, in the proportion of three measures of strong acid to two of water. Allen bases this upon experiments made at his request by Mr. T. Bailey, according to which, in the case of acid of sp. gr. 1.62, the extra gas obtained after further diluting was fully 0.5cc. With stronger acid this source of error is said to become even more serious.

If Bailey's experiment were to be trusted, even the dilution recommended by Allen would not be sufficient, for strong oil of vitriol at 1.84, diluted with two-thirds its volume of water, yields acid of 1.62, at which strength Bailey asserts it to retain still 0.5cc. of gas. If this were correct, one could only wonder that thousands of tests had been made without noticing so grave an error. But this is not the case; the following shows that Bailey's result can only be accounted for by an experimental error, perhaps just in consequence of taking the reading with too little delay.

C. Winkler and J. Kolb have tested the solvent power of strong sulphuric acid for nitric oxide. Both of them found it not appreciable, the acid not having any action upon potassium permanganate, after  $\text{NO}$ , free from air, had been passed through for a long time. These experiments had to be repeated in order to discover any slight action overlooked by Winkler and Kolb. First of all I operated by shaking up from time to time from 6 to 12cc. of sulphuric acid with pure nitric oxide in the nitrometer, reading the volume of gas, diluting with from 4 to 10cc. of water, shaking again, allowing to cool down, adjusting the levels properly and reading again. This was repeated a good many times with new quantities of acid. The increase of the volume of gas on diluting the acid amounted to 0.05 up to at most 0.15cc.; the larger amount was found when diluting more strongly, and was evidently caused by the vapour tension of the dilute acid. The real increase of volume is only 0.05 or at most 0.10cc.—a magnitude to be neglected in most cases, whilst 0.5cc., as stated by Bailey, would cause a gross error. But even the small amount found in the above-mentioned tests probably is not caused by any evolution of  $\text{NO}$ , as will be seen from the following.

I now made a direct test of the solubility of nitric oxide in sulphuric acid. This I did as well by means of my nitrometer, which is most eminently adapted for this purpose, and is altogether in many cases the

*most convenient absorptiometrical apparatus.* A given quantity (from 15-20cc.) of very pure sulphuric acid was introduced into the measuring tube; the air was expelled by raising the level tube; the three-way tap was so placed that the cup communicated with the lateral bore, whereupon the cup was rinsed and dried. Now the tap, still in the same position, was connected with the drying tubes of a gas holder containing nitric oxide, and dry NO was passed through until all air had been expelled from the connecting tubes and the cup. The tap was now turned 180 degrees, so that the lateral bore communicated with the measuring tube; by lowering the level tube a few cc. of NO were drawn in, the tap was closed and the connection with the gas holder severed. The cup was filled with water, in order to remove the NO, the water run off by the lateral bore of the tap, and the cup dried. Now the contents of the nitrometer were thoroughly shaken up from 50 to 100 times, which can be done much more conveniently than with Bunsen's heavy absorptiometer. The level tube was now placed so that the mercury balanced not merely the pressure of the column of acid within the measuring tube, but also the difference between the actual barometrical pressure and 760mm. (Of course it would have been easy to work at a lower or a higher pressure, which is just a special advantage of this apparatus.) After standing some time, the gas was driven out of the measuring tube by raising the level tube and opening the tap, and the latter was sideways connected with a narrow glass tap burette, which allowed reading up to 0.01cc. A current of CO<sub>2</sub> had previously been passed through the burette, and this was continued to the end of the titration, in order to prevent the air from acting upon the NO dissolved in the acid. The acid was now forced over into the burette, and was run from this into a very diluted, but exactly titrated solution of potassium permanganate, until the colour was discharged. Since very slight quantities had to be estimated, only 1cc. of a solution was employed, whose oxidising power was equal to 0.000196grm. O or 0.000245grm. NO; this was diluted and gently heated before running in the acid. Previously it had been found that 1cc. of the permanganate required 28cc. of the acid before treating it with NO; hence for each cc. of strong acid used in titrating, 0.036cc. permanganate had to be deducted.

The observations yielded the following results:—

(a) Concentrated sulphuric acid, of sp. gr. 1.84=96 per cent. H<sub>2</sub>SO<sub>4</sub>, saturated with NO at 18° C. and 760mm. pressure, in two experiments absorbed so much NO that 4.33 resp. 4.22cc. of acid was required to decolourise 1cc. of permanganate; that is a mean of 4.28cc. Deducting from this  $4.2 \times 0.036 = 0.15$ , there remains 4.13cc. acid—i.e., 1cc. acid = 0.242cc. permanganate = 0.000593grm. NO = 0.035cc. NO.

(b) Dilute sulphuric acid, of sp. gr. 1.500=60 per cent. H<sub>2</sub>SO<sub>4</sub>, absorbed so much NO at 18° C. and 760mm. pressure, that in two experiments 1cc. permanganate required 8.42 resp. 8.90, or a mean of 8.66cc. acid. Deducting 0.15, there remains 8.51cc., or 1cc. acid = 0.117cc. permanganate = 0.000287grm. NO = 0.017cc. NO.

Since the acid *a* must be mixed with an equal volume of water to produce the acid *b*, 0.017cc. NO in 1cc. of the acid *b* corresponds to 0.034cc. NO in 1cc. of the acid *a*. In reality the latter had only contained 0.035cc. NO. Hence on diluting acid of 1.84, saturated with NO, with an equal volume of water no nitric oxide at all is set free. Therefore Bailey's observation must be erroneous, and it is not

possible to correct any presumed error in the nitrometer readings by dilution with water. But that error, according to the above experiments, is so slight that it need not be taken into account in any ordinary case.

Mr. Allen's valuable paper has caused me to take up the question of further uses of the nitrometer. I cannot, for most purposes, approve of his plan of substituting strong brine and the like for mercury; and I consider this a distinct and quite uncalculated deterioration of the capabilities of that apparatus, except in a very few cases—for instance, when testing sweet spirit of nitre. Otherwise, I prefer attaching to the side of the three-way cock a light flask, with an inside tube soldered on to its bottom, and connected with the cock by means of a short stout caoutchouc tube, so that it is suspended without any other support. In this I perform the analyses of sodium and potassium carbonate and bicarbonate, of caustic soda or lime (for carbonate), of calcium carbonate, marl, etc., of manganese ore by means of oxalic acid, of oxalic acid or oxalates by means of MnO<sub>2</sub>, of acids, especially acetic acid, by means of carbonates, of the free acid in many metallic salts, and so forth; always employing Dietrich's tables for the solubility of CO<sub>2</sub> in the liquid (Scheibler's co-efficient is altogether wrong). The alkaline bromine solution serves in the same apparatus, not merely for the estimation of urea, but for that of ammonia salts; in both cases taking into account the incompleteness of the reaction, which in the case of urea amounts to 9 per cent, in that of ammonia salts to 2½ per cent., of the total quantity. The evolution of equal parts of oxygen from hydrogen peroxide and an acidified solution of potassium permanganate can be utilised not merely for testing the former, but equally so for the latter, by employing an excess of H<sub>2</sub>O<sub>2</sub>; and I find this a perfectly correct way of standardising permanganate solutions, without the aid of balance, or weights, or substances of known composition. Moreover, I find that bleaching powder and manganese ore can be equally well estimated by means of H<sub>2</sub>O<sub>2</sub>, and H<sub>2</sub>O<sub>2</sub> by the former, the evolution of oxygen following precisely the same law as with KMnO<sub>4</sub>. I have made a great many experiments on all these points, and I find that the nitrometer can be generally employed for all analytical operations in which is evolved a definite quantity of a gas, not soluble to a very considerable extent in the liquid from which it has been evolved, and not acting upon mercury. By a contrary reaction I employ the nitrometer for estimating indigotin in reduced solutions of indigo, by means of the absorption of oxygen. The same apparatus serves very well for measuring and analysing the gases dissolved in water or other liquids. I also utilise the nitrometer as a general apparatus for gas analysis, but in a totally different way from that employed by Mr. Allen—viz., in some cases by acting upon the gases within the measuring tube itself, in others by attaching to its tap Hempel's absorbing pipettes. To all these purposes my nitrometer is adapted by the three-way cock, which is wanting in those other pieces of apparatus whose authors have adopted the name brought forward by me. That cock can be replaced by a plain one when employing the nitrometer as an apparatus for reducing volumes of gases to normal conditions of temperature and pressure, by confining it in a certain volume of air which occupies exactly 100ccm. at 0° and 760mm. All this and several other matters have been described in more detail in the June number of the *Chemische Industrie*, and in the English translation of Clemens Winkler's "Manual of Technical Gas Analyses," now in the press.

ERRATUM.—In Mr. FAWCITT's paper on "Wood Naphtha," printed in the May issue of this Journal, the following error occurs:—In the 6th line of the small table of the Constituents of Wood Naphtha in column 1, page 320, "Di-methyl Acetate" appears instead of "Di-methyl Acetal."

## Communication.

### ON DR. CLARK'S PROCESS FOR THE ESTIMATION OF SULPHUR IN PYRITES.

BY G. LUNGE.

In the *Journal of the Society of Chemical Industry*, May, 1885, p. 329, Dr. Clark describes a new dry process for estimating sulphur in pyrites, which, according to Mr. Tatlock's expectation, is destined to revolutionise the analyses of pyrites. Dr. Clark thinks his process called for, since the ordinary wet process involves certain errors which do not exactly counterbalance each other; but he admits that the wet process, if properly carried out, yields very constant results, and this is indeed best proved by his own experiments as quoted p. 330. His own method generally yields results about  $\frac{1}{4}$  per cent. higher than those of the wet process. I shall not stop to inquire whether Dr. Clark's method is really preferable to the dry methods previously known, especially that of Fresenius. But it is strange that in mentioning the various papers published on the estimation of pyrites by Fresenius and myself, Dr. Clark should have omitted to notice *why* I had objected to Dr. Fresenius' method. My reason for rejecting *any* dry process for the estimation of sulphur in pyrites is that in this way we estimate also the sulphur of galena (which is nearly always present) and of the sulphates of barium and calcium, none of which are of the least use to the consumers of pyrites, whilst in the wet process nearly the whole of that useless sulphur is left behind in the insoluble residue. I should therefore, on behalf of the buyers, strongly deprecate the introduction of Dr. Clark's or any other dry process as the ordinary trade analysis of pyrites, or even the optional use of it by commercial analysts. In this case I cannot agree with Mr. Tatlock that chemists have nothing to do with these matters, their sole concern being to render methods of analysis as perfect as possible. It is a delusion to speak of a more complete estimation of sulphur in pyrites, as something fair and just. Pyrites consumers do not want to buy galena or heavy spar, they want to buy *pyrites*; the chemists who regulate the price to pay for a special parcel for their analysis are not supposed to perform

a scientific operation, irrespective of all other considerations, as they would have to do when working for theoretical purposes, but it is their duty to employ such methods that the results indicate *what the article in question is worth*. This value is entirely depending upon the sulphur of the pyrites itself, and if the chemist in his certificate returns the total sulphur, including that of galena, heavy spar, etc., he actually deceives the buyer as to the value of the ore in question.

Before my process of testing pyrites was generally adopted between buyers and sellers in Germany, there were constant disputes owing to the discrepancies between the returns of different chemists; since that time I am informed that there are hardly any disputes of that kind. Fresenius himself has tacitly given up his opposition to my process; and Dr. Clark's process would be as objectionable in the above respect as that of Fresenius. It is not likely that in future pyrites consumers will quietly submit to paying for an additional half per cent. of sulphur which is of no use to them, and I do not doubt that the attempt to "revolutionise" the analyses of pyrites in this way will fall to the ground.

## Journal and Patent Literature.

### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

*Improvements in Refrigerating Machines for the Production of Clear, Transparent Ice.* Dingl. Polyt. J. 256, 69.

THE "Gesellschaft für Linde's Eismaschinen," Wiesbaden (Ger. Pat. 26,981, July 10, 1883).—A series of lance-shaped paddles is suspended in the freezing tank, which, working by means of a mechanical arrangement, keep the water in motion. The speed of the circulation, through the peculiar construction of the apparatus, decreases in the divisions of the tank with the fall in the temperature of the water. O. Kropf, Norlhausen (Ger. Pat. 28,230, February 16, 1884), recommends for the same purpose the employment of a suction and pressure pump. A. Schwirkus, Berlin (Ger. Pat. 30,051, March 18, 1884), adds lime, and frees the water from gases by means of an air-pump, previous to freezing it.

—F. M.

*Improvements in the Manufacture of Ice and Apparatus therefor.* H. H. Lake, London. Eng. Pat. 9651, July 1, 1884.

The invention refers to improvements in that class of ice-making machines in which cold is produced by vapourising water by means of a vacuum maintained through the rapid removal of vapour as formed, the chief object of the invention being the construction of an improved machine for the production of a block of ice by that method and for its removal when formed. In carrying this out in one way, the inventor uses an inclined cylindrical vessel provided with a piston upon an axis or shaft, which piston on rotating over the mouth of a basin filled to the brim with water, covers one-half of its lower surface with a thin film of water, the other half of its surface being exposed to the refrigerating influence of a vacuum. As the piston revolves it exposes to the cold a continued film of water, and thus gradually increases the thickness of the coat of ice on its lower surface, provision being made for the piston to yield by sliding along of or with its shaft to make room for the increasing thickness of the ice. Upon completion of the block, the upper part of the inclined vessel, together with the piston and its axis holding the block, are removed, and on the admission of steam through the shaft and into the hollow piston, the block is released and slides off. Other arrangements with horizontal and

vertical cylindrical vessels, and including various methods of producing the film of water, are described, and special provision is made in every modification of the apparatus with the view to preventing the exposure to evaporation of any portion of the water used, excepting that which constitutes the film for congelation. By this means the inventor calculates upon maintaining a constant supply of fresh liquid surface for freezing. Sulphuric acid may be employed in aid of the absorption of the vapour abstracted from the vessel, or cold air may be blown into the vessel for the purpose of freezing the film of water, instead of making use of the principle of evaporation in vacuo. The specification is illustrated with fifteen sheets of drawings.—B.

## II.—FUEL, GAS, AND LIGHT.

*The Heat of Combustion of Ronchamp Coal.* M. Scheurer-Kestner. *Bull. Soc. Chim.* Oct. 5, 1883.

This is an account of an experiment undertaken by the author to verify some results obtained by himself and M. Meunier-Dollfus fifteen years ago, which have been disputed by MM. Bunte and Stohmann. The calorimeter used was a Favre-Silbermann, just as in the original experiment. Below are shown the composition of the coal (ashes being deducted), and the results obtained compared with those obtained for samples of nearly similar composition in 1869:—

	No. 1 Sample, 1869.	No. 2 Sample, 1869.	Present Sample, 1881.
Carbon.....	89.96 ...	88.38 ...	89.00
Hydrogen .....	5.09 ...	4.42 ...	5.09
Nitrogen .....	1.28 ...	1.20 ...	1.30
Oxygen and Sulphur	3.67 ...	6.00 ...	4.52

—A. R. D.

*Improved Means for Generating Steam by Chemical Agents.* Amended Specification. H. H. Lake, London. From H. Grünberg and E. Harat, both of Cologne. Eng. Pat. 4295, March 3, 1884.

In the original specification it was proposed to employ the heat developed by the combination of lime or concentrated sulphuric acid with water for the generation of steam. The amendment consists in the omission of sulphuric acid, leaving caustic lime as the sole agent.

—A. R. D.

*Improvements in Apparatus to be employed in the Manufacture of Candles.* L. J. Pirie. Per Carpmæl & Co. Eng. Pat. 12,954, Sept. 29, 1884.

In moulding candles with conical fluted ends, rings are employed to mould these ends. The purpose of the apparatus described is to free the thick ends of the candles from these rings, and it is applicable to the ordinary candle-moulding machines in use in England. It consists essentially of a subsidiary frame with rails, upon which the candles are laid horizontally, after being pushed out of the moulds in the ordinary way; one of these rails is movable, and works a set of plungers, forcing the candles out of the rings, while the rings are themselves retained in their place by another rail.

—W. L. C.

*Improvements relating to the Manufacture of Coke, and to Ovens therefor.* H. H. Lake, London. From Messrs. Wirth & Co., Frankfurt-on-the-Main (Agents of Franz Brucke, Mannheim). Eng. Pat. 8453, February 27, 1885.

ACCORDING to this invention, the retorts are of enphased section, and the side walls thereof are as nearly vertical as possible. This prevents the formation of injurious cracks in the coke cake, and allows the walls

to be very thin, but nevertheless strong. To increase their stability, the partition walls and the heating flues between the retorts rest upon the arch of the heating channel or furnace below. Wherever possible, the coal in the retorts is compressed when filled, and a furrow or trough is made in its upper surface to secure a more equable distillation. With a view to enable the coke cake to retain its heat, this trough or furrow is filled with lime, small coke, or the like. Any mechanical device for compressing the coal and making this trough may be used. Small coke powder added to the coal, and well mixed, has the effect of reducing the number of injurious cross-cracks. Coals rich in gas, and also in water, are mixed with tar and pitch, and made into bricks of a pierced or stellate section, so that the moisture may the more readily escape in the coking process. From the retorts the coke is drawn into a train of slaking waggons which pass below the retort doors. Instead of falling direct into these, it tumbles over sloping, pierced surfaces, or grates, which allow the small coke to pass through, and deliver only pieces of the proper size into the wagon.—A. R. D.

*Improvements in the Manufacture of Hydrogen Gas.* A. H. Reed, London. From G. E. Moore, New York. Eng. Pat. 3776, March 24, 1885.

THIS is a process for treating hydrogen and carbon compounds for the oxidation of the carbon to carbonic acid, in which form it may be readily eliminated, leaving pure hydrogen. The hydrogen and carbon compounds, in a suitably divided state (generally as a gas or fine spray), are brought into contact with the oxide or oxides of iron, manganese, copper, tin, lead or zinc, in the presence of a steam jet. The metallic oxides must be raised to the temperature required by the process, and the steam is preferably superheated. During the operation, the oxides are said to be alternately reduced and reoxidised, acting as carriers of oxygen between the steam and the carbon compounds, so that all the carbon present is converted into carbonic acid, and leaves the chamber in which this is effected mixed with the hydrogen originally present and that resulting from the decomposition of the steam. The carbonic acid may be removed by any known method, such as absorption by lime, or by water under pressure, or by solution of alkaline carbonate.—A. R. D.

*Improvements in and Apparatus for obtaining Gas from Hydrocarbons.* J. F. Schnell, John Read, Jas. Warwick and William Derbyshire, Manchester. Eng. Pat. 9532, March 27, 1885.

THIS invention consists in impregnating atmospheric air with a mixture of "benzoline" and ether, or "gasoline." If for heating purposes, the proportions recommended are a gallon of the first to six ounces of the second or third. If the gas is specially required for illumination, one ounce of paraffin should be added. The impregnation takes place in a closed vessel, divided into compartments filled with pumice-stone. This vessel is filled to a certain depth with the hydrocarbon mixture, and the air is caused to pass through the crevices between the blocks of pumice—openings in the partitions directing it in a zig-zag course through the apparatus.

—A. R. D.

*An Improvement in Gas Producers.* Richard Howson Middlesborough. Eng. Pat. 13,467, April 8, 1885.

ACCORDING to this invention, it is proposed to conduct the air blast downwards, instead of upwards, through the mass of fuel in the producer. The advantages are chiefly that it prevents the charring apparatus from getting unduly heated, while the tar and coal-dust issuing from a fresh charge of fuel are carried through a mass of glowing coke, and thereby vapourised. This also prevents the choking up of the flues.—A. R. D.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

*Note with reference to the Methods proposed for Coking Coal and Recovering Volatile Matters.* H. E. Armstrong. Jour. Iron and Steel Institute, 1885.

THE author is of opinion that in coking coal, the mere collection of the volatile matters evolved is not sufficient for a satisfactory solution of the problem at issue, because, even if the operations be always so conducted as to yield coke of good quality, the quantity and character of the volatile products will vary considerably for each particular class of coal, according to the conditions under which coking is effected. The results obtained by Watson Smith in his examination of the tars from the Simon-Carvès and Jameson ovens, and from the Gartsherrie blast furnaces, afford ample proof of this. Although our knowledge of the chemical composition of coals is very imperfect, the author considers it in the highest degree probable that coals, especially those of bituminous character, for the most part consist of very complex compounds, which are not the mere residues of the primeval vegetation preserved to us as coal, but have resulted from the occurrence during the lapse of ages of a variety of complex chemical changes. The compounds present in ordinary "high-temperature" tars, such as are obtained in gas-making, and in the Simon-Carvès tar are not for the most part immediate products of distillation, but are formed from the latter by a variety of secondary chemical changes, which in part are of an analytical, and in part of a synthetical character. On the other hand, tars such as have been obtained from the Jameson ovens and the Scotch blast furnaces are said to more nearly represent the primary products of distillation of coal, and the author regards these as "low-temperature" products. The Simon-Carvès tar is said to closely resemble ordinary coal-tar. The Jameson tars, however, contain large quantities of paraffinoid hydrocarbons, such as occur in shale oil. The Simon-Carvès tar is stated to be equal in value to ordinary coal-tar; and, although reliable information on this point is wanted, the opinion appears to be gaining ground that the Simon-Carvès tar is a satisfactory product, because it resembles coal-tar, whilst the Jameson tar, being unlike coal-tar, is an unsatisfactory product, and contains little that is of immediate value. Hence the Simon-Carvès oven has been strongly advocated as affording a solution of the problem at issue. The author is entirely opposed to this opinion, and considers, moreover, that chemically the method followed in coking coal in the Simon-Carvès oven is irrational as compared with that followed when coking is effected in the beehive oven as modified by Jameson. Coal-tar is a mere by-product of the manufacture of coal-gas, and in its production no attempt is made to secure a product having special qualities; it therefore by no means follows that because a product equal in value to ordinary coal-tar is obtained in coking coal, the best product which it is possible to obtain from the material at disposal has been secured, or that, in obtaining this product, much that is valuable has not been lost. Moreover, coal-tar is what the author terms a "final" product; it cannot well be dealt with in any way so as to improve its quality, whilst the Jameson oil is not a final product, since its quality can be improved. By passing it through red-hot retorts, it may be made to yield a considerable quantity of very rich illuminating gas, and a large proportion of benzene and other valuable products such as are present in ordinary coal-tar. (This Journal, vol. iii., 462.)

The author's objections to the construction of the Simon-Carvès oven are—firstly, because the heat is applied externally, and, therefore, more or less wastefully; and, secondly, because the mass of coal is first heated to redness on its exterior, and all the products of distillation are then necessarily forced to pass through a red-hot carbonaceous shell, thus giving opportunity for the occurrence of a variety of chemical changes which tend to deteriorate the product. His idea of a theoretically-perfect coke-oven is somewhat as follows:—It would consist of an oven resembling the present beehive oven, but with the upper part largely extended so as to form a furnace

chamber of the type recommended by F. Siemens. Heat would be radiated upon the surface of the charge of coal, which would soon become coked, thus forming a protecting layer below which distillation would take place, the products being drawn away as rapidly as possible, and at as low a temperature as possible through the cool bottom of the oven. As slight an excess of air as possible, if any excess, being admitted to the furnace above, the small proportion of products of combustion which penetrated the uppermost layer would carry no oxygen with them. On this account, and because of the large volume of steam and of other gases generated within the mass, and because of the low temperature, the ammonia would probably almost entirely escape destruction. The gas sucked away would be of low quality as an illuminant, and would be available for carbonising, oil and ammonia having been removed from it by efficient scrubbing.

—D. B.

*Recent Results with regard to By-products obtained in Coking Coal in the Simon-Carvès Coke-Ovens.* Watson Smith. Jour. Iron and Steel Institute, 1885.

IN view of the fact that the Bear Park Company has recently started operations with fifty of the Simon-Carvès coke-ovens, with improved recuperating arrangements, and at the same time with a different class of coal to that used by Messrs. Pease (see *Jour. Iron and Steel Institute*, 1884, 2, 509; and this Journal, vol. iii. 505), the author gives an account of the results obtained by this firm in the direction of the recovery of by-products. The temperatures obtained in the Bear Park ovens are, if anything, higher than those at Pease's West, near Darlington. Analyses of the tars obtained at Messrs. Pease's and at the works of the Bear Park Company show that the tar obtained from the ovens employed by the Bear Park Company much more closely resembles normal gas-retort coal-tar than that obtained from the coke-ovens at Pease's West. It is generally richer in benzenes and phenol, and though less rich in naphthalene and anthracene, it is, nevertheless, still a tar very rich in these substances. The author is of opinion that in the English works employing the Simon-Carvès oven, condensation is still imperfect, and the methods for most efficiently recovering tar and ammonia are not much beyond the stage of infancy, so that it is somewhat premature, as yet, to attempt to set bounds to the value of the Simon-Carvès ovens as producers of coal-tar and ammonia. With respect to the employment of very high temperatures in carbonising coal in closed vessels, it is interesting to find that practically the very highest temperatures that can be employed are the best for the production of benzene. The author regards the tar obtained at present in the works of the Bear Park Company as equal to the best Lancashire coal-tars. The proportion of tar obtained on the coal carbonised is also stated to be greater than that obtained elsewhere. One difference from ordinary gas-retort tar is observable even in the Bear Park product—viz., that the carbolic acid is less in amount in this latter tar, about 0.3 per cent. against about 0.5 per cent. as the lowest average from the ordinary gas-retort. The author thinks this less quantity of phenols is due to the fact that the tar vapours in the Simon-Carvès ovens have to pass through a very considerable mass of superincumbent coke at a very high temperature, and the rate of aspiration from the highly-heated atmosphere of the ovens is comparatively and of necessity very slow.

Referring to Schulze's theory, that the primary products of the dry distillation of coal are phenols (this Journal, vol. iv. 335), the author states that if this view be correct, and phenols are primarily formed on the distillation of coal, then with a lower distilling temperature we might expect to obtain tars richest in phenols, and at more elevated temperatures the phenols should diminish and hydrocarbons proportionately increase. This is so in the case of both Pease's and the Bear Park tars, but when a close distillation is carried on at low temperatures, with shales or cannel coal, as in the Scotch paraffin industry, tars are obtained which are rich in paraffin but poor in phenols. This circumstance does not seem at first sight to bear out Schulze's theory, unless it be considered that the points of temperature at which a

maximum yield of phenols is obtained, and that at which they decompose to yield hydrocarbons, lie somewhat near together, and that the temperature employed in the distillations in the paraffin industry are in the main below those necessary to produce aromatic substances, and amongst them phenols.

The author has found the benzenes distilling constantly between 80° and 82°, and prepared from the tar from the Simon-Carvès coke-ovens, to be very rich in thiophen, by comparing the indophenin reaction obtained with such benzenes with the reaction obtained with benzenes of other origin, from which he concludes that a high temperature and exposure to prolonged contact with red-hot coke rather favours than otherwise the production of thiophen. By applying the indophenin reaction to the benzene obtained from light shale naphthas or spirit, no trace of thiophen was found to be present; this experiment would appear to show that the temperature of formation of thiophen lies higher than that necessary for the formation of benzene, and it is possible that a carbonising temperature might be adopted, at which benzenes are produced more or less free from the thiophens.

Since the reading of the author's paper before the Iron and Steel Institute, in Chester, in 1884, Maderspach and Siersch have adapted the Appolt coke-oven for the recovery of by-products. It is proposed to use a similar alternate regenerative heating arrangement to that adopted by Otto in the case of his coke-ovens. The author thinks that, as a whole, ovens with bottom flues, as well as side flues, must work better. The ovens patented by Maderspach and Siersch have side flues only.

—D. B.

*Recent Results and Further Development of the Simon-Carvès Coking Process (Utilisation of By-products).*  
H. Simon. Jour. Iron and Steel Institute, 1885.

AFTER referring to the progress made in the Simon-Carvès coking process during the twelve months which have elapsed since the last summer meeting of the Iron and Steel Institute, the author discusses the working and construction of the ovens. To give the best results these ovens must be driven at a temperature varying as little as possible. Variations of temperature affect the quality of coke and influence the wear and tear of the ovens. It is also of extreme importance to charge and draw the ovens regularly, as this is the only way of obtaining the maximum of good results, not only in quality and quantity of by-products, but also in obtaining these by the least expenditure of intelligent labour and of wages. The author then refers to the utilisation of by-products at the works of the Terrenoire Company, near St. Etienne, where the gas, after having undergone the usual treatment for the recovery of by-products, is, before being burned in the ovens, subjected to a further process for the extraction of benzene and other light hydrocarbons. (See this Journal, iv. [5], page 338.)

—D. B.

*Natural Gas Fuel, and its Application to Manufacturing Purposes.* A. Carnegie. Journ. Iron and Steel Institute, 1885.

THE author gives a detailed account of the four gas producing districts near Pittsburg. At the principal field, that of Murrayville, nine wells have been sunk yielding as much as 30,000,000 cubic feet of gas in 24 hours. The wells of Washington County are less productive than those of the Murrayville district, whilst the Butler gas fields and the wells of the Terrentum district supply a considerable portion of the gas used. The cost of piping is now estimated, at the present extremely low prices, with right of way at £1500 per mile, the cost of drilling being about £1000. The mode of procedure is described in detail in the original paper. The pressure of the gas as it issues from the mouth of the well is about 200 pounds per square inch. At the works where the gas is used, nine miles from the wells, the pressure is 75 pounds per square inch. Eleven lines of pipe convey gas from the various wells to the manufacturing establishments in and around Pittsburg.

5	6.10	22.30	28.70	1.00	41.90	164,161

The author has compared the heating power of natural gas with bituminous coal, and found that 54.4 pounds of coal slightly above the general average of Pittsburg coal are equal in heating power to 1000 cubic feet of gas, so that at a cost of five shillings per ton of coal (2000 pounds) 1000 cubic feet of gas are worth for their heat units 1.632 pence. In comparing this gas with anthracite coal, it was found that 1000 cubic feet of gas are equal to 58.4 pounds of coal. If this coal cost 26 shillings per ton, 1000 cubic feet of natural gas are worth nine and a-half pence for heating power.—D. B.

IV.—COLOURING MATTERS AND DYES.

*Method for the Manufacture of Azo-colours.* Verein Chemischer Fabriken, Mannheim. Ger. Pat. 29,957, February 19, 1884.

Two molecules of a phenol in an alkaline solution are acted upon with one molecule tetrazodityldisulphonic acid. In this manner yellow colouring matters are obtained from phenol, cresol, and xylol. The naphthols and their sulphonic acids yield red colouring matters, of which those derived from  $\beta$ -naphthol are especially beautiful.—F. M.

*Improvements in and relating to the Manufacture of Colouring Matters.* William Robert Lake, Southampton Buildings. From Léo Vignon & Co., Lyons, France. Eng. Pat. 6872, April 26, 1884.

THIS invention relates to the production of azo-colours from  $\alpha$ -naphtholdisulphonic acid, and the diazo compounds of amines or their sulphonic acids. The  $\alpha$ -naphtholdisulphonic acid is prepared by heating  $\alpha$ -naphthol with three times its weight of mono-hydrated sulphuric acid to from 100 to 110° for 8 to 10 hours. A list of the colouring matters produced by the different diazo-compounds is given in the specification; these vary from orange-red to violet-red.—R. M.

*Process for Separating the  $\alpha$ -monosulpho Acid of the  $\beta$  naphthol from certain Admixtures.* Herbert John Hadlan, 67, Strand, Westminster. From the Farben-fabriken vorm. Fr. Bayer & Co., of Elberfeld, Germany. Eng. Pat. 8495, May 31, 1884.

THE object of this invention is to purify the sulphonic acid obtained by rapidly sulphonating  $\beta$ -naphthol at 50–60° from Schäfer's acid, "and another body which is probably also a monosulpho acid of the  $\beta$ -naphthol." The method of separation depends upon the facility with which tetrazodiphenyl and its homologues combine,

first with the "foreign body," then with Schäffer's acid, and lastly with the  $\beta$ -naphthol- $\alpha$ -sulphonic acid. The latter, which is the most valuable product, is required for the crocin scarlet, and by fractional precipitation with tetrazodiphenyl, the "foreign body" and Schäffer's acid are first removed. The advantages claimed for this process are that the by-products which are first precipitated are economically valuable, being valuable claret-red dyes.—R. M.

*Improvements in the Process of Manufacturing Chloro-iodic Bases and Colouring Matters.* Eugen Ostermayer, Württemberg; and Max Dittmar, Königsberg. Eng. Pat. 9252, June 20, 1884.

THE bases of the pyridine and quinoline series, when treated in hydrochloric acid solution with iodochloric hydrochloride, form crystalline compounds. In the case of quinoline the substance has the formula  $C_{10}H_7NCl$ . When the neutral aqueous solution is boiled the compound gives off iodine. The following illustrations of the process are given:—(1) 5 kilos. of iodine are suspended in 20 kilos. of water, and chlorine is introduced till the iodine is dissolved. The solution of  $IClHCl$  is then mixed with a hydrochloric acid solution of 5 kilos. of quinoline, and the orange-yellow precipitate filtered, washed with water till of a bright sulphur yellow, and then pressed. (2) 5 kilos. of  $KI$  are dissolved in 5 kilos. of water, and 25 kilos.  $HCl$  added; 4 kilos. of sodium nitrite are gradually added till a clear solution is formed, when the latter is mixed with 3.5 kilos. of quinoline in hydrochloric acid as before. Instead of quinoline and pyridine, their homologues may be employed (tolquinoline, quinaldine, tolquinoline, etc.), and also the chloromethylates. Examples are given showing the process employed in the case of quinoline-chloromethylate, tetrahydroquinoline-chloromethylate and oxyquinoline-chloromethylate. When these chloriodised bases are heated with aromatic amines (equal molecules of each), red, violet, and blue colouring matters are produced. Thus, with dimethylaniline a blue violet colour is formed. By the addition of benzyl chloride during the reaction the colour obtained is greenish blue.—R. M.

*Improvements in the Production of Colouring Matters suitable for Dyeing and Printing.* John Erskine, Glasgow. From the Farbenfabriken vormals Friedrich Bayer & Co., Elberfeld. Eng. Pat. 9518, June 28, 1884.

THE new colouring matter described in this specification is a secondary azo compound resulting from the combination of diazoxylene-azobenzene-sulphonic acid with  $\beta$ -naphthol- $\alpha$ -sulphonic acid. The formula of the compound is:—

The solution of the diazo-azo compound is mixed with the well-cooled solution of the naphthol sodium salt in the presence of ammonia and the colouring matter salted out.—R. M.

*Improvements in the Manufacture of Dye-wood Extracts, etc.* Harold Rimmer, Liverpool. Eng. Pat. 9570, June 30, 1884.

THE liquors are concentrated by heat nearly to  $10^\circ\text{Tw.}$ , reducing the temperature to  $50$ – $90^\circ\text{C.}$ , and then completing evaporation by the application of air, which is forced through the liquid until the desired strength is attained. For the latter purpose perforated pipes or a rose may be used and supplied by any suitable blowing mechanism or exhauster. "The strength of  $10^\circ\text{Tw.}$  can be obtained without discolouring the liquid, but if a temperature of above  $80^\circ\text{C.}$  or  $90^\circ\text{C.}$  be used for higher concentration, the liquor is liable to be discoloured or 'burnt.'" "By this invention the liquor can be brought to a greater density than can be accomplished by the vacuum process, and the liquor can be concentrated at a higher temperature without the danger of discolouring than by the ordinary open process."—H. A. R.

*Improvements in the Manufacture of Dyes or Colouring Stuffs.* Emil Capitaine, 89, Chancery Lane, Middlesex. From Adolf Ewer and Paul Pick, of Berlin, Germany. Eng. Pat. 9632, July 1, 1884.

THE object of this invention is to prepare colouring matters varying from yellow to brown by acting with cyanic acid and its derivatives upon primary, secondary, or tertiary amines, or tetra-alkylised derivatives of diamidobenzophenone in the presence of condensing agents. Of the derivatives of cyanic acid the authors specify the ethers, the polymerides and their ethers, the derivatives of urea, and the sulphonyl-derivatives of cyanic, isocyanic, and cyanuric acids, and the sulphonyl-derivatives of urea. The condensing agents mentioned are potassium pyrosulphate, meta- and pyrophosphates, phosphorus trichloride, pentachloride and oxychloride, the chlorides and fluorides of boron and silicon, and the chlorides of zinc, magnesium, calcium, and aluminium. Of the colouring matters producible by these reactions the inventors claim only those which, by the action of strong mineral acids, split up into ammonia or a primary aromatic amine, and a tri-, di-, mono-, or non-alkylised diamidobenzophenone. Examples illustrative of the mode of working are given in the specification.—R. M.

*Improvements in Producing Sulpho-colouring Matters by Electrolysis.* Emil Capitaine, 89, Chancery Lane, Middlesex. From Messrs. Ewer and Pick, Berlin, Germany. Eng. Pat. 9756, July 4, 1884.

THIS invention is based upon the observation that when two plates of platinum are immersed in a solution of paramidodimethylaniline in dilute sulphuric acid, and the solution saturated with sulphuretted hydrogen, the liquid round one of the platinum plates assumes a blue colour when this plate is made the positive and the other plate the negative pole of a voltaic battery or a dynamo-machine. The blue colour formed round the positive plate soon disappears and a grey film collects on the plate; when this film is brushed off the blue colour is again developed, so that if the positive plate is kept clean by constant brushing, the blue colour formed does not disappear, and the colour of the solution becomes deeper as the electrolytic operation proceeds owing to the conversion of the "methylene white" into "methylene blue." In illustration of the mode of working, the inventors describe and figure a form of apparatus which consists of a wooden vat varnished inside, and containing an insulated wooden shaft provided with arms for stirring the liquid, and also with a set of arms provided on their opposite faces with bristles for cleaning the electrodes. The latter are platinised copper plates fixed horizontally in the vat at such a height that they are swept by the brushes on the revolving shaft. A solution of 1 part of paramidodimethylaniline in 40 parts of water and 4 parts of sulphuric acid of  $66^\circ\text{B.}$ , is first run into the vat, and the stirring apparatus and the electric current started. A solution of sodium sulphide is then run in till the vat liquor is saturated with  $\text{SH}_2$ . From time to time the liquor is tested for paramidodimethylaniline, and when the substance is no longer present the supply of sodium sulphide is stopped, the excess of  $\text{SH}_2$  removed by blowing air through the solution, and the electric current continued till all the "methylene white" has become converted into "methylene blue." The latter is then precipitated by zinc chloride and common salt in the usual way. The process is applicable to other alkylised derivatives of para-dianilines, and also to the production of methylene blue directly from nitrosodimethylaniline by first reducing this substance at the negative electrode and then proceeding as before. A form of apparatus for working this last process continuously is described (see this Journal, iv. [5], 310).—R. M.

*Improvements in the Manufacture of Colouring Matter.* William Robert Lake, Southampton Buildings, London. From Léo Vignon & Co., Lyons, France. Eng. Pat. 9808, July 5, 1884.

THIS invention relates to the preparation of a yellow colouring matter by nitrating  $\alpha$ -naphtholdisulphonic

acid. The latter is prepared by heating 30 parts a-naphthol with 180 parts of sulphuric acid of 66° B. to from 80-100° C. for 8-10 hours. The product is mixed with ice and the diluted solution nitrated by gradually adding 90 parts of nitric acid of 40° B., not allowing the temperature to exceed 30° C. The temperature is afterwards raised to 40° for a few minutes, and then reduced to from 12-15° C., and the precipitate collected, pressed, and converted into a potassium salt. The original feature of the invention is stated to be the employment of the sulphuric acid of 66° B. instead of fuming sulphuric acid. —R. M.

#### *Improvements in the Manufacture of Colouring Matters.*

William Robert Lake, Southampton Buildings, London. From Léo Vignon & Co., Lyons, France. Eng. Pat. 9812, July 5, 1884.

The object of this invention is to prepare a series of blue and violet colouring matters containing sulphur from paradianilines produced by the reduction of amidoazo compounds. The process consists of three operations:—(1) The formation of paradianilines by the reduction of the amidoazo compounds by means of sodium sulphide or other reducing agents; (2) The conversion of the paradianiline into a thio-base in the wet way by the prolonged action of sulphureted hydrogen, or in the dry way by fusion with sulphur according to Lauth's method; (3) The oxidation of the thio-base by means of ferric chloride, potassium bichromate, etc. Amidoazobenzene gives a blue, amidoazotoluene a violet dye, by these operations. The colours are said to be easily applicable to mordanted cotton and to be fast both to light and soap. —R. M.

### V.—TEXTILES: COTTON, WOOL, SILK, Etc.

*An Improved Substitute for Gut, applicable to Lawn Tennis and other Rackets; also suitable for Clocks and other Mechanical Purposes.* Robert Müller. Eng. Pat. 6446, April 17, 1884.

The inventor prepares artificial gut by dipping twisted silk cords in a mixture of gelatin and glycerin, the latter being added to give pliability. From 8 to 10 parts of glycerin to 100 parts of gelatin forms a good average mixture. It should be applied at a temperature of 70° C. —E. J. B.

*Improvements in the Manufacture of a Combined Paper and Cloth Material for Bookbinding, etc.* S. Barlow, Castleton, Manchester. Eng. Pat. 9727, June 3, 1884.

INVENTOR passes the two materials, cloth and paper, through a pair of bowls, one of which has a rigid surface and the other a resilient one. The cloth may be previously stiffened by an ordinary mangle or back-starcher. The adhesive substance used to unite the two materials may be starch, gum, or any other convenient substance. Inventor claims that previous attempts to combine cloth and paper in this manner have been failures, owing to the use of rollers or bowls entirely with rigid surfaces. For rigid bowls he employs brass, copper, hard wood, iron or steel. For the resilient rollers either indiarubber, or metal coated with indiarubber, gutta-percha, cotton, or paper, is employed. The combined material is dried by passing over the steam cylinder as usual, or by any convenient drying process, and may then be calendered, embossed, or finished in any way required. —H. A. R.

*Improvements in the Method of and Apparatus for Carbonising and Drying Woollen Pieces, Wool Noils, Waste or Rags.* Duke Fox. Eng. Pat. 9273, June 21, 1884.

AN apparatus is employed for treating woollen materials from which it is desired to remove vegetable matter with hot hydrochloric acid gas. The patentee claims "wool or rag carbonisers constructed with a central chamber connected with retorts, the chamber is fitted

with a series of swing grids arranged for lowering the material to be operated upon from one grid to another." The specification is accompanied by drawings illustrating the construction of the apparatus. —E. J. B.

*An Improved Method or Process of Destroying Vegetable Substances contained in Wool or Woollen Fabrics.* George Sales Jarman. Eng. Pat. 9373, June 24, 1884.

THIS process consists in heating wool or woollen fabrics in a bath of dilute hydrochloric acid. After washing and drying, the material can be readily freed from vegetable matter by mechanical means. The strength of acid and duration of treatment can be varied according to circumstances. With an acid of 1½ Tw., and a temperature of 200° F., about 105 minutes' immersion will suffice at 8° Tw. and a temperature of 180° F.; the treatment should be continued for twenty-six minutes. If the temperature be allowed to rise above 200° F., the woollen material is liable to be affected. —E. J. B.

### VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

*On Printing with Artificial Indigo.* H. A. Costebadie. Bull. Soc. Ind. Rouen, 1884, 757.

ORTHOITROPIENYLPROPIOLIC ACID, which at the time of its appearance attracted a great deal of attention, has now almost fallen into oblivion, most printers having given up using it on account of its high price. Yet, the artificial indigo produced from it possesses certain advantages over the natural product, and for this reason some printers are still using it, especially for light shades. In this case the high price does not form such a great drawback to its application. The treatment of the printed cloth is very simple. It is hung up at a temperature of 25° C. for twelve hours until the blue is fully developed, then soaped at 75° C. and steamed in a Mather & Platt's apparatus. By the process of steaming the disagreeable odour adhering to the cloth (derived from a decomposition product of the xanthate used as a reducing agent) is completely removed. Propiolic acid is also suitable for producing even sky-blue shades by the patting process, upon which discharge patterns can be obtained in the same manner as on vat-blue. Also resist patterns not readily obtainable with natural indigo can be produced with propiolic acid in the manner below described. The mordants thickened with British gum are first printed on the cloth and then dyed up in a colour bath. In order to produce white resist patterns on a blue ground, a mixture containing citric and oxalic acids, and consisting of 96 litres lemon juice 28° B., 24 litres caustic soda 36°, 2 litres oil or tallow, 36kilos. dextrin, and 1½kilos. oxalic acid, are printed on. After ageing, the cloth is padded with propiolic acid, hung up for twelve hours for the purpose of developing the blue, and passed once more through this process. The standard colour mixture is composed of 3½kilos. starch, 36 litres water, 31½kilos. 20 per cent. propiolic acid paste, and 5½kilos. borax. A printing colour is prepared by adding to 5 litres of this mixture 500 grammes sodium xanthate, a padding colour by mixing 4 litres of this printing mixture with 12 litres of starch paste. The development of the blue being completed, the pieces are passed through a bath of sodium arsenate at 75° C., and then through the colour bath, the temperature of which should be kept as low as possible to avoid deterioration of the blue colour. The pieces are finally soaped at a temperature below 75° C. A resist for chrome yellow and orange is obtained by adding to these colours oxalic acid in the proportion of 15 grammes per litre. Fine orange shades might also be obtained by dyeing up the resist mordant in a nitroalizarin bath. Catechu brown is turned much darker through the influence of the padding colour, this phenomenon being probably due to a peculiar action of the soda xanthate. —F. M.

*Effects produced by the Sulphurous Acid of the Atmosphere of Towns.* G. Witz. Bull. Soc. Ind. Rouen, 13, 161.

THE author has proved the prevalence of sulphurous anhydride in the atmosphere of the town of Rouen by observations on certain bills printed with lead pigments, chiefly minium, and posted on walls of various aspects. Certain of these which were observed to fade very rapidly were examined, and found to contain both sulphate and sulphite of lead. Bills of the same kind posted along the country roads, although more exposed to the weather, showed a decreasing decolorisation of the printed matter in proportion to the distance from the town. It was also observed that notices printed in the same pigments, and exposed in shop windows where gas was burnt, showed a similar decolorisation, and the presence of sulphite of lead was similarly established. The presence of sulphurous acid in an atmosphere may be readily demonstrated by introducing a glass vessel filled with ice; the humidity condensed on its surface may be tested by the ordinary reagents for this compound. More simply still, the moisture condensed on the windows of a room when gas is being burned will be found to decolorise iodide of starch. The condensation of sulphurous acid together with the moisture in fogs and hoar frosts has been found by the author seriously to affect goods printed with colours sensitive to sulphurous acid; of these he specifies logwood and Brazil wood shades, and aniline black (compare *Ibid.* 1879, 185; 1877, 263; 1876, 310; and 1873, 76). The author especially commends these results and his method of observation to the notice of dyers and calico printers.—C. F. C.

*An Improved Apparatus and Process for Bleaching, &c., Fibrous Materials.* W. D. Gedge, London. From C. F. Glaser, Berlin. Eng. Pat. 7900, March 19, 1884.

THE chief point of this invention is the placing in the interior of the boiling kiers, fitted as required and usual, one or more proportionately light and easily removable vessels, with perforated bottoms, which are charged with the goods to be acted upon; and the arrangement of the space between the inner and outer vessels, by partitions, in such a manner that the agents which are introduced or made to circulate in the boiler may be forced to pass through the materials to be acted upon, and that however high the pressure may be during the operation, the strain on the inner vessel may never exceed that which is necessary for the penetration of the goods.

—H. A. R.

*Improvements in Washing and Dyeing Machinery.* J. Worrall, Salford. Eng. Pat. 7709, May 14, 1884.

THE main feature of this invention is in a washing and dyeing machine, the combination of a tank for containing liquor, with a frame carrying a ring of guide rollers, and two rings of winches or beaters concentric with the rollers, the guide rollers serving to present the fabric, as it is drawn through the machine, to the action of the beaters, such beaters being driven by gearing operated from the central shaft, and serving, while the cloth is presented to the action of the liquor, to impart to the cloth a rapid vibratory motion.—H. A. R.

*Improved Apparatus to be used in Bleaching and Dyeing Piece Goods.* J. Worrall, Salford. Eng. Pat. 9582, June 30, 1884.

IN treating velvets, velveteens and similar goods, great difficulty has hitherto been found in preventing the formation of creases in the goods, which creases are due to the curling up of the selvages as the fabric is travelling through the bleaching, washing or dye vat. In order to counteract the said curling up, the inventor passes the cloth, during the time of its being acted on by various agents, round a drum surrounded by eight or twelve pressing cylinders, there being fitted between these cylinders, except at the part where the cloth enters and leaves the apparatus, guide bars, tubes or rollers,

for holding the cloth away from the drum while it is receiving a supply of bleaching or dyeing liquor. The supply is delivered to the cloth through some or all of the guide bars or tubes, which are slotted for that purpose, and are in communication with a supply cistern or pump. The guide bars, or every alternate one, will be furnished with diagonal ribs, inclining towards a central line, and serving to put a slight lateral strain on the cloth as it passes over the bars, so as to keep the selvages well extended. For drawings and details the original specification should be consulted.—H. A. R.

*Printing one or more Colours simultaneously on Cotton or Woolen Hanks and the like.* T. G. Charlesworth, Leicester. Eng. Pat. 9614, July 1, 1884.

THE inventor claims the method of dyeing or printing hanks by a sideways passage through the rolls. The method of printing two or more colours simultaneously by a sideways passage through rolls divided into sections, one for each colour, and corresponding divisions in the colour trough, one for each colour, the combination with the colouring rolls of a hank-feeding device consisting of an endless travelling chain with hooks, upon which the hanks are hung. The rolls are covered with felt, rubber, or some similar soft absorbent substance; and one passage through the rolls completes the printing, after which the hanks are dried as usual.—H. A. R.

*A New Mode of Dyeing Cotton and other Vegetable Fibres with Insoluble Azo-colouring Matters.* Dan Dawson, Huddersfield. Eng. Pat. 9701, July 3, 1884.

THE inventor claims that by bringing about a slow and gradual combination of materials used to produce the colour, aided by the "catalytic" action of the cotton when immersed in the bath, the dyeing can be done at one operation. It is proposed to accomplish this by keeping the bath free from mineral acid, and only having a small quantity of a weak organic acid present—*e.g.*, acetic acid. The bath is prepared as follows: A body—*e.g.*, naphthylamine—is diazotised as usual. Strength of solution to be about one per cent. of chloride, and plenty of HCl required present. The bath is neutralised by means of chalk. Then are added finely-precipitated naphthol and acetate of soda, with a little acetic acid. It is claimed that cotton immersed in the above bath will fix the colouring matter as it forms. The fixing of an insoluble soap before dyeing causes the operation to take place more quickly, and deeper shades to be obtained.—H. A. R.

*A New or Improved Bleaching Solution.* R. B. Lyth, Belfast. Eng. Pat. 9802, July 5, 1884.

THE inventor prepares a bleaching solution by charging a solution of chloride of lime with sufficient carbonated water to precipitate the lime held in solution. It is claimed that a much shorter time is required for bleaching the goods, that less boiling is required, that the application is much safer and turns out the goods stronger, and also that it is cheaper than any other process hitherto applied.—H. A. R.

*An Improved Process in Dyeing with Substances containing Tannin, or Tannic Acid, or Gallo-tannic Acid.* Henry Grandage and Robert E. Steel, Bradford, Yorkshire. Eng. Pat. 12,490, September 12, 1884.

THE invention consists in an improved process of dyeing fibres where tannin or tannic acid is employed, and has for its object the union with the fibre of a larger quantity of tannin or tannic acid from a given solution than can be united by processes at present in use in dyeing. To obtain this result it is proposed to add to the solution containing the tannin itself obtained from myrabolans, sumac, divi-divi, galls, gambier, &c., before employing it for dyeing, one or more of the following salts—*viz.*, sodium chlorate or bichlorate, potassium chloride, or ammonium chloride. The quantities of the above salts found to give the best results were found to be sodium chloride 10 per cent., borax  $\frac{1}{2}$  per cent., potassium

chloride 10 per cent., ammonium chloride 2 per cent. The percentages are calculated on the crude tannins from which the solutions are made. Inventors do not claim as original any process for extracting tannin, but claim as novel and original the adding of certain salts to the tannin solutions in order to cause fibres to assimilate more tannin.—H. A. R.

## VII.—ACIDS, ALKALIS, AND SALTS.

*New Chemical Apparatus for the Recovery of Nitrous Compounds in the Manufacture of Sulphuric Acid.* Dingl. Polyt. J. 256, 125.

For the recovery of the nitrous compounds in the manufacture of sulphuric acid, the Société Anonyme des Produits Chimiques de la Manufacture de Javel, Paris, proposes (Ger. Pat. 30,749, August 12, 1884) to wash the

sulphuric acid of 60-62° B. falls from the acid distributors *a*. The construction of one of these distributors working under the pressure of a column of liquid in the pipe *E*, three to four metres high, will be understood from the wood-cut (Fig. 3). The small spreading disc *a* is fixed to one end of the rod *b*, which passes through the vessel *D* and is surrounded by the pipe *F*. The other end of the rod is furnished with a thread, and by means of the nut *d* fixed upon *D*. In accordance with the more or less cone-shaped form of *a*, the liquid which passes through the annular opening of the vessel *D* falls in a rain of greater or smaller radius.—F. M.

*Process for Decomposing the Chlorides and Oxichlorides of Magnesium, Manganese and Chromium.* Dingl. Polyt. J. 256, 125.

For the purpose of decomposing the chlorides and oxichlorides of magnesium, manganese, and chromium, the

gases previous to their passage into the Gay-Lussac apparatus with a spray of concentrated sulphuric acid, the latter being only intended for retaining those nitrous compounds which have been carried away mechanically. The lead-lined tower *A* (Figs. 1 and 2) contains a small quantity of coke *C* upon a grid fixed at a height of about one metre above the bottom, and serving for the distribution of the gases entering by the pipe *B*. A fine rain of

concentrated solutions of these salts, according to a patent of R. Nithack, Nordhausen (Ger. Pat. May 29, 1884), are in a fine state of division brought into contact with hot bodies. The pipe *R* (Fig. 4) is connected with the flue *F*, and serves as a super-heater. A spray producer *Z* connected with the pressure vessel containing the salt solution is fixed in the wall of the long narrow chamber *C*. The latter and the larger chamber *K*, in

which rows of fire-clay tiles are set up, are furnished with a kind of false bottom, likewise consisting of slanting tiles, through which the solid masses fall, and can be removed through the openings O or c. The plates E are either fixed or arranged so that the distance between them is adjustable. From the chamber K, the fine C<sub>2</sub> leads into another chamber, and so forth; the gases pass at last through a system of regenerators into the condensers. The method of working this apparatus consists in first heating up the flues and chambers, and then blowing in the solution through the nozzle connected with the spray producer Z. The fine particles of the salt solution coming in contact with the hot air from F and the walls of the chambers are decomposed according to the equations  $MgCl_2 + H_2O = MgO + 2HCl$ ;  $2HCl + O = Cl_2 + H_2O$ , etc.—F. M.

*On the Composition of the Gases produced by the Combustion of Iron Pyrites.* M. Scheurer-Kestner. Bull. Soc. Chim. 1885, xliii. p. 9.

THE author has made thirteen more analyses of the gas from Maletta burners. In only one case was sulphuric acid absent. The rest gave results ranging from 0.4 to 9.3 SO<sub>2</sub> per 100 parts of SO<sub>2</sub>. There appears to be no connection between the percentages of sulphuric and sulphurous acids present in the burner gases. The acid liquors condensing in the connections leading from the burners generally have a sp. gr. of from 1.6 to 1.689. The author explains the absence of anhydride as such by showing that the moisture in the pyrites and the air consumed, is more than sufficient to hydrate the whole of the sulphuric anhydride formed. The bulk of this anhydride (consequently as sulphuric acid) he supposes is condensed in the Glover tower, which coincides with the fact that the acid used here is observed to increase in its passage from the top to the bottom. It is true Mr. Forster, eleven years ago, gave it as his opinion that this increase was entirely due to the oxidation of sulphurous acid by the nitrous acid from the Gay-Lussac; but as Mr. Forster's burner gases seem to have contained no sulphuric anhydride, and as his Glover tower was of a very low concentrating power, the author cannot regard this as a refutation of his opinion, the more especially as Mr. Forster's own calculations show a deficiency of sulphurous acid leaving the Glover; and the manner in which his experiments were made leaves it open to question whether this deficiency was not even greater than stated. Experiments extending over sixteen days showed that from fifteen to twenty per cent. of the total acid produced were condensed in the Glover tower. This may be supposed to include both the sulphuric anhydride proved by the author to exist in the burner gases, and the sulphuric acid formed in the Glover itself by the action of the nitrogen compounds upon the sulphurous gas, as stated by Mr. Forster.—A. R. D.

*Improvements in Apparatus to be employed in the Production of Carbonate and Bicarbonate of Soda from Sulphate of Soda, or from Chloride of Sodium.* Holbrook Gaskell and Ferdinand Hurter. Eng. Pat. 8804, June 10, 1884.

THIS apparatus consists of arrangements for preparing solutions of sodium sulphate, and of apparatus for saturating such solutions with ammonia and carbonic acid gas—viz., a series of cylinders, through which the ammoniacal solution of sodium sulphate and carbonic acid gas under pressure, flow in opposite directions.

—F. H.

*Improvements in the Manufacture of Chlorine.* Thomas Macfarlane. Eng. Pat. 9234, June 20, 1884.

DRY manganese protochloride, obtained by evaporation of residual solutions of the manufacture of chlorine, is ground and mixed with from one to four times its weight of dry ferric oxide. The mixture is heated in a muffle

furnace to about 400° C., and dry air passed over it. The air is dried by means of calcium chloride. The manganese chloride is decomposed, manganese sesquioxide and dioxide are formed, and chlorine gas evolved. The chlorine diluted by nitrogen, and containing some hydrochloric acid, is cooled, washed and absorbed by lime to produce bleaching powder. The mixture of manganese oxides and ferric oxide is treated with hydrochloric acid, which attacks the manganese oxides, whereby chlorine is liberated, while the ferric oxide remains for the most part unchanged. The mixture of solution of manganous chloride with ferric oxide is evaporated to dryness, and the dry residue is heated as above described. This round of operations may be continued indefinitely.—F. H.

*Improvements in obtaining partly in the Free State and partly as Vapour of Hydrochloric Acid, the Chlorine of the Chloride of Magnesium of Aqueous Solutions of Chloride of Magnesium, or of Mixed Solutions of Chloride of Magnesium and Chloride of Sodium.* Walter Weldon. Partly from A. R. Pechiney & Co., Salindres. Eng. Pat. 9306, June 23, 1884.

SOLUTIONS of magnesium chloride, which may contain sodium chloride (such as are obtained by decomposing by magnesia the ammonium chloride contained in certain residual solutions of the manufacture of soda by the ammonia process), are concentrated by evaporation as far as can be done without evolution of hydrochloric acid. Sodium chloride salts out, and is removed by fishing. To the boiling concentrated solution of magnesium chloride is added, and intimately mixed therewith, from one-half to one and one-half equivalents of magnesia, such as results from a subsequent operation. A solid hydrated magnesium oxychloride is thus obtained. This oxychloride is first desiccated at a comparatively low temperature (150° to 300° C.). The water, together with a small quantity of hydrochloric acid, are driven off. The desiccated oxychloride is then further heated in contact with a current of air (preferably in apparatus as described in Eng. Pat. 9304, 1884). The chlorine of the oxychloride is thereby driven off, partly as free chlorine, partly as hydrochloric acid. The latter is condensed, and the chlorine then utilised. The resulting magnesia is used in part as above described.—F. H.

*Improvements in the Manufacture of Chlorine and Hydrochloric Acid.* Walter Weldon. From A. R. Pechiney & Co., Salindres, France. Eng. Pat. 9307, June 23, 1884.

MAGNESIUM chloride containing water is first heated in vessels resembling retorts or muffle furnaces, with little or no access of air, to a temperature at which the water reacts upon the magnesium chloride, yielding magnesia and hydrochloric acid, which is condensed. The resulting mixture of magnesium chloride and magnesia is then heated in a current of air. The chlorine contained in the solid residue of the first operation is thus driven off, partly as hydrochloric acid, but largely as free chlorine. The two operations may be carried out in two distinct pieces of apparatus, or in one single apparatus, for which that described in Eng. Pat. 9304, 1884, is recommended.

—F. H.

*Improvements in the Manufacture of Sulphite of Soda.* Eustace Carey and Holbrook Gaskell the younger. Eng. Pat. 9458, June 26, 1884.

MONOHYDRATED sodium carbonate, either pure or in the crude state (salts), according to the desired purity of the product, is exposed to the action of sulphurous anhydride so long until sufficient sulphurous anhydride is absorbed to correspond to a neutral sulphite. The product contains sodium bicarbonate. The monohydrated sodium carbonate is exposed in revolving cylinders, through the hollow axes of which the sulphurous anhydride enters, and the carbonic acid together with inert gases leave. Several cylinders are employed in series if the sulphurous anhydride is obtained by combustion in air of brimstone or pyrites. If wet, the sulphurous anhydride must be dried by means of sulphuric acid.—F. H.

*Improvements in the Manufacture of Chlorine and Hydrochloric Acid from Chloride of Magnesium.* Walter Weldon. From Pechiney & Co., Salindres. Eng. Pat. 9688, July 2, 1884.

SOLID hydrated magnesium chloride, whether crystallised or not, is first heated to a temperature of from 150° to 200° C. By this operation the water can be reduced to about two equivalents, without the evolution of more than a very small proportion of the chlorine (chiefly in form of hydrochloric acid). The partially dehydrated magnesium chloride is then heated to a higher temperature in contact with air. Vapour of hydrochloric acid and free chlorine is evolved; but the latter in much greater proportion than would have been the case if the previous dehydration at lower temperatures had been omitted. The dehydration is carried out by passing over the solid hydrated magnesium chloride air or gases previously heated to the requisite temperature. The dehydrated magnesium chloride is heated in muffle furnaces, or in apparatus described in Eng. Pat. 9304, June 23, 1884.—F. H.

*Method for the Manufacture of Sulphur from Sulphuretted Hydrogen.* Oesterreichische Soda-Fabrik, Hruschlau. Ger. Pat. 30,746, July 26, 1884.

The sulphuretted hydrogen is passed over heated sulphates of alkalis or alkaline earths, whereby the oxygen of these salts decomposes the sulphuretted hydrogen, a sulphide and free sulphur being formed. By the action of atmospheric air upon the sulphide, sulphate is regenerated, which may again be used in the process.—F. M.

*Improvements in the Methods of obtaining Ammonia and Hydrochloric Acid in the Manufacture of Soda from Sodium Chloride by the Ammonia Process.* A. M'Dougall, Penrith. Eng. Pat. 2048, Feb. 10, 1885.

THIS invention consists of the substitution of magnesia for lime in the decomposition of the ammonium-chloride formed in the ammonia-soda process. Rather more than an equivalent of magnesia is added to the ammonium chloride in a suitable still, and heat applied till all the ammonia is liberated. A further heat, aided towards the end of the operation by stirring, and the introduction of a steam jet, now drives off the hydrochloric acid, which may be recovered in any suitable way, while the magnesia is left ready to be used over again.—A. R. D.

*An Improved Method of treating Ammonium-chloride.* W. P. Cochrane, Redcar; and W. Bramley, Middlesbro'. Eng. Pat. 11,222, March 14, 1885.

FROM the residual liquors of the ammonia-soda process, the small proportion of sodium chloride present is eliminated by "fishing." To the remaining solution of ammonium chloride magnesia is added in the proportion of rather more than two molecules for every two molecules of ammonium chloride present. On the application of heat the ammonia is readily liberated, especially if the mixture be stirred and kept at the consistency of milk of lime. The residual liquor contains magnesium oxychloride, which may be recovered by evaporation and used for the production of free chlorine, hydrochloric acid, and magnesia.—A. R. D.

*Improvements in the Manufacture of Salt, and an Improved System and Apparatus employed therein.* J. E. Higgin and T. H. Higgin, Liverpool. Eng. Pat. 9179, March 16, 1885.

THE evaporating pan is supported on pillars, and the space beneath it is enclosed with brickwork sides and ends. The floor slopes upwards towards the back. In front is a row of fireplaces with tightly-fitting doors, and provided, instead of firebars, with perforated iron plates—the holes being  $\frac{5}{8}$  of an inch in diameter. Extending the length of the fireplaces is an air main having a branch delivering beneath the fire-bearing plates of each fireplace. Air in quantity more than sufficient for the combustion of the fuel is blown or injected through

the main into the fireplaces, and so passes along the enclosed space under the pan. After it emerges from the other end of this it is caused to circulate through an air-heater consisting of a series of pipes through which the fresh supply of air needed by the process is drawn by the blower. The advantages claimed are economy in fuel, and a superior quality of salt, with fewer impurities.—A. R. D.

*Improvements in Apparatus for the Manufacture of Vinegar.* W. H. Perry and J. O. Boulton, both of Nottingham. Eng. Pat. 9967, April 8, 1885.

THIS invention refers to apparatus in which the wash or liquid from which the vinegar is made is passed over beech or other wood shavings in presence of a current of air. Three casks are set at different heights, one above the other. The middle one, called the aceticler, is larger than the others, and has a false bottom of perforated wood or of wickerwork. On this false bottom are piled wood shavings to a suitable height. Above these is fitted a false top forming a kind of shallow well with the sides of the cask. This false top is drilled with small holes so that the liquor it contains may be well distributed over the shavings. Air-holes between the true and false bottoms, and higher up in the sides of the cask, provide for a constant current of air. The topmost cask supplies the liquor to the aceticler. A pipe from its lower portion dips into the shallow well above described, while another pipe from its top does the same, but does not go quite so deep. This latter is an air-pipe, and regulates the flow from the former. If its end is sealed in the well, the supply-pipe ceases to deliver; if, however, this end is unsealed, the supply-pipe delivers till it is sealed again, and so a constant depth of liquor is maintained in the well. The lowest cask is simply a receiver. It may be made interchangeable with the supply cask.—A. R. D.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, CEMENTS.

*Improvements in Coating or Surfacing Bricks and Tiles.* H. M. Smith, London. Eng. Pat. 9887, July 8, 1884.

THIS invention has for its object the application of a vitreous face or coating to an ordinary brick or tile. The brick in the green state is dipped in a "slip" of the vitreous material, or such faces as it is desired to treat are similarly treated, and the whole is fired in the usual manner. Another manner of securing the object of the invention is to apply the coating in the mould in which the brick or tile is pressed. The vitrified faces may or may not be glazed in the usual manner after the process of vitrification. The claim is for the process as described.—C. C. H.

*Improvements in Colouring Stones for Buildings and other Purposes.* L. E. A. E. D. De-Liebhaber, London. Eng. Pat. 9888, July 8, 1884.

THE object of this invention is to change the colour of the stones used in building without the introduction of any fresh colouring matter, and particularly to impart a red or brown colour. The stone of the ordinary description used in building, such as Bath stone, etc., is heated to, or above, the temperature of melting lead, and this can be conveniently carried into effect by immersing the stone in a bath of melted lead, the melting point of which can be lowered or raised by the introduction of tin or zinc.—C. C. H.

*Improvements in the Means of accelerating the Setting and Hardening of Cements.* W. Millar and C. F. Nichols, London. Eng. Pat. 2886, March 4, 1885.

IN place of the water usually mixed with cements or concretes to render them plastic, the inventors add aqueous solutions of certain chemicals, which have the effect of (1) accelerating the setting properties of

cement; (2) indurating it, or increasing its natural hardening properties; "and (3) acting upon the cement or concrete, when set, in such a manner as to enable the mass to be handled in from one hour upwards." The ingredients used for accelerating the setting of cements are sodium carbonate, alum and ammonium carbonate; for indurating or increasing the hardening properties of cements, calcium chloride, magnesia and magnesium chloride; and for obtaining an intense hardness, magnesium oxychloride. As an after process for further indurating cements, "silicon, boron, or some combination of these two chemicals with bichromate of potash" may be used.—E. G. C.

## X.—METALLURGY, MINING, Etc.

*Treatment of Slag and Phosphates.* A. Frank, Charlottenburg, Prussia. Eng. Pat. 7039, April 30, 1884.

MOLTEN liquid slag, or finely-divided solid slag, is treated with magnesium chloride solution, by which the sulphides are decomposed, hydrogen sulphide being produced; also free lime, if present, forms calcium chloride and magnesia, and thus indirectly produces a concentration and greater solubility of the phosphates contained in the slag. The powdery slag, with the adhering magnesium chloride, is further heated by an oxidising flame, and thus lower oxides of iron and the like are partly oxidised, in consequence of which the oxides become less soluble in acids. The same method is applicable for the cleansing and concentrating of natural or artificial phosphates, especially such as contain lime uncombined with phosphoric acid. If such phosphates contain carbonate of lime, the latter must be rendered caustic by burning.—J. T.

*Extraction of Dangerous Compounds of Lead, Arsenic, etc.* W. H. Tooth and J. E. Rooker, London. Eng. Pat. 7977, May 20, 1884.

THE object of the invention is to remove volatile compounds in such a manner as not to be injurious to the workmen. The ore, etc., is heated in a retort connected with a series of condensing pipes, which are partially exhausted by means of a steam jet. Superheated steam or air may be passed into the retort.—J. T.

*Utilising Phosphoric Slag.* E. Capitaine, London. Eng. Pat. 8890, June 12, 1884.

THE author finds that phosphoric slag liberates ammonia from ammoniacal salts in the form of gas, just as lime does. This discovery he utilises by using phosphoric slag in the place of lime in the ammonia-soda industry, and in all cases where lime may be used for the liberation of ammonia. The slag is used in the raw state; it is advisable to break it into small pieces, but during the process the pieces become completely disintegrated. When the slag is so exhausted as not to expel any more ammonia, the excess of bases that it contains passes into solution as salts corresponding to the ammoniacal salts. The residual slag still contains the whole of the phosphoric acid. The further treatment of this enriched material offers no difficulty.—J. T.

*Separation of Ores and Mineral Products.* F. J. King, London. Eng. Pat. 15,027, November 14, 1884.

THIS invention relates to the separation of substances which are partially magnetic, or have been made so by previous treatment. These substances are passed underneath a cylinder of iron bars, which are alternately magnetised and demagnetised, by which the magnetic material is removed from the non-magnetic.—J. T.

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

*Method for the Purification of Mineral Oils.* C. Roth, Berlin. Ger. Pat. 30,786, June 17, 1884.

IN order to free mineral oils from substances which are liable to resinify so as to make them suitable for lubri-

cating purposes, etc., from 1 to 5 per cent. of potassium permanganate are added previous to the process of distillation, which is conducted slowly. The distillate is first treated with sulphuric acid of 1.53 to 1.6 sp. gr., and then with caustic soda of 1.4 sp. gr. The treatment with potassium permanganate, sulphuric acid and caustic soda is once repeated. Mineral oil purified in this manner possesses a slightly yellow colour, with a green fluorescence, and after three days' exposure to air at 35° C. exhibits but slight signs of the formation of resinous bodies.—F. M.

*Improvements in Cooling Apparatus for Cooling Glycerine and other Liquids.* A. Kind, Venice. Per W. P. Thompson & Co. Eng. Pat. 7072, July 2, 1884.

By means of suitable machinery and an arrangement of concentric cylinders, the liquid to be cooled, and the refrigerating medium, are made to move in opposite directions on either side of a partition, to which ribs are attached in order to increase the length of path travelled by the liquid to be cooled. Drawings are given.—W. L. C.

*Improvements in the Process of Extracting Fat from, and drying Bones and the like.* F. Seltmann, Bavaria. Per W. P. Thompson. Eng. Pat. 10,208, July 16, 1884.

IN the ordinary extraction processes, difficulties arise from the presence of water in the bones. The patentee proposes to overcome these by the use of a solvent (usually a hydrocarbon from petroleum, etc.), the boiling point of which considerably exceeds that of water. The temperature in the extraction being raised by steam above 100° C., the water is expelled from the bones, and the extraction of the fat is more complete. The quality of the gelatin and crushed bones ultimately produced is said to be much improved.—W. L. C.

*Improvements in the Manufacture of Soap and Saponaeous Compounds.* S. N. Dimbleby. Per Tongue and Birkbeck. Eng. Pat. 11,305, August 15, 1884.

THE juice of the plant *Hamelis Virginica*, or common Wych Hazel, is mixed with soap, and with various compounds for toilet purposes which contain soap. Such compounds are said to be beneficial in the case of bruises and lacerations of the skin.—W. L. C.

*An Improved Process for Extracting Oil and Albumenoid from Maize and other Grains.* Dr. F. V. Greene, Philadelphia, U.S.A. Per Allison Bros. Eng. Pat. 3101, March 10, 1885.

THE so-called "starch milk," which is a by-product in starch manufacture, contains an emulsion of oil and of the albumenoid matter of the grain. The patentee proposes to separate these substances from the water, rendering the latter innocuous, and producing valuable substances. Various methods are proposed—filtration, precipitation by various salts and acids, but notably by sulphate of alumina. From the mixed products, partly dried, the oil is separated by a solvent, and the albumenoids are used as fertilisers. The method is also applicable to the residues left after distilling spirit from corn.—W. L. C.

## XII.—PAINTS, VARNISHES, AND RESINS.

*Compositions for Protecting Iron Surfaces from Damp and Corrosion.* J. Brydson, Kingston-on-Hull. Eng. Pat. 9105, June 17, 1884.

THREE compositions are applied to the surface to be protected, which is first cleared from rust and scale. The first composition used is a varnish consisting of linseed oil, magnesia, sugar of lead, and litharge, heated and mixed while hot with a solution of resin in turpentine. After the mixture has cooled, zinc oxide and

calcium hydrate are added, and the whole is allowed to stand for several days before use. The next composition is a liquid gum consisting of alcohol, copal gum, dragons' blood, sugar of lead, beeswax, and turpentine; and the final composition consists of carefully-sifted wood powder, calcined wood powder, and amber, made up with water and calcium hydrate, and stove-dried. This can be at once applied over the gum, and the surface will then be ready for receiving paint or other decoration.

—E. G. C.

#### XIV.—AGRICULTURE, MANURES, Etc.

*Influence of Certain Salts on Nitrification.* P. Pichard. Bied. Centr. 14, 152-156.

THE experiments were made on coarse and on fine sand of the composition here indicated, mixed with earth-nut cake, in quantities such as to give N = 0.15 per cent. of the mixture.

	SOLUBLE IN AQUA REGIA.				INSOLUBLE.
	Fe <sub>2</sub> O <sub>3</sub> and Al <sub>2</sub> O <sub>3</sub>	CaO	MgO	K <sub>2</sub> O	
Coarse sand	1.300%	0.068%	0.025%	0.007%	98.600%
Fine sand...	0.100%	0.050%	0.020%	0.005%	98.825%

	Total N	Nitric N	K <sub>2</sub> O	Total Ash.
Earth-nut cake...	7.700%	0.029%	1.250%	4.400%

Each of the following salts were added to separate portions of this mixture in quantities approximating to the actual proportion generally found in soils. The salts employed were the carbonates and sulphates of potassium, sodium, calcium, and magnesium. In two cases no salts were added, and in two other experiments the earth-nut was replaced by ammonium sulphate on coarse sand, mixed with calcium and magnesium carbonate respectively. These mixtures were made up on the 30th May, 1883; they were placed in glass vases, with a layer of glass fragments below and a layer of pure sand on the top; they were kept moistened with distilled water, and were sheltered from rain and dust. On August 30 slight nitrification had taken place in the ammonium sulphate mixtures, but not in those containing earth-nut. The author attributes this formation of nitric acid to simple atmospheric oxidation. On August 31, to start nitrification, each mixture was seeded by the addition of about 0.75 per cent. of soil. At the close of the experiments, March 15, 1884, the mixtures were heated to 70° to arrest nitrifying activity, and were then analysed, the quantity of nitric acid being estimated by Boussingault's indigo method. In the coarse sand series the percentages of the total nitrogen nitrified were as follows:—In the mixture containing potassium carbonate 4.96, sodium carbonate 2.14, calcium carbonate 26.15, magnesium carbonate 24.47, potassium sulphate 12.59, sodium sulphate 15.61, calcium sulphate 28.82, magnesium sulphate 3.94, and where there was no salt added, 3.54; whilst in the fine sand the corresponding percentages of total nitrogen nitrified were potassium sulphate 20.86, sodium sulphate 24.96, calcium sulphate 46.29, magnesium sulphate 11.55, and with no salt added, 4.86. In the mixtures containing ammonium sulphate the percentage of nitrogen nitrified was with calcium carbonate 3.86, and with magnesium carbonate 3.18; in both these cases the remainder of the ammonia had disappeared, presumably by volatilisation as carbonate. With regard to the adaptability of the salts for aiding nitrification, the author arranges them in order of merit indicated by the above analytical numbers, heading the list with gypsum. He explains the special activity of the latter substance by the supposition that in the presence of organic matter it is readily reduced, then by contact with air is re-oxidised, and in this manner acting as a conveyer of oxygen it aids nitrification.—D. A. L.

*Loss of Nitrogen during Fermentation of Farmyard Manure.* H. Joulie. Bied. Centr. 14, 158-163.

SIX mixtures of 75 grms. of chopped straw and 50 grms. of dry powdered horse droppings were taken and soaked with 300cc. putrid human urine, and 275cc. of water; the solid materials contained in a suitable glass vessel were supported on iron wire-gauze; the liquid filtering through was poured over the mixtures every two or three days. No. 1 received nothing in addition, No. 2 received 10 grms. phosphoric acid, No. 3 10 grms. phosphoric acid and 10 grms. gypsum, No. 4 10 grms. phosphoric acid and 10 grms. calcium carbonate, No. 5 10 grms. of calcium carbonate, No. 6 10 grms. gypsum, whilst a 7th mixture was composed as follows: 150 grms. straw, 200 grms. horse excrement, 400cc. urine, and 850cc. water. After 6½ months there were only traces of humic acid found in Nos. 3 and 6; 0.92 to 0.96 per cent. of the organic substance employed in Nos. 2, 4 and 5, whilst Nos. 1 and 7 contain 1.3 to 1.4 per cent. Complete analyses of mixtures 1 and 7 showed the manures were similar to fermented farmyard manure, allowing for difference caused by use of human urine instead of that of cattle. The losses of solid matter per cent. in each case were as follows:—

Mixture	1.	2.	3.	4.	5.	6.	7.
Losses	53.71	57.92	49.74	56.35	58.00	52.61	56.20

Whilst the losses per cent. of nitrogen are indicated by the following analytical data:—

Mixture	1.	2.	3.	4.	5.	6.	7.
Losses	18.04	21.08	39.00	31.27	40.60	33.98	21.26

These numbers were obtained by analysis of both the liquid and solid matter; nitrogen as ammonia, as nitric acid, and in organic combination being estimated in all cases. In all cases there was a large decrease in ammoniacal nitrogen, ranging from 50 to 85 per cent.; and a large increase in organic nitrogen, from 35 to 63 per cent. On the other hand, the nitrogen as nitric acid only appeared, and then only in small quantities, in the mixtures 3 and 6, where gypsum had been added, which mixtures, it will also be observed, were almost free from humic acids. Apparently, then, much of the ammoniacal nitrogen is rendered insoluble by becoming organic, whilst much of it is lost. This is shown below:—

NITROGEN AS AMMONIA. PER CENT. OF THAT INTRODUCED.

Mixture	1.	2.	3.	4.	5.	6.	7.
Disappeared	49.96	49.47	71.43	61.40	70.41	67.34	85.30
Transformed	24.82	20.09	11.09	17.83	13.84	19.98	44.54
Lost	25.14	29.38	54.34	43.57	56.57	47.36	40.76

This loss of ammoniacal nitrogen would probably be larger in the great heaps in the farmyard, where the temperature much exceeds that obtained in these experiments; this is indicated by the greater loss in No. 7, where the composition was similar, but the mass and surface exposed were greater than in mixture 1. The loss is probably by volatilisation as ammonium carbonate, or perhaps fermentative. It is evident that gypsum and chalk, either alone or otherwise, increase the loss of nitrogen considerably.—D. A. L.

*Presence of Amylase in Leaves.* L. Brasse. Bied. Centr. 14, 169-170.

THE author has found amylase in all leaves he examined, including potato, dahlia, maize, turnip, tobacco, castor-oil plant, etc.; also in poppy, pink, sun-flower, and castor-oil seeds. It was extracted by Dubrunfaut's method. The leaves or seeds were bruised in a mortar, macerated for twenty-four hours in cold water, pressed, and the solution mixed with one-and-a-half times its volume of 90 to 93° alcohol and filtered. A similar quantity of alcohol was added to the filtrate, and the precipitate which contains the amylase was collected on a filter and washed with 65° alcohol. To prove the presence of the amylase in the precipitate, 0.5 grm. starch, 20cc. water, and 10cc. of an aqueous solution of the amylase, which

quantity corresponded to 10 grms. of fresh leaves, were placed in small flasks, and along with other flasks, containing the amylase solution alone, were kept in a water bath at a temperature of 63°, and the reducing sugar estimated by difference. Eight to ten drops of chloroform were added to each flask, and they were then closed with corks. Microbes were not detected in the solutions; in all cases the starch was converted into a reducing sugar and dextrin.—D. A. L.

*Poisonous Effects of Arsenic, Lead and Zinc on Vegetable Organisms.* F. Nobbe, P. Baessler, and H. Will. *Bied. Centr.* **14**, 175-183.

YOUNG and healthy growing plants were introduced into nutritive solutions to which varying quantities of potassium arsenite had been added; in many of the experiments the quantity of arsenic added in this form amounted to 0.003, 0.033, 0.333, and 1.0 grm. per litre. In all cases control cultivations were conducted with similar plants without arsenic. With the arsenic the plant withers and fades, the older leaves first, then the stem; it then recovers slightly, especially if removed to a fresh non-poisonous solution, but only to sink again and finally perish. The rapidity of this poisonous action increases with the strength of the arsenic solutions, but it also depends to some extent on the kind of plant. Peas and oats succumb quicker than maize and shrubs. Following the order of strengths given above, peas perish either in twelve, four or three days respectively. The quantity of arsenic taken up by the plant is very minute. The roots always contain more than the other parts of the plant. Many other experiments tend to show that the root is the vulnerable point: for instance, comparative arsenic cultivations were conducted in the dark in moist atmospheres, and in the light in the ordinary atmosphere. In the former case the action of the arsenic was retarded,—showing, firstly, that the roots were attacked more than the above-ground growth; and, secondly, that the transpiration or absorption faculty was effected in some way. The following experiment illustrates the latter effect:—Young alder plants were set in solutions containing 0.0003 arsenic per litre, and observations of transpiration and absorption were made every two hours during the day. After the first two hours the plant had only absorbed 40 per cent. of the normal quantity of water, and throughout the experiment the transpiration almost always exceeded the absorption, hence the plant lost in weight, and after three days, when the plant was almost dead and the experiment ended, this loss amounted to 19.2 per cent. When analysed in this condition, the dry matter of the root contained 0.008 per cent. arsenic, whilst the other part of the plant contained only 0.0029 per cent. Solutions containing only one per million of arsenic are still injuriously active, and the harmless limit of dilution has not yet been reached. The arsenic apparently attacks the protoplasm of the roots, impeding their osmotic action, and consequently diminishing the quantity of water absorbed. Similar experiments with lead and zinc demonstrate that these metals are extremely injurious to plants, whether presented in a soluble form as nitrates or in an insoluble form as carbonates; even if they are present in such small quantities that the plant appears healthy externally, their deleterious action is evident in the diminished yield of the plant. Zinc is more poisonous even in form of carbonate, than lead, and is also taken up by the plant in much greater quantities than the latter metal is. Solutions containing one-thousandth part of zinc kill plants (peas) in three days, whilst solutions of lead containing similar quantities produced a similar effect in eleven days. (See Action of Zinc Salts on Plants, this Journal, iv. [6], 408).

—D. A. L.

*Detection of Fungoid Spores and Putrefaction Germs in Cattle Foods.* A. Emmerling. *Bied. Centr.* **14**, 212-213.

SMALL quantities of the materials made into a thin magma with water are introduced into clean glass tubes, using all necessary precautions against the introduction of

foreign organisms. After being heated for twenty-four hours at 35° C., the contents of the tubes are examined microscopically. This method, when worked with care, has been found to give concordant results, and is therefore regarded as satisfactory for the detection of mould-spores, etc. Samples of sesame cake and earth-nut meal were found to be free from fungoid-spores, whereas rice meal was found full of them. With regard to bacteria, sesame cake contained bacilli and sometimes mycoderma; and earth-nut cake and rice meal, micrococci and bacilli.—D. A. L.

*Improvements in the Treatment of the Lupinus (Lupine) to adapt it for use for Cattle.* Emil Capitaine, London. Eng. Pat. 10,495, July 23, 1884.

THE object of this invention is to extract from the lupinus the bitter principle which renders it unsuitable for use as a cattle food, without at the same time impairing its nourishing properties. The plants are first kiln-dried at a temperature not exceeding 70° C., and then placed in water at a temperature ranging between 65° and 85° C. If the temperature be lower than 65°, part of the albumen is dissolved and lost for feeding purposes; if higher than 85°, a considerable portion of the proteid matter is rendered insoluble.

—E. G. C.

## XV.—SUGAR, GUMS, STARCHES, Etc.

*The Position of Sorghum Saccharatum in Agriculture and the Sugar Factory.* E. Szechenyi, jun. *Bied. Centr.* **14**, 186.

MINNESOTA amber-cane (sugar-cane) was cultivated in Hungary, and the produce treated for sugar in the American fashion. When the seed was sown before the end of April, the plants developed to complete ripeness, but seeds sown later did not ripen. The yield per joek was 115 metr. centr. of canes, 14.65 of seeds and stalks, 6.60 of cane-leaves. The 115 metr. centr. of cane gave 34.55 of green sap; and the syrup obtained from the sap by means of milk of lime, etc., when concentrated contained per cent. cane-sugar 52.10, invert sugar 28.62, water 15.74, ash 1.95, non-saccharine matter 1.50, which by centrifugalising yielded a brown cane-sugar containing over 80 per cent. of crystalline sugar. The dried seeds and stalk had the following composition (water 14.3%):—

Fat.	Albumenoids.	Non-nitrogenous nutritives.	Woody fibre.	Ash.	Sand.
3.25.....	11.20.....	80.25.....	3.25.....	1.95.....	0.10 = 100

—approximating to that of barley. The pressed canes when fresh are eaten by cattle, but not by sheep; when treated otherwise, cattle will not consume them without they are previously mixed and warmed with chaff, straw, and water. According to the author, sorghum is not an exhausting plot for the soil.—D. A. L.

*Extracting Sugar from Molasses and Saccharine Solutions.* Jünnemann. *Bied. Centr.* **14**, 216.

FOR this purpose the author recommends the use of a certain soluble magnesium hydroxide; it forms an insoluble magnesium saccharate, which, when decomposed with carbonic anhydride, yields pure sugar. The mode of preparing the hydroxide is not given.—D. A. L.

*Improvements in Purifying or Clarifying Sugar, and in Apparatus therefor.* Eugen Langen, London. Eng. Pat. 10,367, July 19, 1884.

THIS invention relates to the process of purifying sugar by washing out the molasses from the crystallised sugar by means of pure syrup. It differs, however, from the ordinary process in that it is continuous, the sugar being made to traverse the apparatus in one direction, whilst the syrup with which it is washed moves in the opposite

direction. Hence the pure syrup comes into contact with nearly pure sugar, and, as it becomes more and more impure, it meets also with less pure sugar. Special apparatus in which to carry on the operation is described.

—A. J. K.

## XVI.—BREWING, WINES, SPIRITS, Etc.

*Cultivated Wine Yeast.* A. Rommier. Bied. Centr. 14, 203-204.

IN previous communications the author has shown that the addition of cultivated wine yeast to must from different varieties of grapes accelerates fermentation at relatively low temperatures, and produces wine quicker than the natural fermentation would do; moreover, the cultivated wine yeasts, without previous sterilisation of the must, prevents secondary fermentation, which would spoil the wine. The present experiments were conducted during warm weather, hence the accelerating effect was not observed; anyway, the yeast prevented the development of deleterious germs, therefore it exerts a preservative influence on the wine, and in cold weather increases the rapidity and regularity of fermentation.

—D. A. L.

*Apparatus for the Treatment of Wine with Sulphurous Acid.* J. Nessler, Karlsruhe. Ger. Pat. 29,590, May 13, 1884.

THE cylindrical vessel A, made of tin plate and lacquered, contains an iron spoon B, and is furnished with a pipe C. When in use the apparatus is by means of the cork G fixed upon the vessel in which the sulphurous acid is to act. Some spirit is then poured into the copper vessel F (partly filled with sand or asbestos) and set on fire; the sulphur contained in the spoon B is, after previous heating of the latter, likewise set on fire, and again put into A.

The air in the ball E is heated by the burning spirit, and thus causes a draught, which supplies the sulphur with air and causes the sulphurous acid to pass into the vessel where it is wanted. In this manner sulphurous acid can be used for killing the mould and mycoderma-vinui or aceti plants in an empty or partly full cask, in which otherwise the sulphur would not burn.—F. M.

*Improvements in Making an Extract and Beverages from Clover.* J. Walker, Leeds. Eng. Pat. 8916, June 13, 1884.

THE dried clover is chopped and mashed in water; the extract so obtained is boiled with hops, and the liquor therefrom treated with citric, tartaric, or acetic acid, afterwards with a little carbonate of soda to neutralise the excess of acid, and then fined and filtered. The golden-coloured liquid so obtained is made into a syrup

with sugar, and may then be used for the production of an aerated or non-aerated beverage, or used to flavour other liquors. It may also be added to malt worts previous to fermentation, producing a beer of a fuller character and less intoxicating. It is also valuable as an anti-scorbutic.—C. C. H.

*A Process for the Continuous Distillation and Rectification of Alcohols, or other Volatile Substances, and Apparatus for the Purpose.* J. C. Mewburn, London. From E. A. Barbet, Nord, France. Eng. Pat. 9397, June 25, 1884.

THE improved process involves the employment of a distilling column or purifier in which the ethers are separated first from the alcoholic solution, and a rectifier in which the alcohol obtained in the purifier is further submitted to distillation. Both columns resemble each other in construction, and differ only in proportion of parts. The liquid undergoing distillation is first heated in the lower part of the column by the heat of the condensed material running from the column, and is then introduced into the column at the top, and in its descent undergoes fractionation, the ether condensing and collecting at the bottom, whence it runs to a receiver, and the alcohol passing to a condenser, and from thence to the second column, where it is similarly treated to the liquid in the first column. The process of distillation is therefore continuous with the operation of rectification. The interior of each column is fitted with shelves and cups, in a manner similar to the shelves used in stills. The claims are: (1) for the process of continuous distillation, (2) for the apparatus, (3) a specially constructed shelf and cup.—C. C. H.

*An Improved Method of Converting the Juice of the Jerusalem Artichoke into Levulose, and the Application of the latter for Obtaining Various Products by Fermentation and Distillation.* A. M. Clark, London. From E. L. J. Boniface, Paris. Eng. Pat. 10,686, July 28, 1884.

THE synanthrose and inulin contained in the tubers of the artichoke can only be partially converted into alcohol by distillation, various essential oils being also formed at the same time. The object of this invention is to prevent the formation of the essential oils, and to secure the maximum amount of alcohol. The tubers are pulped, and afterwards treated with a mineral acid and heated; the whole of the sugar-yielding substances being thus converted into levulose. The quantity of the acid is from 0.0005 to 0.005 of the weight of the juice, and the small excess of the acid does not necessitate the neutralisation of the juice before undergoing fermentation. A syrup may also be made by concentrating the juice in the same way as in the concentration of glucose syrups; the patentee points out that it differs essentially from glucose syrup, and consists only of levulose, and is not a mixture of dextrin and glucose. A beer may also be made in the manner usually pursued, but in this case a mineral acid must not be used.—C. C. H.

## XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

*Improvements in the Preservation of Meat Extracts.* F. Walton, Twickenham. Eng. Pat. 16,376, December 12, 1884.

MAINLY consist of processes of varnishing the external surfaces of the skins enclosing the essences or other meat preparations.—E. G. C.

*Effects produced by the Sulphurous Acid of the Atmosphere of Towns.* G. Witz. Bull. Soc. Ind. Rouen, 13, 161.

ATTENTION has been directed to the marked diminution of the quantity of atmospheric ozone during the recent epidemic of cholera in France. The observations taken at Paris and Marseille, the results of which were com-

communicated by M. Onimus to the Academy (December 15, 1884), clearly indicate a correlative bearing of the quantity of ozone upon the fluctuations of the epidemic. At Marseilles, during the month of July, the mean quantity was 0.86, as against 2.17 in the preceding year. In Paris, the mortality was at its height during the fortnight ending November 15, and the mean proportion of ozone during that period was 0.27, as compared with 2.60 for the corresponding period of 1883. Commenting upon these figures, in their purely chemical aspect, the author points out a factor of the results which has been hitherto ignored—viz., the sulphurous anhydride proceeding from the combustion of coal and coal-gas, the quantity of which in large towns must be very considerable. The necessary destruction of ozone by this gas is the explanation advanced by the author of the definite variations of the proportion of ozone observed at Montsouris, with variations in the direction of the wind. The report furnished by this observatory for 1884 states that with the winds from south to west the proportion of ozone is large; but from south-west, through north to east-south-east, the quantity is small. Observations extending over seven years show a constant minimum coincident with the prevalence of north winds. The position of Montsouris to the south of Paris suggested to the author the influence of the atmosphere of large towns upon the ozone of the air; and in considering this influence, *a priori*, the part played by sulphurous acid appeared to be probably the most important agency in the destruction of the active oxygen.

*Some Constituents of Rain Water.* Chaur. Bied. Centr. 14, 209.

RAIN water collected at the Meteorological Observatory of Algiers, was examined throughout the year, and the following substances determined:—Sodium chloride was present in quantities varying from 17.4 to 52.6 per million, iron as oxide or carbonate from 0.7 to 7.8 per million, whilst the quantity of ammonium nitrite varied from 0.14 to 0.29 per million, whereas of ammonium nitrate only traces were detected, and in two cases none at all. Neither iodine nor hydrogen peroxide were detected in a litre of water.—D. A. L.

*A New Method or System of Treating Acid Waters to Purify them.* B. Littlewood, Huddersfield. Eng. Pat. 8047, May 22, 1884.

A CISTERN is packed with a mixture of substances containing lime or its carbonate, potash or silica. Materials recommended are burnt clay, oyster shells, and a lime mortar carbonated by exposure to the air. The water is caused to rise through a mass of such material, and to flow over through a pipe at the top of the cistern.

—C. C. H.

*An Improved Mixture for Disinfecting, Deodorising, and Antiseptic Purposes.* G. R. Tweedie, London, and Hartins Crimson Salt Company, Limited, Worcester. Eng. Pat. 9538, June 28, 1884.

THE improved mixture is formed of one or more of the manganates or permanganates of the alkali metals, one or more alums, chloride of sodium or potassium, borax or other combinations of the alkali metals with boric acid. Such a mixture is said to be more powerful for the purpose set forth than any of the components alone. The following proportions are given as yielding good results:—Potassium permanganate, 1 ounce; potash alum, 8 ounces; borax, 1 ounce; common salt, 6 ounces. The proportions may be varied with equally good results. The compound may be applied in the usual way in the form of powder or as a solution, in which case it is much more powerful.—C. C. H.

*Improvements in the Treatment of Sewage or Foul Waters, or other Solid and Liquid Impurities or Foul Matters, for the purpose of Deodorising the same, and for the Prevention of the Formation of Sewer Gas.* J. Hanson, Wakefield. Eng. Pat. 9587, June 30, 1884.

TO effect the deodorisation of sewage and matters of a similar nature, the patentee proposes to add a solution of the waste product known as "black-ash waste." The

drawings from waste heaps may also be used with an equally good effect. The "decoction" may be prepared by the addition of 25lb. of the waste to 100 gallons of water. The deodorisation is stated to be effected by "the vapours or vapourisable matters becoming fixed, and they cannot afterwards decompose."—C. C. H.

*An Improved Compound for Disinfecting.* H. B. Condy, Battersea. Eng. Pat. 10,015, July 10, 1884.

THIS invention deals with the production of permanganate of alumina for use as a disinfectant, this salt having the advantage of yielding, for the purpose of oxidation, five-sevenths of the oxygen it contains. In 1000 parts by weight of a solution of sulphate of alumina, containing one-third of its weight of the sulphate, 53 parts of permanganate of potash are dissolved by heat; the mixture is allowed to cool, and the potash alum formed crystallises out, leaving the permanganate of alumina and the excess of the sulphate of alumina in solution. The proportions given above may be varied, but those stated are the most convenient. In some cases where the solution is intended to be used quickly, it may be found advantageous to add the equivalent quantity of sulphuric acid instead of the sulphate—say, 1 part of acid for each 7 parts of the sulphate of alumina.

—C. C. H.

*Improvements in Apparatus or Means to be employed in effecting the Softening or Purification of Water and for other Purposes.* H. Porter and J. H. Porter, London. Eng. Pat. 10,459, July 22, 1884.

THIS invention has for its object an improved method of supplying automatically the solution of lime to the hard water undergoing treatment by the Clark process, and is an improvement upon former patents taken out by one of the present patentees. The lime water is admitted into a vessel containing an indiarubber or flexible bag, which bag is afterwards distended by water, admitted under pressure, and thus forces out the reagent into the vessel in which the admixture with the hard water is effected.—C. C. H.

*An Improved Process of Deodorising, Disinfecting, Precipitating, Drying, and Pulverising the Solid Portions of Sewage to render it a Marketable Manure.* W. Astrop, Tottenham. Eng. Pat. 11,901, Sept. 2, 1884.

THE precipitation of the sewage is effected in tanks in the usual way with a combination of sulphate of calcium, carbonate of alumina, sulphate of potash or soda, and finely-ground ashes. The reagent is obtained by mixing milk of carbonate of lime with sulphate of alumina, or soda of potash alum; "carbonate of alumina" is formed, the calcium carbonate is transformed into hydrated sulphate of calcium, and the potash or soda salts remain as their respective sulphates. After the precipitation is effected, the sludge is collected from the tanks and discharged on to a travelling band which passes over vacuum boxes, the water thereby being removed to a considerable extent. The partially-dried sludge is then passed through rollers, where a further quantity of moisture is removed. The cake passes on the same band, and is discharged into a revolving drum formed of open wire-work, through which a current of hot air is drawn by a fan or other means, the dried sludge finally being discharged through the meshes of the drying cylinder ready to be bagged as a manure.—C. C. H.

*Improvements in Filtering Compounds and in the Construction of Filters for Industrial and other Purposes.* C. E. Chamberland, Paris. Eng. Pat. 3423, March 17, 1885.

THE filtration of water, especially that used for domestic purposes, is effected through a medium composed of pipe clay and porcelain clay, the proportions of which may vary. The mixture is moulded into the desired shapes, and baked at a temperature of 2400° F. The apparatus consists of a number of tubes made as above described,

and placed in the interior of a cylindrical vessel into which the water is forced; it filters through the tubes into the lower part of the apparatus effectually purified. Three claims are made for the compound as described and the apparatus.—C. C. H.

*Destroying and Utilising Sewage in Buildings, Towns, and Cities.* A. Engle, Metz, Iowa, U.S.A. Eng. Pat. 4046, March 31, 1885.

To effect the objects described in the title, the patentee proposes to collect the excreta, both solid and liquid, in a vessel in connection with the pan of the closet, etc., from whence it falls, on the opening of a suitable valve, into a retort. When the retort is charged the whole is submitted to destructive distillation; the gaseous bodies are collected into a pipe and passed through the furnace surrounding the retort, so that they are not only effectually destroyed, but also afford heat for the distillation of the contents of the retort itself.—C. C. H.

*Improvements in Processes for Treating Sewage and other Waste Waters for obtaining the Fats, Fatty Acids, and Fibrous Matter contained in the same, and in Apparatus to be employed therewith.* W. H. Beck, London. From H. Wagener and Professor Dr. A. Müller, Berlin. Eng. Pat. 4207, April 2, 1885.

The object of this invention is the extraction and utilisation of fat, grease, cellulose and fibrous matter from sewage. The sewage is first settled in a tank in order to deposit the sand and heavy ponderable matter, after which it is passed through an apparatus described in the specification at great length. The operation is as follows:—The sewage water is led through a succession of pipes to a receptacle where the remainder of the fine sand is settled out and carried away by a screw in the lower part of the U-shaped tank. From this tank the liquid passes into a conical screen, where the coarser fibrous matter is intercepted, and delivered on to a travelling band, which carries it from the machine, to be treated as described further on. The finer fibrous matter is then taken out by a travelling wire-work screen, provided with brushes, and delivered into a tank at the end of the machine. The liquid sewage passing from the machine is treated with lime or any other process, and the fine mud collected, and after treatment by an acid to liberate the fat from the lime soap formed, is shaped into cakes in a filter press, and treated with any suitable solvent to extract the grease. The fibrous matters are finally treated in a similar manner to obtain the fatty matters, and the residuum made into paper or coarse cardboard.—C. C. H.

## XVII.—ELECTRO-CHEMISTRY.

*Decomposing Metallic Haloid Salts by Electrolysis.* C. Hoefner, Berlin. Eng. Pat. 6736, April 23, 1884.

In the electrolysis of haloid salts of the light and heavy metals, especially those of the alkalis, the difficulties resulting from polarisation have hitherto hindered an advantageous application of electricity on the large scale. The present process consists chiefly in preventing polarisation by the use of depolarising substances at the cathode, or by circulation of the electrolyte. It is thus possible to decompose chlorides, and to utilise the chlorine therein. Thus, to prepare by electrolysis from any chloride, the chlorine required for the extraction of metals, a conducting substance which cannot be attacked by chlorine, such as carbon or manganese ore, is used as an anode in the solution of the chloride, this solution being caused to continually flow in and out at the same, whereby the chlorine liberated is carried away. According to the speed of flow of the liquid, so can it be more or less saturated with chlorine. To avoid the separation of hydrogen at the cathode, the latter, which may consist of any conducting material, is surrounded with a substance which prevents polarisation; such substances are those which are reducible by hydrogen. The salt lyes, charged with chlorine, by this

method may be employed for the extraction of silver and gold. The chloride lye is first saturated with chlorine at the anode, then mixed with auriferous ore and reduced at the cathode, and then returned to the anode for a fresh charge of chlorine. Other applications of the process are indicated.—J. T.

## XIX.—PAPER, PASTEBOARD, Etc.

*Improvements in Sulphite Wood Pulp.* S. Pitt, Surrey, England. From R. P. Piect and G. L. Brélat, Switzerland. Eng. Pat. 9509, June 27, 1884.

The chief points of interest in this specification are:—(1) The use of supersaturated aqueous solutions of sulphurous acid gas, having a gaseous tension of from 5 to 6 atmospheres at a temperature below 100° C. (2) The use of a vacuum for mechanically removing the air contained in the wood, to facilitate the penetration of the acid liquid into the fibres, (3) Employing temperatures below 100° C., in order to avoid the decomposition of the resins, etc., incrusting matters in the wood, (4) "Retreating the solutions from the boilers, and recovering a large portion of sulphurous acid gas contained in these liquids," (5) Preparation of "gums, resins, tannin, alcohol etc.," from the solutions of incrusting matter. Attention is drawn to the fact that the high temperature which it is essential to employ with sulphites of soda, etc., cause the formation of particles of tar or pitch which penetrate the fibre, and render bleaching laborious and very costly. The washings, etc., which then become essential, much injure the whiteness of the product; the yield is reduced, and the strength of the fibre impaired by the repeated action of bleaching liquor. When the wood is sufficiently boiled, the acid solution contains a number of different products, of which the following are the principal: (1) A large proportion of gums, resins, and glucose from the incrusting substances and essential oils of wood. (2) Sulphate of lime in small proportion. (3) Almost the whole of the sulphurous acid. "The bleaching by chloride of lime is preceded in this manufacture by the action of sulphurous acid, which diminishes very considerably the cost of this operation."—H. A. R.

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

*Method for the Preparation of Quinoline Disulphonic Acids.* N. La Coste, Aachen. Ger. Pat. 29,920, April 20, 1884.

The mixture of the two isomeric monosulphonic acids obtained by the treatment of quinoline with fuming sulphuric acid, is heated with the double quantity of fuming sulphuric acid to 200-240°. From the product the sulphuric acid is separated in the usual manner, the disulphonic acids are converted into the potassium salts, and separated by repeated crystallisation; potassium  $\alpha$ -quinoline disulphonate being the more soluble one. By melting the potassium or sodium salts of the quinoline disulphonic acids with about 3 parts caustic potash or soda at 180-200°, the salts of the corresponding oxyquinoline sulphonic acids,  $C_9H_7N.SO_3H.OH$ , are formed. By increasing the quantity of caustic alkali to 5 parts for 1 of quinoline disulphonate, and raising the heat to 290-310°, dioxiquinolines,  $C_9H_7N(OH)_2$ , are formed. In order to separate the  $\alpha$ -dioxiquinoline, which is the principal product of the reaction, the melt is carefully neutralised with hydrochloric or sulphuric acids, and the  $\alpha$ -dioxiquinoline extracted by means of ether. By evaporating the neutral or slightly acid solution of the melt to dryness, the dioxiquinoline or its salts can also be extracted from it by alcohol, wood-spirit or similar solvents.

—F. M.

## XXI.—GENERAL ANALYTICAL CHEMISTRY.

*Method for the Estimation of Free Sulphuric Acid in Vinegar.* B. Kohnstein. Dingl. Polyt. J. 256, 128.

100cc. of vinegar are neutralised with the necessary quantity of pure magnesia, and filtered. From 25cc. to

30cc. of the filtrate are evaporated to dryness in a platinum basin. The residue is gently ignited until all the magnesium acetate is decomposed. Water containing carbonic acid is then added, and the whole again evaporated to dryness, in order to render the magnesium carbonate formed during the process of ignition more granular, as in this state it is easier to wash. The magnesium sulphate is extracted from the carbonate by means of hot water. After separating the small quantity of lime which may happen to be present in the filtrate, the magnesia contained in it is estimated as pyrophosphate. From the quantity of the latter the quantity of free sulphuric acid contained in the vinegar may be calculated. The author gives the results of some analyses of mixtures of pure dilute acetic and sulphuric acids of known composition, which testify to the value of his method. The small quantities of magnesium salts usually occurring in vinegar may influence the results, but the error is so slight that it may safely be neglected.

—F. M.

## Monthly Patent List.

### ENGLISH APPLICATIONS.

1885.

#### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

8190 J. C. Mewburn, London.—Communicated by F. C. E. Simon, France. Improvements in evaporating, distilling, and refrigerating apparatus. July 6  
8225 H. C. Paterson, Glasgow. Improvements in smoke-consuming furnaces. July 7  
8301 T. C. Fawcett, Halifax. Improvements in machinery for making sappers, crucibles, and similar moulds, also applicable to the moulds of brick-making machines. July 9  
8353 A. E. Robinson, Edgbaston. Improvements in appliances for producing and condensing vapours. July 10  
8327 W. R. Lake, London.—Communicated by J. W. Hyatt, United States. Improvements in filtering apparatus. July 11  
8315 H. Kullig, London. Improvements in Royle's condensation apparatus. Complete specification. July 16  
8306 E. Edwards, London.—Communicated by L. Rohrmann and M. Heller, Germany. Improvements in apparatus for effecting the absorption of gases or vapours by liquids. July 16

#### II.—FUEL, GAS, AND LIGHT.

7381 E. Capitaine and O. Brunler, London. Improvements in the production of compressed gaseous compound for use in gas motors and for other purposes, and apparatus therefor. Complete specification. June 22  
7615 J. D. Bodwell, London. Improvement in apparatus for the combustion of liquid fuel. Complete specification. June 23  
7645 L. A. Groth, London.—Communicated by F. Garavagne & Co., Italy. A new or improved gas carburetted apparatus. June 23  
7791 S. Butler, London. Improvements in apparatus for mixing and heating materials for the manufacture of patent fuel. June 23  
7815 R. Dempster, Manchester. Improvements in the construction of stand pipes for gas retorts. June 27  
7893 T. G. Marsh, Falsworth, Lancashire. Improvements in gas-lighting and heating. June 30  
8305 W. A. Melakosh Yalon, London. Improvements in machinery or apparatus for the manufacture of compressed artificial fuel. July 1  
8097 H. J. W. Raphael and J. Syme, London. Improvements in means for preventing nuisance from smoke, and for utilising the gaseous products of combustion from furnaces or the like for lighting or other purposes. July 3  
8316 T. Chappell and C. H. Adames, Blackstock Road. Improvements in the manufacture of fuel. July 14

#### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

7563 A. M. Clark, London.—Communicated by A. Cozé, France. Improvements in retorts for the distillation of coal and other solid matters, and in apparatus connected therewith. June 20  
8184 L. T. Wright, London. Improvements in or connected with the hydraulic means used in the distillation of coal. Complete specification. July 6

#### IV.—COLOURING MATTERS AND DYES.

7191 H. J. Hadden, London.—Communicated by Dr. R. Worms, Saxony. A new manufacture of blue colouring matter. June 19  
7620 C. E. Avery, London. The improved manufacture of extracts and liquors of logwood. Complete specification. June 23  
7731 L. Heffter, London. Drying alizarin and dissolving it afterwards. June 25  
7841 H. H. Lake, London.—Communicated by Wirth & Co., agents for A. Liebmann, Germany. Improvements in the manufacture of naphthylamine sulpho-acid. June 27  
8211 T. Frusher, London. Improved manufacture of ink from waste dye liquors. July 7

#### VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

8143 A. Howell, London. Improvements in apparatus employed for bleaching purposes. July 13

#### VII.—ACIDS, ALKALIS, AND SALTS.

7511 G. H. Bolton, Liverpool. Improved fastening device applicable to, or improvements in, heats and lids or covers of caustic soda or other drums, etc., in which a nearly cylindrical part is required to be quickly fastened and loosed. June 21  
7517 E. W. Farnell and J. Simpson, Liverpool. Improvements in the separation of sulphuretted hydrogen from nitrogen. June 24  
7691 R. F. Freeman, London. An improvement in nitrous oxide gas, or other compressible gases or gas bottles. June 24  
7831 T. Copper, London.—Communicated by Dr. S. Piek, Austria. Improvements in apparatus for making bicarbonate of sodium. June 27  
7841 O. N. Witt, London. A process for the manufacture of hydrochloric acid adapted to be used in connection with the ammonia soda process. June 27  
7867 A. Brin, London. Improvements in the manufacture of bixide of barium and its use in making oxygenated water for bleaching or for other purposes. June 29  
8071 C. C. Springer, Manchester. Improvements in the manufacture of sulphurous acid gas (SO<sub>2</sub>), and in the apparatus employed in such manufacture. July 3  
8194 B. J. B. Mills, London.—Communicated by J. M. Duncan, United States. Improvements in means or apparatus employed in the manufacture of salt from brine, and in producing a means for the manufacture of soda ash, and other chemicals. July 6  
8260 T. Robinson, Glasgow. Improvements in the manufacture of alum and sulphate of alumina. July 8  
8304 T. B. Saunders and A. V. Saunders, Bradford. Improvements in the method of, and apparatus for, generating dry hydrochloric acid gas for the carbomisation of vegetable matter mixed with wool and woollen rags. July 9  
8322 H. Richardson, Jarrow-on-Tyne. Improvements in the manufacture of hydrate, sulphate, and other salts of alumina. July 11  
8322 W. P. Thompson, Liverpool.—Communicated by B. Osann, Germany. A new or improved process of manufacturing caustic alkalis during the purification of iron by the Thomas-Gilchrist process. Complete specification. July 11  
8410 E. W. Farnell and J. Simpson, Liverpool. Improvements in obtaining sulphuretted hydrogen from sulphide of ammonium. July 13  
8470 F. Maxwell-Lyte, London. Improvements in the production of chlorine and apparatus therefor. July 13  
8490 W. Allen, London. Improvements in acid taps and valves and seats for chemical works. July 11  
8341 H. Leplay, London. Improvements in decarbonating the carbonates of strontia and baryta, and in apparatus therefor. Complete specification. July 11  
8092 N. Glendinning, Liverpool. Improvements in the treatment of copper liquors. July 16  
8323 S. H. Johnson and C. C. Hutchinson, London. Improvements in preparing milk of lime, and in apparatus to be used therefor, and for other such like purposes. July 16

#### VIII.—GLASS, POTTERY, AND EARTHEN-WARE.

7397 C. C. Thompson, London. Improvements in machines for making pottery, glass-ware, and articles of all kinds from soft plastic materials which are capable of being moulded. Complete specification. June 30  
8354 W. P. Thompson, London.—Communicated by C. Potts and A. Potts, United States. Improvements in machinery applicable for finely dividing and tempering clay. Complete specification. July 15

#### IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

7912 W. B. Smith, London. Improvements in binding bricks and other building blocks. June 30  
8153 W. P. Thompson, Liverpool.—Communicated by R. Bosse and F. Wolters, Germany. Improved process for rendering cements hydraulic, that is to say, capable of setting and hardening under water. July 6

8347 T. C. Fawcett, Halifax. Improvements connected with machinery for making bricks, tiles, pipes, and tubes. July 10  
 8353 J. Matthew, London. Improvements in the treatment of stone in order to produce a glazed surface thereon. July 10  
 8368 H. Stanley, London. Improvements in machinery for pressing and moulding bricks, tiles, and the like. July 11

## X.—METALLURGY, MIXING, ETC.

7510 P. Jensen, London.—Communicated by J. Omholt and The Chemische Fabrik Gossnitz, Germany. Improvements in the continuous manufacture of light metals by application of electrolysis and in apparatus therefor. June 19  
 7571 G. A. Jarvis and A. E. Tucker, Shifnal. Improvements in Bessemer or basic converter bottoms, plugs, or blocks. June 22  
 7597 J. Y. Johnson, London.—Communicated by E. Deligny, France. An improved process for purifying copper precipitates. June 22  
 7740 A. M. H. Munro, London. Improvements in the treatment of basic cinder. June 25  
 7762 E. Robbins, London. Improvements in plain, ornamental, decorative, and constructive works manufactured from slag. June 25  
 7802 E. Fletcher, London. Improvements in the treatment of pig iron for eliminating impurities during the process of its conversion into malleable iron or steel, also applicable for analogous purposes. June 25  
 7845 J. Platt, Sheffield. Improvements in furnaces for metallurgical and other purposes. June 25  
 7846 T. Hampton, Manchester. Improvements in the manufacture of steel ingots. June 29  
 7858 H. von Groussillers, London. A process for producing aluminium (Al) from chloride of aluminium (AlCl<sub>3</sub>) by employing pressure. Complete specification. June 29  
 7856 J. Y. Johnson, London.—Communicated by J. Jacobi, Austria. Method of obtaining phosphatic slags of high titre by the Thomas-Gilchrist process. June 29  
 7859 J. P. Reitz, Bockenheim, Germany. Acid-proof gun-metal. June 29  
 8008 P. C. Bunn, London. The utilisation of the by-products or waste of lead ores for the manufacture of pigments therefrom. July 1  
 8039 H. Bain, London. Tinning and finishing tin and terne plates and in machinery used therefor. July 2  
 8161 W. E. Gedge, London.—Communicated by G. Guillemin, France. A novel alloy intended to replace copper in its principal applications. July 6  
 8291 P. Norénfeldt, London.—Communicated by C. G. Wittenström, Sweden. Improvements in the manufacture of castings from wrought iron and steel. Complete specifications. July 8  
 8295 P. J. Davies, London. Improvements in apparatus for lead burning. July 8  
 8318 T. Bayley, Birmingham. Improvements in the treatment and utilisation of scrap tin plates. July 9  
 8336 C. D. Abel, London.—Communicated by F. C. Glaser, Germany. Manufacture of blocks of combined ingot iron and powder or fuzet from iron. July 9  
 8390 E. Watkins, Eagleville, California. Improved welding compound and process of preparing the same. July 10  
 8418 J. Y. Johnson, London.—Communicated by E. Deligny, France. An improved process for purifying copper precipitates. July 11  
 8478 J. T. King, Liverpool.—Communicated by S. T. Owens, United States. Improvements in metallurgical furnaces. Complete specification. July 11  
 8484 A. H. Emery, London. Improvements in wrought metal plates for use in the construction of boilers, ships, and other bolted or rivetted work, and in the manufacture and treatment of the same. July 11  
 8487 A. H. Emery, London. Improvements in wrought metal columns, beams, girders, and other members designed to bear compression or transverse loads in bridges, buildings, and other structures, and in the manufacture and treatment of the same to increase their rigidity and strength. July 14  
 8574 H. K. Cassel, London. An improved process and apparatus for treating metals, alloys, and especially auriferous ores, by electrolysis. July 15

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

7645 T. Berliner, London. Process and apparatus for extracting fat from bones and other fatty matter. June 23  
 7701 J. Y. Johnson, London.—Communicated by C. Goublier, France. Improvements in the manufacture of candles. June 24  
 7972 O. C. Hagemann, London. Improvements in the purification of glycerine. July 1  
 7973 O. C. Hagemann, London. Improvements in purifying and concentrating glycerine, applicable also to the concentration of other matters. July 1  
 8041 O. C. Hagemann, London. Improvements in the treatment of soap lye to obtain products therefrom. July 2  
 8250 F. Walton, London. Improvements in the manufacture of oxidised or solidified oil, and in the application of the same to wires and strands. July 7  
 8403 A. Michel, London. Improvements in apparatus for treating fatty matters in order to obtain fatty acids and glycerine therefrom. July 11

## XII.—PAINTS, VARNISHES, AND RESINS.

7485 A. McLean, London. Improvements in the manufacture of pigments. June 19  
 7494 H. H. Lake, London.—Communicated by S. Roebuck, United States. An improved composition or paint for coating brickwork, ironwork, and the bottoms of ships, and for similar purposes. Complete specification. June 19  
 8008 P. C. Bunn, London. The utilisation of the by-products or waste of lead ores for the manufacture of pigments therefrom. July 1  
 8059 T. Ferrell, London. Improvements in the preparation of pigments from sulphate of iron. July 2

## XIII.—TANNING, LEATHER, GLUE, AND SIZE.

7561 W. Paul, London. Improvements in machinery for heating, softening, and graining leather. Complete specification. June 20  
 7818 A. Johnson, Liverpool. Improvements in leather, and in the manufacture or treating of the same. June 27  
 7945 T. R. Clark, London. Improved process for the manufacture of glazed leather. Complete specification. June 30  
 8235 G. F. Iedema, London.—Communicated by A. Hockingham, Belgium. The manufacture of an improved material to be used as a substitute for leather, and for other purposes. July 16

## XV.—SUGAR, STARCH, GUM, ETC.

7533 A. Ralu ( fils ), J. Grathwohl and H. A. Brown, London. Solidifying syrups and molasses, especially those of sorgho and sugar cane, by mixing them with substances adapted for distillation. June 20  
 7590 E. Hoefling, London. Improvements in the manufacture of gelatine. June 22  
 7657 J. H. Bridges, London. Improvements in or connected with vacuum apparatus employed in the manufacture or refining of sugar, or for other purposes. June 23  
 7745 C. W. Guy, London. Improvements in sugar-cane crushing mills. June 25  
 7811 F. Wihoff, London. Improvements in vulcanised soft rubber, and process of making the same. Complete specification. June 30  
 8000 A. Seyberlich and A. Trampedach, London. Improvements in the manufacture of crystallised grape sugar. July 1  
 8275 H. H. Lake, London.—Communicated by F. O. Matthies, United States. Improvements relating to the filtration and decolourisation of sugar liquor, or syrup, and to apparatus therefor. July 8

## XVI.—BREWING, WINES, SPIRITS, ETC.

7531 A. Ralu ( fils ), J. Grathwohl and H. A. Brown, London. Utilising as a commercial and industrial substance, sweet potatoes and yams (Yponomea, Batatas, and Dioscorea), by means of desiccation and pulverisation. June 20  
 7535 A. Ralu ( fils ), J. Grathwohl and H. A. Brown, London. Distilling spirits from desiccated or tritured sweet potatoes and yams. June 20  
 7750 T. J. Cassel, London. An improved self-acting apparatus for heating and circulating worts in brewers' mash tuns. June 25  
 7744 E. Luck, London. Improvements in or additions to apparatus for the manufacture of perfumed or flavoured spirit. June 25  
 7788 L. Cuisinier, Liverpool. A new and useful process for preventing from any possible alterations the saccharification of amylaceous substances by malt. June 26  
 7830 T. P. Hinde, Darlington. Boiling malt liquors, etc., by the application of steam. June 26  
 7835 A. A. Vale, London.—Communicated by The Chemische Fabriks Actien Gesellschaft, Germany. A method of rendering spirits unfit for use as liquors for drinking. June 27  
 8442 G. Smallman, Newnham. The better ventilating and heating of steeping and malt kilns. July 6  
 8453 S. Rhoden, London. Improvements in brewers' and distillers' mash tuns. July 15

## XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, ETC.

7703 B. D. Henley, Liverpool. Improvements in furnaces for burning town refuse and decomposing the fumes therefrom. June 25  
 7714 P. Smith, Fallowfield, Manchester. Improvements in the means and apparatus for the separation of solids and semi-solids from sewage and other liquids. June 25  
 7750 J. M. H. Munro, S. H. Johnson, and C. C. Hutchinson, London. Improvements in the treatment of sewage. June 25  
 7955 W. H. Hartland, Glasgow. Improved means for filtering and purifying water. June 29  
 8055 W. B. G. Beuret, London. Improvements in the method of and arrangements for treating and disposing of sewage, and purifying foul water. July 2  
 8081 S. Hubbard James, Tottenham. Improvements in the treatment of sewage. July 3  
 8462 W. Hicks, London. Improvement in the separation or filtration of solid and liquid matter. July 6

8282 O. F. Öberg, London. A new mode of manufacturing filtering material for purifying water from micro-organisms. Complete specification. July 8  
 8406 W. D. Borland, Stowmarket. Improvements in disinfectants. July 11

### XIX.—PAPER, PASTEBOARD, ETC.

7495 H. J. Hadden, London.—Communicated by C. H. Voigt, Saxony. Process for preparing fodder from certain waste products obtained in the manufacture of cellulose or paper pulp. June 19  
 7772 J. Petrie and F. W. Petrie, Rochdale. Improvements in machinery for cleansing "Esparto" and other grass and fibrous material used in the manufacture of paper. June 26  
 7886 J. G. Stephens, London. Improved method of and apparatus or machinery for cleaning and separating the pulpy matters from the fibres of leaves and plants. June 29  
 7932 C. H. Roekner and F. L. Roekner, London. Improvements in pulp strainers. June 30  
 8012 A. J. Boulton, London.—Communicated by W. C. Zeidler, Canada. Improvements in the treatment of celluloid, xylonite, and of similar substances. Complete specification. July 1  
 8073 C. C. Springer, Manchester. Improvements in the construction of boilers for treating wood and other fibre in the manufacture of paper and other pulp. July 3  
 8130 T. R. Shillito, London.—Communicated by C. Arnold, Germany. Improvements in the manufacture of paper parchment or vegetable parchment. Complete specification. July 4  
 8244 G. M. Peters, London. Improvements in machines for manufacturing cartridge shells from paper, wood pulp, etc. Complete specification. July 7  
 8396 H. Mason, London. A machine for the manufacture of parchment paper. July 11  
 8434 J. Wood and J. R. Penman, Edinburgh. An improved pulp strainer for straining pulp before it passes to the paper-making machine. July 13  
 8616 F. N. Black, London. Improvements in pulp-screening machinery. Complete specification. July 16

### XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

7527 H. N. Draper, Rathmines. The preparation of a colourless or decolourised solution of iodine. June 20  
 8323 H. E. Newton, London.—Communicated by G. Michaelis and W. T. Mayer, United States. Improvements in the manufacture of chloroform and acetic acid or purified acetates. Complete specification. July 11  
 8357 E. Kent, London. Iodine colloid for external medicinal use. July 16

### XXI.—EXPLOSIVES, MATCHES, ETC.

7640 A. J. Boulton, London.—Communicated by W. F. Wolff and M. de Forster, Germany. An improved method of charging hollow projectiles with compressed granular explosive substances. Complete specification. June 23  
 7725 T. Smith, London. Safety dynamite shells, or shells loaded with other dangerous explosives. June 25

### XXII.—ANALYTICAL CHEMISTRY.

8610 C. G. P. de Laval, London. A new method of and apparatus for determining the quantity of fat in milk. July 16

### ENGLISH PATENTS PUBLISHED.\*

APPLIED FOR DURING 1881 AND 1883.

#### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

1884.

10812 J. Maclear. Furnaces for chemical processes. 6d

1885.

5903 O. Inray.—Communicated by H. B. Scott. An improvement in filter presses. 1d  
 6053 E. Burton. Furnaces for the combustion or destruction of refuse. 6d

\*Any of these specifications may be obtained by post, by remitting the cost price, plus postage, to Mr. H. Reader Luck, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 8d. ....	1d.
Above 8d. and not exceeding 1s. 6d. ....	1d.
" 1s. 6d. " " 2s. 4d. ....	1d.
" 2s. 4d. " " 3s. 4d. ....	2d.

#### II.—FUEL, GAS, AND LIGHT.

1881.

11040 A. F. Link.—Communicated by T. Baucr. Improvements in the construction of coke ovens. 6d  
 11543 T. Nordenfelf.—Communicated by L. Nobel, C. G. Wittenstrom, E. Faustman and P. Ostberg. Apparatus to be employed in burning naphtha or other volatile liquid, applicable especially for melting metals which are difficult of fusion. 8d

1885.

802 A. J. Boulton.—Communicated by J. Hanlon. The manufacture of illuminating gas from hydrocarbon or other oils and apparatus therefor. 8d

### CHANGE OF ADDRESS REQUIRED.

A. French, 1/o 29, Washington Street, North Shields.

## INTERNATIONAL INVENTIONS EXHIBITION, LONDON.

### REPORT ON THE EXHIBITS RELATING TO THE CHEMICAL INDUSTRIES.

BY WATSON SMITH,

Lecturer in Chemical Technology in the Victoria University,  
Manchester, etc.

[In this Report the exhibits of the various industrial branches will be described as nearly as possible in the order observed in the general arrangement of the matter printed in this Journal.]

### FUEL, GAS, LIGHT, ETC.

#### THE SIMON-CARVÉ COKE-OVENS, WITH ACCESSORY PLANT (Group II. No. 210).

An inspection of the fine model of the Simon-Carvé coke-oven, together with the specimens exhibited, will practically answer any questions that may be asked concerning these ovens. The colouring matters and dyed specimens shown are sufficient to prove to the most sceptical that the tar contains the aromatic

substances always found in ordinary gas-tar, and that it is identical with the latter in composition. The specimens of ammoniacal liquor and ammonium sulphate indicate the value of the aqueous by-product. The Carvès oven is not one which has been suddenly developed in its present form. Mons. Carvès was certainly the first, many years ago, when he improved the old Knab's coke-oven, to recognise the fact that an aromatic tar must be a high-temperature tar, that it must be generated in a closed coking-space, and that the high temperatures required must be evenly applied throughout the mass of fuel. He solved the problem both as regards the coke for blast-furnaces and other metallurgical purposes for French and Belgian coals, and Mr. Henry Simon of Manchester, in conjunction with M. Carvès, is solving it very satisfactorily in the case of many of the English coals. However, the solution of the coke problem is, after all, by no means a one-sided matter, for it is the great ironmasters of this country that must decide the question as to whether it will stand as well and go as far as the cokes produced in other forms of coke-oven. The tar and ammonia questions have no charms for them, except in cases in which they have coke-ovens of their own, and hence the test of their experience may be looked upon as a crucial one. Quite recent work in these ovens with Staffordshire coal is yielding coke so exactly identical, even in appearance, with that from the Beehive ovens, that it is being bought by ironmasters for blast-furnace use as fast as it can be made, and at the usual prices.

In the exhibit are shown, in diagram form, comprehensive plans and sketches of a Simon-Carvès coke-oven plant, with apparatus for the recovery of tar and ammonia, and of benzenes from the gas, before the latter is burnt in the ovens. There are also to be seen specimens of coke produced from coals of various districts where the Simon-Carvès ovens are being worked.

Other exhibits of interest, under this heading, not in the Chemical Section, are (*Group XVI*):—

THOMAS FLETCHER, OF WARRINGTON (1534).  
Gas-fires and furnaces, burners, etc.

T. J. CONSTANTINE (1536).  
Improvements in furnaces for steam boilers, for the consumption of smoke, etc.

ROBERT WALKER (1539).  
Patent hydrocarbon furnace without smoke, sparks, or ashes.

FREDERICK SIEMENS (SUCCESSOR TO THE LATE SIR WM. SIEMENS) (1544).

Regenerative gas-furnaces and gas-producers of improved forms, for the manufacture of open-hearth steel and of glass, in a continuous manner (see also this Journal, iv. [7], 439).

C. KINGSFORD (1546).  
Steam boiler combined with coke and other ovens for utilising heat hitherto wasted.

#### DESTRUCTIVE DISTILLATION, TAR PRODUCTS, ETC.

BRUCE T. T. P. WARREN'S PATENT PETROLEUM (*Group XIV*, No. 1430).

The patent process in question is described in abstract form in this Journal, iii. [9], 475; and in Eng. Pat. 5525, November 26, 1883.

The object of the process is to obtain a neutral and inodorous product from petroleum volatilising at a low temperature without residue. The raw petroleum is repeatedly treated with sulphuric acid, and afterwards the sulpho-acids are carefully removed, and also all moisture. It is then found that the resulting spirit is miscible with chloride of sulphur, without in the least involving its decomposition, a matter of great importance in preparing so-called cold-cured water-proof fabrics. Possessing considerable solvent power, the spirit, it is stated, may be used for all the purposes to which carbon bisulphide is applied; and the fact is pointed out that a poisonous article like carbon bisulphide being replaceable by a harmless one, may be of great advantage to many industries.

Among the articles exhibited, the following are noteworthy:—

*Anthracene* obtained from the ordinary "crude pressed," without the serious loss entailed by its previous sublimation. This article is almost pure, and bears exposure to light without changing colour.

*Elastic Varnishes*, coloured with pigments, to show the non-acid character of the solvent.

*Inodorous and Quickly-drying Paints*, suitable for iron, wood, etc.

*Coloured Lacquers*, showing its suitability to replace alcohol or similar solvents.

YOUNG'S PARAFFIN LIGHT AND MINERAL OIL COMPANY, LIMITED (*Group XIV*, No. 1426).

Messrs. The Young's Paraffin Light and Mineral Oil Company, Limited, show specimens of the various products made by them. Their exhibit includes samples of shale, crude oil, the various burning and lubricating oils, and candles; they also show a number of extremely handsome lamps, made at their lamp factory at Birmingham.

Among the most interesting of this company's exhibits are two very large and splendid blocks of refined paraffin wax of a pure white colour, and weighing respectively 3cwt. and 7cwt.; also burning oils specially prepared for use in lighthouses and on board steam-ships. These oils have a "flashing point" very much above the Government standard, so that perfect safety is thereby secured. A great variety of lubricating oils adapted for special purposes are also shown.

Of more particular chemical interest is a set of solid paraffins, with melting points ranging from 70° to 150° F. There are also preparations of the various bodies found in crude oil, got by the destructive distillation of bituminous shale; these consist of (1st) a series of paraffins ( $C_nH_{2n+2}$ ) from heptane  $C_7H_{16}$  upwards; (2nd) the phenols and allied bodies removed by treatment with caustic soda; and (3rd) the basic compounds, leucoline, iridoline, etc., prepared from the tar obtained when the crude oil is treated with sulphuric acid.

Among the specimens of special interest exhibited are—

1st.—A cylinder of a yellow powder marked chrysene. If this body has been fully proved to be chrysene, its existence amongst the highest boiling constituents of a tar composed so chiefly of paraffins is very interesting, especially if it exist in such apparent quantity, and unaccompanied by other aromatic hydrocarbons, usually found with it.

2nd.—A series of products of value obtained by carefully working up the various by-products of this interesting industry; these are—

(i.) *Oxalic acid*, obtained by treating some of the less useful oils with nitric acid.

- (ii.) *Alum*, prepared by the action of "spent vitriol" or "acid tars" on spent shale.  
 (iii.) *Sulphate of ammonia*, very white in colour, is also obtained by the use of "acid tars."  
 (iv.) *Copperas crystals (ferrous sulphate)*, also obtained by the action of the sulphuric acid of acid tars on spent shales.

The lamps exhibited are beautifully designed, and are excellent examples of the perfection to which these have now been brought. The burners made by this company are specially adapted for burning their oil, and their Duplex and Champion Burners give an illuminating power of 41 and 46 candles respectively. Specimens of miners' lamps recently introduced for burning a specially-prepared paraffin wax in place of oil or tallow, are also shown. For them it is claimed that a better and clearer light is got, while at the same time a considerable economy is effected.

The shales worked now by this company, are from the lower carboniferous formation abounding in the company's works in the counties of West- and Mid-Lothian.

#### PRODUCTION PER ANNUM.

Shale distilled	500,000 tons.
Crude oil distilled and refined	16,000,000 gallons.
Burning oil produced	6,500,000 "
Naphtha	500,000 "
Mineral lubricating oil	9,000 tons.
Solid paraffin	6,000 "
Candles	4,000 "
Ammonium sulphate	4,000 "
Number of pits	11
" " employes	3,700
Horse-power of steam boilers	9,000

#### MESSRS. BURT, BOULTON & HAYWOOD (Group XIV. No. 1428),

Exhibit several large diagrams.

No. 1 shows the principal substances obtained from coal as the result of the manufacture of illuminating gas.

No. 3 represents a wrought-iron tar still containing 2500 to 2750 gallons of tar for a charge.

No. 2 shows the distinctive properties of the more important of the distillates obtained from the tar still, the first rough division of these products being into the three groups, *oils lighter than water or crude naphthas; oils heavier than water, or dead oils, heavy oils or creosote oil; and pitch.*

The distillates are afterwards separated and purified by various processes, and finally a large number of products is obtained, and in this exhibit the ultimate destinations of these products is clearly shown. These are timber preservers, alizarin makers, manufacturers of aniline and other dyes, soap makers, indiarubber manufacturers, manufacturers of sanitary antiseptics, patent fuel makers, manure manufacturers, manufacturers of illuminants, of lubricants, etc., etc.

A complete series of the coal-tar products is shown, both in the condition in which they are prepared for use in the various manufacturing industries, as well as in the form of laboratory specimens of great purity. The inspection of this exhibit would afford a rare opportunity to the student of organic chemistry, comparing the crude materials with the substances as obtained in the pure state; and by referring to the large diagram above the case, the names, chemical formulae, boiling and melting points, etc., are found, thus making the comparison a complete one.

Very few chemists will have seen before so magnificent a specimen of chrysene, the very name of which must convey some idea of the difficulty of obtaining it in so pure a state as to take the form of these delicate white plate-like crystals exhibited.

The beautiful sample of chrysoquinone ( $C_{18}H_{10}O_2$ ) is also well worthy of special notice. It may be interesting to note here that it was by strongly heating this chrysoquinone with lime that Graebe and Bungener obtained a small quantity of a new hydrocarbon, believed to be phenylnaphthalene. This, taken in conjunction with the fact that the above chemists obtained chrysene by passing benzylnaphthylmethane through a red-hot tube—

would prove that chrysene is a phenylnaphthalene derivative of the formula—

Further light has been thrown on this interesting question by an investigation in which the pyrogenetic method is avoided. This is of quite recent date, and the tendency is so far quite to confirm Graebe and Bungener's conclusions (see Baumberger and Kranzfeld, *Ber.* 18, 1931). Another rarity is to be seen in the finely-crystallised specimen of acridine hydrochloride (fine golden flakes); and here is also to be seen a large specimen of pure acridine. As an example of a liquid exhibiting fine blue fluorescence, attention is called to the specimen of a solution of dichloranthracene sulphonic acid. Messrs. Burt, Boulton & Haywood are also large importers of timber, and thus they prepare by the creosoting process. The creosote used consists of those crude oils which are intermediate between the so-called "heavy oils" of tar, and the "green or red oils" from which the crude anthracene is obtained. Timber preserving was the original industry of this firm, and before finally settling down to the sole employment of the creosoting process they had tried a number of others, such as those involving the uses respectively of sulphate of copper, chloride of zinc, and mercuric chloride, etc., all of which materials were found inferior to the first. Diagrams 4 and 5 show experiments in illustration of Mr. S. B. Boulton's patent, No. 1954, 1879, for improvements in the process of timber preserving, and an excellent model is shown under glass of the apparatus for carrying out this process (see this Journal, iii. [12], 622, and *Journal of Institute of Civil Engineers* for May, 1884). The exhibits, as well as the data given, show that when properly treated by this process, the resistance of timber to all influences which decay or rot, as well as to the devouring attacks of marine and land insects, is almost unlimited. Any causes of failure in the use of the creosote may be invariably traced to one of two causes: 1st, to the neglect of the absolutely essential precaution of divesting the timber of moisture before injecting the creosote under pressure; 2nd, to the exclusive use of a too light, thin or volatile description of creosote. Experience has shown that such volatile oils rapidly disappear from the timber, and that the efficacious agents of preservation are the constituents of the heavier portions of the creosote.

#### THE BRITISH ALIZARIN COMPANY, LIMITED (formerly MESSRS. BURT, BOULTON & HAYWOOD) (Group XIV. No. 1427).

The specimens exhibited are not only of the greatest present interest, but as illustrating the history of the development of the madder and alizarin industries it is an absolutely unrivalled exhibit.

*Firstly*, There is a series of specimens illustrating the growth and form of the madder plant and various dyeing products derived from it. Amongst these is a living specimen of the madder plant (*Rubia tinctorum*).

*Secondly*, A series of specimens illustrating the old processes of painting, dyeing, and printing from the products of madder and murex.

*Thirdly*, Series of products illustrating the processes of manufacture of alizarins, flavo-purpurins, and anthrapurpurins from anthracene (see the President's Address, July number, pages 432-434).

*Fourthly*, Numerous specimens of printed and dyed cottons, muslins, velvets, cretonnes, etc.; also specimens of dyed Turkey-red cloth and yarn, all dyed with the products from coal-tar anthracene. Some of these specimens show alizarin in conjunction with other colouring matters.

Readers interested in this subject are referred to this Journal, iii. [12], 594; and iv. [1], 18, where full accounts by Professor Hummel, of Leeds, on dyeing wool with alizarin colours, and by Mr. Sansone, of Manchester, on dyeing cotton with the same, will be found.

THE ALIZARIN INDUSTRY was commenced in England by Messrs. Perkin Bros., in 1859, and about the same time in Germany, where quite another process was used. In 1874 Messrs. Perkin ceded their works at Greenford, with their patents, to Messrs. Brooke, Simpson & Spiller, who in 1876 sold them to Messrs. Burt, Boulton & Haywood. The latter firm considerably extended the manufacture, the seat of which was removed to Silvertown, where larger works were erected. In 1883, at the time of the expiration of the patents, the large consumers of alizarin in this kingdom became desirous of ensuring a regular supply of alizarin of British manufacture. A committee was formed of the largest Turkey-red dyers and printers of the Glasgow and Manchester districts, who arranged with Messrs. Burt, Boulton & Haywood for the purchase of their Silvertown works, where this manufacture is now carried on by a company formed for that purpose, and this is the BRITISH ALIZARIN COMPANY, LIMITED (see Mr. Levinstein's paper at the Manchester Section, this Journal, ii. [5], 213, 220, 226).

The following statistics relating to this industry are furnished:—

"During the 15 years ending 1870 the average value of imports of madder and madder products into the United Kingdom amounted to £1,000,000 sterling per annum. It has never fallen to less than £30,000 per annum. But the new alizarin has not only replaced the madder root, it has done much more. At the present time three distinct bodies are recognised as forming the principal colouring matter of these dyes—viz., alizarin, anthrapurpurin, and flavopurpurin, which give distinct varieties of shades. The knowledge of this fact enable the manufacturer so to vary his process of production as to enable him to supply the consumer with different brands of the colouring matter capable of producing a variety of recognised shades. Again, the increased and uniform tinctorial strength of the perfected colour, and its freedom from wood-fibre, grit, and other impurities, are enormous advantages to the dyer and printer. Very important improvements in the art of calico-printing and Turkey-red dyeing have been thus rendered practicable, and styles can be produced which were impossible with the madder products. A great increase in these industries has taken place since 1870. The average yearly consumption of alizarin in Great Britain may now be calculated at 3400 tons of 20 per cent., the strength at which it is now sold, or 6800 tons of 10 per cent. Now, according to the best authorities, a ton of 10 per cent. alizarin does the work of 9 to 10 tons of madder root. Taking the lowest computation, there-

fore, the 6800 tons of alizarin at present consumed annually in these islands represent 61,200 tons of madder."

The cost of 61,200 tons of madder, at the average prices of the 15 years ending 1870, would amount to the enormous sum of	£2,907,000
---	------------

The cost of 6800 tons of alizarin, at the present market price, amounts to	456,960
--	---------

Therefore, in addition to other advantages, a saving is effected to the textile manufacturers of this kingdom, per annum, amounting to	£2,450,040
--	------------

The consumption of alizarin in the United Kingdom is about equal to that of the whole of the rest of the world.

## MANUFACTURE OF PRODUCTS FROM COAL.

MR. GEORGE E. DAVIS (MESSRS. NEWTON, CHAMBERS & Co.) (*Group XIV*, No. 1467).

Mr. Davis carbonises coal in retorts similar to those used in gas works, and he refrigerates the illuminating gas, which latter is then scrubbed by being passed through oils cooled to 4° C. In this way he claims a more rapid and perfect extraction of the benzenes from the gas than when refrigeration is not used (see this Journal, ii. 372, 515; also iii. 369 and 433). For the refrigeration a No. IV. Linde ice machine is used, and this is also employed in preparing pure benzene and carbolic acid. In the specimens exhibited, the 97 per cent. metaxylene necessary for the preparation of xylydine for the manufacture of scarlet dye, and the sulphocyanide of ammonium prepared from waste liquors, deserve special notice.

## THE DISTILLATION OF SHALE, Etc.

MESSRS. WM. YOUNG AND G. BEILBY (*Group XIV*, No. 1467; and *XV*, No. 1486).

Messrs. Young and Beilby, of the Oakbank Oil Company, Midcalder, exhibit apparatus used in the distillation of shale. The first section includes especially appliances for the production of fuel-gas, and among these, retort gas-producers for the manufacture of heating-gas and ammonia, with also gas-condensers and scrubbers.

The exhibit relating to paraffin oil manufacture comprises:—1. Retorts for the distillation and treatment of shale for the production of paraffin oils and ammonia. 2. Stills for the continuous and fractional distillation and fractional condensation of paraffin oils. 3. A new form of gas or air thermometer, suitable for stills and condensers. 4. Apparatus for cooling paraffin oil for the crystallisation and separation of solid paraffin.

*Fuel Gas Production.*—Messrs. Young and Beilby have for some years been engaged in working out a practical process by which a larger proportion of the nitrogen of coal may be obtained as ammonia. Under Young and Beilby's system coal is first distilled in a current of steam, and the coke, or carbonaceous residue, which retains about 60 per cent. of the nitrogen, is burned in a mixture of steam and air, the former being in such large excess as to preserve from decomposition the ammonia derived from the nitrogen of the coke. When this process is properly carried out ammonia is produced equal to from three-fifths to four-fifths of the nitrogen of the coal, or from three to four times as much ammonia as is produced by the most efficiently performed destructive distillation.

It must be noted that this result can only be obtained by the partial or total consumption of the carbonaceous residue, so that the process is applicable to the production of gas rather than coke, from coal. It is believed by the inventors that the great future of the process will be as a gas-producing system, since one-half of the fixed carbon of the coal is oxidised by the oxygen of steam setting free an equivalent amount of hydrogen. The gas obtained is very much richer in hydrogen than ordinary producer gas, and is therefore a more valuable fuel. Comparative analyses of the gas from a Wilson producer and from Young and Beilby's retorts give the following results:—

	Wilson Gas.	Y. and B. Gas.
Carbonic acid .....	5.14	15.40
Hydrogen .....	12.15	34.53
Carbonic Oxide .....	19.83	19.72
Marsh Gas .....	3.91	4.02
Nitrogen .....	57.24	35.33
	99.27	100.00

The models and drawings illustrate two forms of retort gas-producer. The first form is designed for supplying the heat to shale retorts. It consists of a vertical retort built of brick, closed by a door at the top, and provided with an exit pipe which connects the retort with a system of mains and condensers. At its lower end the retort terminates in a closed fireplace and ashpit, with regulating doors or dampers. The dross or small coal is introduced by the top door, and, resting on the firebars, fills the retort from top to bottom. The upper part of the retort, being surrounded by flues through which fire gases are led, is kept at a full red heat. The coal at this part of the retort is distilled, and parts with gases and vapours which pass away by the exit pipe to be cooled and condensed. As the coke passes down in the retort it is met by a current of steam, which is partly decomposed, burning the carbon, and producing ammonia and "water gas," which pass off along with the other volatile products. When such a coke as has escaped the action of the steam reaches the firebars, it is turned into carbonic oxide by a regulated admission of air. This red-hot carbonic oxide passes off by ports at the lower end of the retort, and is burned in the flues surrounding the shale retorts. The gases from the upper part of the retort, after having been deprived of their condensable constituents, are also returned and used in firing the retorts. By this system of firing, less fuel is used than by the open furnace, and the ammonia and tar recovered from the coal more than pay its first cost. About 200 of these retort producers are in use in Scotch oil works.

The second form is for the production of gas for firing steam boilers or for metallurgical operations. The shell of the retort is built of grooved bricks as before, but it is of circular section, and of much larger diameter than the early retorts. The top is closed by a shallow hopper of cast iron, with two small charging doors; through the centre of this hopper a large iron pipe is led half-way down the retort. This pipe is for the exit of the gases, and passes up into a large dust-box which runs along the bench. From the dust-box the gas is conveyed by large pipes to the condensers and exhauster. The bottom of the brick retorts rests on an iron snout-piece, which is provided with a door at the outside of the setting. The steam and air are blown in at the front of this snout-piece. The gas and air for heating the setting are led up by pipes between the walls of the building, and are thereby heated before they take fire. The fire gases surrounding the retorts are drawn downwards by chimney draughts, and before entering the main flues at the bottom of the setting

they give up their heat to the iron snout pieces, through which the steam and air are entering.

*Gas Condensers and Scrubbers.*—In carrying out the process of gasifying carbonaceous residues in excess of steam, a great deal of heat is carried away from the operation by the large quantity of gas produced. To recover a part of this heat, and to make it again available in the process, certain forms of regenerative condenser have been devised. In these the hot gases from the retorts pass through tubes which are immersed in water or are kept wet by a shower or spray of water. The tubes are enclosed in a box or case through which a current of air is forced. The air becomes saturated with water vapour to an extent depending on its own temperature and that of the wetted tube surface. This saturated air, by the further addition of steam, is available for the incineration of the coal in retort gas-producers. As the principal outlay of heat in the vaporisation of water is that portion which is latent in the steam, the economy of this method of producing water vapour from heat of comparatively low grade is very evident. Air at 150° F. takes up one-fourth of its weight of water, at 165° one-third, at 175° one-half, at 185° an equal weight, and at 200° twice its weight; it is therefore possible to raise into vapour large quantities of water by means of a comparatively small volume of air. Condensers of this construction have been working satisfactorily in the Clippens Company's Works at Pentland for nearly two years.

*Paraffin Oil Manufacture.*—The production of paraffin oil from shales and cannel coals by distillation at a low red heat may be said to date from 1850, when Mr. James Young applied for his celebrated patent. Since then the process of shale distillation has passed through three well-marked phases. During the first phase the so-called "low-red heat" was, in actual practice, more nominal than real. Retorts of small capacity were used, and in order that they might exhaust a sufficiently large quantity of shale in a given time, the metal of the retort was raised to a very bright-red heat, such a heat that the life of a retort was only from six months to a year. The crude paraffin oil produced by these retorts was black and tarry, and contained only about eight per cent. of solid paraffin.

The second stage dates from 1867, when Mr. William Young designed retorts with the express object of working them really at a low-red heat. By this improved system crude oil of much greater purity, and containing 10 per cent. to 11 per cent. of solid paraffin, was produced. Although the advantages of this system of working were clearly shown in 1868, the necessary plant was only perfected in 1873, when Mr. N. M. Henderson patented the retort which bears his name. In this retort the principle of low-red heat distillation was practically realised, and in addition the residual carbon of the exhausted shale was used as fuel for heating the retorts.

The third phase dates from 1881, when Messrs. William Young and George Beilby patented their process for the distillation and treatment of shale. By this system shale is first distilled at the low-red heat most suitable for the production of paraffin oil, after which the coke or residue, instead of being used merely as fuel, is incinerated in an atmosphere of steam and air so that the nitrogen is obtained as ammonia, the residue being discharged from the retorts as an ash. In the upper parts of the retort the shale is distilled yielding crude paraffin oil. The exhausted shale is then drawn down into the lower parts in which the fixed carbon is burned in steam or steam and air, the nitrogen being obtained as ammonia, and the shale being reduced to ash. The

following figures show the influence of the new process introduced in 1881. There are at present in course of erection, or in actual use, about 2000 retorts capable of distilling and treating under the new system 750,000 tons of shale per annum. Among the companies which have adopted these retorts are:—Young's Paraffin Light Co., The Clippens Oil Co., Oakbank Oil Co., Pumpherston Oil Co., West-Lothian Oil Co., Dalmeny Oil Co., etc. The admitted gain of sulphate of ammonia, by the new process, is not less than 4½ lb. per ton of shale, or 4687 tons per annum, which, at £10 per ton, is equal to £46,870. But, in addition to this gain of ammonia, there is also an increased yield of solid paraffin valued at about £40,000 per annum. As the costs for labour, fuel, and maintenance of the new retorts do not exceed those incurred under older systems of working, the whole of the above saving of £86,000 may be credited to the new process.

Stills for the continuous and fractional distillation and condensation of paraffin oils are also shown. Fractional distillation plays a most important part in the refining of crude paraffin oils. Hitherto fractional condensation, which has been so successfully employed in the rectification of alcohol and of benzene, and of other substances of comparatively low boiling point, has not been used for the separation of oils of high boiling point, such as the burning and lubricating paraffin oils, which boil at from 212° to 800° F. The still is a long cylindrical boiler, partitioned so that oil fed in at one end follows a tortuous course in reaching the opposite end. Each partitioned space is provided with a separate off-take pipe and set of condensers. The oil as it flows from space to space parts with its successively less volatile portions until it reaches the end space, from which it is removed as a thick residue. The greatest heat is applied at the end from which the residue passes, while the partially spent heat is applied at those parts of the still containing oils of lower boiling point. The tubular condensers are kept at temperatures just sufficiently low to condense oils of the particular volatility it is desired to retain, so that the vapours of the more volatile oils pass onwards to successive condensers to be further differentiated.

Besides the foregoing, Messrs. Young and Beilby exhibit a new form of gas thermometer suitable for oil, stills, and condensers. Thermometers are required for the regulation of the temperature of stills and condensers for the fractionation of paraffin oils. As a large proportion of these oils boil at temperatures above the boiling point of mercury, Mr. Beilby has been led to construct a gas or air thermometer by which temperatures up to and beyond the softening point of glass can be readily observed. This instrument was recently described by the inventor in a paper read before the Society of Chemical Industry (see this Journal, vol. iv. page 40). The parts common to the various forms of the instrument are: (1) A bulb or expanding vessel filled with dry air or other suitable gas; (2) A measuring tube in which the air expelled from the bulb is measured at constant temperature and pressure; (3) A connecting tube of comparatively small capacity between the bulb and the measuring tube; (4) A jacket or casing surrounding the measuring tube in which steam, water, or other medium is contained or circulated so that the temperature of the measuring tube is maintained at a constant known temperature; (5) A pressure regulator by which the air or gas within the apparatus is maintained at a constant pressure. The graduation of this thermometer is very different from that of an ordinary mercurial thermometer. As every increment of temperature expands the gas in the bulb, a corresponding portion is expelled into the

measuring tube; but every portion so expelled reduces the mass of the gas in the bulb so that successive equal increments of heat cause the expulsion of decreasing amounts of gas, therefore the degrees diminish in length as the temperature rises.

There are also some interesting apparatus for cooling paraffin oils for the crystallisation and separation of solid paraffin. While fractional distillation is a most valuable and useful process for the separation of oils of different boiling points, the separation of the solid from the less volatile liquid paraffins cannot be so effected, as these distil over together. If, however, the solution of solid paraffin be lowered in temperature, the paraffin crystallises out, and may be separated from the solvent oil by straining or filtration. In applying artificial cooling for the separation of solid paraffin from oil, it has hitherto been the custom to reduce the temperature of the solution quickly by running it over a cold metallic surface, the solidified film being scraped off in a pasty state. The effect of this sudden cooling is to make the paraffin amorphous or imperfectly crystalline, so that it is only with difficulty separated from the oil. The system adopted in Beilby's apparatus is the slow regular cooling of the solution, so that large, or at least well-formed crystals are produced. A further feature in the apparatus is the saving of manual labour in crushing the mass of solidified oil and paraffin after it has been cooled. The vessels in which the oil is cooled are rectangular cells 16ft. long, 8ft. deep, and 1ft. in width. A number of these cells are built up together in blocks, say of ten cells each. Between each pair of oil cells is an interspace or intermediate cell through which cold brine or cold air is circulated. Four days is the time required thoroughly to cool and crystallise the cell full of oil. At the end of that time the cell contains a solid slab of oil and paraffin 16ft. long, 8ft. deep, and 1ft. thick. The crushing and shearing strength of the slab is about 3lb. per square inch. The slab has to be mashed down so that it can be withdrawn from the cooling cell by the ordinary filterpress pumps. To provide for this each cell has a screw lying in the bottom along its whole length of 16ft. The diameter of the screw is 1ft., so that it occupies the full width of thickness of the cell. A central shaft on which the screw is keyed projects through a stuffing gland on one end of the cell, and can be rotated by worm gearing. By rotating this screw the slab of paraffin is sheared or bored away along its whole length, the sheared or mashed paraffin being thrown by the screw through a sluice valve at the opposite end from the driving gear. As the bottom of the slab is sheared away and discharged, the weight of the whole mass causes it to follow down on to the screw, until the slab is completely sheared away. This downward slipping of the slab is favoured by making the cells rather wider at the bottom than the top. Complete plant according to this system has been erected at Oakbank Works, Midcalder, for the cooling of 8000 gallons of oil and paraffin per day.

#### MANUFACTURE OF SULPHATE OF AMMONIA.

R. R. KELLY, LONDON (*Group XIV. No. 1453*), Exhibits specimens of raw materials and products in this manufacture.

#### MANUFACTURE OF PATENT CARBOLIC POWDER FOR DISINFECTANT AND OTHER PURPOSES.

JAS. B. AUSTIN, BRISTOL (*Group XIV. No. 1461*).

## REFRIGERATING APPARATUS.

J. J. COLEMAN (*Group XIV. No. 1429*)

Exhibits a model of the well-known refrigerating apparatus of the Bell-Coleman Company, so arranged that by an accumulator the cold air can be reduced to  $120^{\circ}$  below zero F., at which temperature carbonic-acid gas can be liquefied continuously in a coil without pressure above that of the atmosphere, and ethylene and marsh gas at very moderate pressures, as mentioned in Mr. Coleman's "Address to the Chemical Section of the Philosophical Society," reported in the *Chemical News*, April 10, 1885, page 175. This arrangement of apparatus is also substantially the same as was employed for some years on a very large scale at the Bathgate Works of the Young Paraffin Light and Mineral Oil Company, Limited, where the waste gases of the oil works were compressed by a pressure of 120 lb. to the square inch, thus separating some volatile liquids, after which the residual gas was expanded in doing the work of compressing fresh portions of gas—the ejected cold gas being employed in cooling that which has been compressed previously to its arrival at the expansion cylinder, by which a second crop of very volatile liquids was obtained. (See *Journ. Chem. Soc.* 1875, 856; also this Journal, iii. 357, 613, 614; also iv. 323 and 325.)

DR. C. A. BURGHARDT, OF MANCHESTER (*Group XIV. No. 1467*).

Exhibits a model of a condensing apparatus for volatile liquids, or rather for condensing and recovering the vapours of such volatile liquids as are used, for example, by the india-rubber manufacturer in vulcanising and in waterproofing, etc., and which are generally allowed to escape, rendering the atmosphere of the factory noxious for the workpeople, dangerous for fires or explosions, and generally a source of loss.

The model exhibited is not on a reduced scale, but actually represents the invention in working dimensions. It is declared by the inventor to act most efficaciously in condensing to the liquid form all vapours of naphtha, bisulphide of carbon, and the like. Annexed is a woodcut, showing the principle of construction of this small column condenser, which resembles in appearance, as well as to some extent in structure, a small dephlegmating column.

In the woodcut the twelve transverse lines marked A represent the sheets of wire-gauze, B representing the annular condensing space. When this apparatus is employed for recovering naphtha used in india-rubber manufactories, a blower is employed to drive the vapour in, and with water at  $55^{\circ}$  F., 30 to 35 per cent. of the naphtha used in the machine can be recovered. If artificial cold be employed and the temperature reduced to  $35^{\circ}$  F., then 60 to 70 per cent. of the naphtha can be regained. These condensers are also being used successfully to take the place of worm-coils, etc., in ordinary distilling operations.

MESSRS. F. C. CALVERT & Co. (*Group XIV. No. 1466*)

Exhibit specimens illustrating the various stages of the manufacture of carboic acid of a melting point of  $42^{\circ}$  C. from coal-tar oils, as well as the various rectifications of the liquid carboic acid, consisting principally of cresol and other homologous phenols.

This firm also exhibits a series of sulpho-phenates of various metals, the salts being very finely crystallised.

A number of dye-stuffs obtained from phenol is also shown, especially new blue and yellow dyes, the effects of which are shown both in printed and dyed specimens. These colours are said to possess very considerable resistance both towards light and soap. The new colours are termed "Azuro-" and "Auro-phenylene," respectively, and are quite extra to the aurin and picric acid for which, with the pure phenol and the phenol hydrates discovered by Mr. Chas. Lowe, this firm has so long been famous. (See Eng. Pat. 5458, March 26, 1885.)

There is, further, a new red or crimson dye named "Rosphenylene,"—a pararosaniline derivative,—also patented by Mr. Lowe. The "Azuro-phenylene" is a derivative of the old Azuline of M. Marnas, and the Auro-phenylene is a nitro-derivative of this latter.

## MANUFACTURE OF BENZENE COMPOUNDS FROM THE BENZENE OF COAL-GAS.

MESSRS. SADLER & Co., MIDDLESBROUGH (*Group XIV. No. 1467*).

Since 1862 various attempts have been made to extract benzene from coal-gas, but although processes with this object have even been worked on a large scale, yet the great variations in the price of benzene

seem to have prevented their continuous successful operation since the time they were first originated.

Leigh, in 1863, patented the manufacture of nitrobenzene by passing coal-gas through nitric acid or nitric acid mixed with sulphuric acid; and in 1869, Messrs. Caro, Clemm, and Engelhorn patented a process for extracting benzene from gas by means of heavy oils, which latter were made to pass through the ordinary coal-gas scrubbers or washers. This process was worked on a large scale by the inventors for a time.

The manufacture of nitrobenzene from coal-gas appears never to have been successful. This is due in great measure to the fact that in ordinary coal-gas there are hydrocarbons present which by reacting with the nitric acid form water. The acid mixture then becomes too dilute to absorb the benzene. When gases are used which contain only a small proportion of benzene a considerable volatilisation and loss of nitrobenzene and nitric acid takes place. Besides these difficulties it was found that the nitrobenzene actually obtained was far from pure, other liquid nitro-compounds being formed at the same time.

In 1881, Mr. Kendall patented the manufacture of dinitrobenzene from coal-gas (see this Journal, i. [4], 143; and [11], 444). This product being non-volatile and easily crystallisable, could be obtained in a pure state without difficulty. In this process the gas is first purified by passing it through concentrated sulphuric acid, and it is then passed into a mixture of nitric acid with an excess of sulphuric acid. It was found that when suitable coal-gas was used, the whole of the benzene could thus be extracted with facility and economy. Mr. Kendall's second process was patented in 1882. By submitting coal-gas to a "superheating" process in red-hot retorts, it was found that the amount of benzene could be largely increased, while at the same time the objectionable hydrocarbons before alluded to could be destroyed. As consequences of this discovery, it became possible in the first place to manufacture pure nitrobenzene direct from coal-gas, and in the second place, it was found that almost any variety of coal-gas, including that from coke-ovens, could be used for the purpose. In dealing with such crude gases it will be obvious that the ordinary nitric extraction method will be inapplicable, and only a very partial extraction of the benzene can be effected by the ordinary oil process. But by destroying the interfering hydrocarbons and simultaneously increasing the percentage of benzene, the gas is rendered quite suitable for the chemical methods before described.

Messrs. Sadler & Co., of Middlesbrough, are carrying on the entire process of making coal-gas and extracting the benzene in the form of nitro compounds by the above processes, the "spent" gas being used for heating purposes.

They exhibit specimens of nitro- and dinitrobenzene prepared by the processes named.

#### MANUFACTURE OF AURIN.

MESSRS. ROBERTS, DALE & CO., OF MANCHESTER  
(Group XIV. No. 1467).

This firm exhibits (1) Specimens of aurin; (2) A series of samples of constituents with derivatives of American petroleum prepared and separated for the first time by Prof. C. Schorlemmer, F.R.S., of Manchester.

Though the specimens in this exhibit are neither large, nor in any way striking to the eye, yet associated with the names of Schorlemmer, and

Dale and Schorlemmer, they at once become invested with a high degree of interest, both for the theoretical chemist and the chemical technologist.

Turning to the aurin specimens, illustrating the researches of R. S. Dale and C. Schorlemmer, we find the crude article and the pure crystalline substance, and, besides, various aurin derivatives. Certainly the most remarkable, and for the technological chemist the most interesting, is pararosanine, first prepared by Dale and Schorlemmer from aurin by simply heating the latter with aqueous ammonia in sealed tubes to 200° C., the following simple reaction then taking place:

This remarkable transformation by Dale and Schorlemmer laid the foundation for the work of Messrs. E. and O. Fischer, who subsequently proved that aurin, and consequently pararosanine, are substituted derivatives of the hydrocarbon triphenylmethane, the simplest analogue of which is common marsh-gas (methane),  $\text{CH}_4$ . E. and O. Fischer, for the above purpose, first converted aurin into pararosanine, according to the method of Dale and Schorlemmer. Pararosanine was then reduced to paleuco-rosanine, the latter after conversion into its nitrate was diazotised, and the diazotriphenylmethane nitrate thus obtained. After converting the nitrate into the acid sulphate by treatment with sulphuric acid, which is easily effected, the acid sulphate was boiled with alcohol. Thus, a hydrocarbon was obtained which was found to be in every respect identical with triphenylmethane, otherwise prepared. (See President's Address, this Journal, iv. 429, 431, and 435.)

MESSRS. BROOKE, SIMPSON & SPILLER, OF THE ATLAS WORKS, HACKNEY WICK (Group XIV. No. 1467).

Show a collection of about eighty specimens illustrating the manufacture of coal-tar colours and products applicable to dyeing and printing.

These consist not only of the finished articles, some of which were actually discovered by the firm, but include a series of chemical products arising out of such manufacture or incidental thereto.

The exhibitors claim the production of a variety of colouring matters of uniform strength and shade, and of superior quality as regards purity. The consumer may also glean information regarding the effects of the various dyestuffs on the fibre, for around the neck of each bottle is arranged a skein of silk dyed with some of the contents.

The following are exhibited:—

Large bottles of—

Coal tar, Orthotoluidine, Pure aniline,

With specimen bottles containing—

Benzene	Non-mordant cotton blue
Nitrobenzene	6 B., Fast blue
Binitrobenzene	Dragon green
Diphenylamine	Hofmann violet, 2 B.
Para-toluidine	Methyl violet, 6 B.
Naphthalene	Phosphin
$\beta$ -Naphthol	Primrose
$\beta$ -Naphthylamine	Fast yellow
Benzoic acid	Albany
Rosaniline base	Citronine
Golden roscine	Atlas orange
Regina purple	Pure scarlet
Pure opal blue	Atlas scarlet
Pure soluble blue	Safranin
XL Soluble blue	Eosine, y. s.

Fast pink  
 Stœline, b. s.  
 Bismarck brown  
 Nitrochlorbenzene  
 Metadinitrobenzene  
 Metatolylenediamine  
 Paraacetoluid  
 Metaacetoparaacetoluid  
 Metanitroparaacetoluid  
 Orthoacetoluid  
 Tropæoline, OO  
 Citronine sodium salt  
 Rosaniline base, crystal-  
 lised  
 Orthorosaniline  
 Pararosaniline  
 Pararosaniline hydro-  
 chloride  
 Xylidine red  
 Triphenylorthorosaniline  
 hydrochloride  
 Triphenylpararosaniline  
 hydrochloride

Triparatolylorthorosaniline  
 hydrochloride  
 Triparatolylpararosaniline  
 hydrochloride  
 Methyl violet zinc chloride  
 Helianthin  
 Helianthin (acid)  
 Acid maroon  
 Resorcinol  
 Phthalic anhydride  
 Aniline oxalate  
 Aniline sulphate  
 Chrysoidine crystals  
 Chrysoidine sulphonic acid  
 Sulphanilic acid  
 $\alpha$ -Naphthalene sodium sul-  
 phonate  
 $\beta$ -Naphthalene sodium sul-  
 phonate  
 Diphenylamine opal  
 Alkaline green  
 Indulin opal

at first the only known source of it. (See President's  
 Address, this Journal, iv. 428 and 429.)

#### ANILINE AND NAPHTHOL-COLOURS AND RAW MATERIALS.

I. LEVINSTEIN & Co., OF MANCHESTER (*Group*  
*XIV. No. 1162*).

The following is a numbered list of the colouring  
 matters and dyes, together with the raw materials  
 and intermediate products, manufactured by this  
 firm. In the United States, the firm bears the title  
 of Levinstein, Campbell & Co., and enjoys there  
 the same well-merited reputation as in this country.  
 The exhibit, as a whole, is equally well calculated  
 to instruct the student of applied chemistry in an  
 examination of the specimens shown, as it is to  
 interest the intelligent consumer or the technologist,  
 for not only the final products, the dyestuffs them-  
 selves, are exhibited, but also the materials forming  
 the starting points, as well as the intermediate pro-  
 ducts forming the steps. In handsome specimen  
 cases, skeins of dyed cottons and silks are also to be  
 seen.

The following is the numbered list of specimens  
 exhibited, followed by some details of more special  
 interest, from information kindly furnished by Mr.  
 Levinstein:—

1 Benzene	25 Binotroloene
2 Toluene	26 Metatolylenediamine
3 Xylene	27 Sulphanilic acid
4 Nitrobenzene	28 Barium sulphanilate
5 Nitrotoluene	29 Ammonium amidazo- benzene sulphonate
6 Nitroxylene	30 Potassium amidazo- benzene sulphonate
7 Aniline	31 Sodium amidazoben- zene sulphonate
8 Orthotoluidine	32 Amidazobenzene disul- phonic acid
9 Xylidine	33 Benzaldehyde
10 Cumidine	34 Resorcinol
11 Monomethylaniline	35 Phthalic anhydride
12 Dimethylaniline	36 Phtosafranin
13 Mono-ethylaniline	37 Tolosafranin
14 Diethylaniline	38 Lenco-malachite green
15 Diphenylamine	39 Lenco-ethyl green
16 Aniline nitrate	40 Naphthalene
17 Toluidine nitrate	41 Nitronaphthalene
18 Xylidine nitrate	42 $\alpha$ -Naphthylamine
19 Nitrotoluidine	43 $\beta$ -Naphthylamine
20 Nitrotoluidine hydro- chloride	44 $\alpha$ -Naphthalene sul- phonic acid
21 Nitroxylidine	
22 Nitroxylidine sulphate	
23 Amidazobenzene	
24 Binotrobenzene	

3. XYLENE.—This firm has a cheap method for  
 producing metaxylene from commercial xylene.  
 That there are difficulties in the way of a smooth  
 passage on the practical scale from metaxylene  
 into xylidine, will be evident from the follow-  
 ing facts. If pure metaxylene be converted into its  
 nitro-compound, and afterwards the latter be con-  
 verted into the amido-derivative, the reaction pro-  
 ceeds on the large scale in a manner analogous to  
 that by which benzene is converted into aniline, but  
 if the metaxylene contain only a few per cents. of  
 orthoxylene, tarry matters are at once formed, hin-  
 dering the practical formation of the xylidine. The  
 improvement in question is one by which this diffi-  
 culty is avoided, the methods known to science being  
 too expensive. At the present time the price of  
 xylidine is not more than 1s. 2d. per lb., which fact is  
 certainly a criterion as to the successful manner in  
 which metaxylene is extracted from commercial  
 xylene, and afterwards converted into xylidine on the  
 large scale by the present most improved methods of  
 working.

10. CUMIDINE.—As a special feature in this pre-  
 paration, as carried on in Messrs. Levinstein's Works,  
 may be mentioned an improvement in the method  
 of methylating xylidine so that enamelled autoclaves  
 need not be used. These enamelled autoclaves are  
 expensive articles, and when worn through they  
 cannot be re-enamelled in England. The improve-  
 ment consists principally in using sulphuric in place  
 of hydrochloric acid, when un-enamelled cast-iron  
 vessels may be used.

16, 17 and 18. ANILINE, TOLUIDINE AND XYLIDINE NITRATES.—The materials used in preparing these salts are so manipulated that the formation collaterally of nitro-products is prevented.

19, 20, 21, 22. NITROTOLUIDINES AND XYLIDINES.—No simple method was at first known for converting such aromatic bases as aniline, toluidine, xylidine, naphthylamine, etc., into nitro compounds. This problem has now been solved (Ger. Pat. 30,889), so that it is at present both easy and profitable to make tons daily of these hitherto rare preparations. Especially is the practical value of this method exhibited in one specimen—viz.:

METATOLYLENEDIAMINE OR  $\beta$ -DIAMIDOTOLUENE (1, 3, 4—CH<sub>3</sub> in 1), see list, No. 26. This is produced by reduction of the corresponding nitrotoluidine, and also by that of colouring matters made from the former. Specimens of such colours are Nos. 71, 72 and 74, which are distinguished by their great purity.

38 AND 39. LEUCOMALACHITE GREEN AND LEUCOETHYL GREEN.—As is generally known, "malachite green" owes its formation to the interchange reaction between dimethylaniline, C<sub>6</sub>H<sub>5</sub>N(CH<sub>3</sub>)<sub>2</sub>, and benzyltrichloride, C<sub>6</sub>H<sub>5</sub>.CCl<sub>3</sub>, in presence of zinc chloride. Zinc chloride forming a difficultly-soluble double salt with the basis of "ethyl green," is also used in presence of hydrochloric acid for precipitating, in the crystalline form, the colouring matter bearing that name.

In the new method of condensation employed, in the case of neither of the above-mentioned dyestuffs is zinc chloride made use of. Specimens are shown of the zinc chloride double salts, of the hydrochlorides of the tetramethyl- and tetraethyl diamidodiphenyl-carbinol, and the oxalates of the latter. The oxalate of the ethyl green base is a beautifully crystalline preparation.

48 AND 49.  $\alpha$ - AND  $\beta$ -NAPHTHOLS.—In the usual process for the manufacture of the naphthols, the respective isomeric naphthalene sulphonic acids are fused with excess of caustic soda, the result of the fusion being the formation of the sodium salts of the respective naphthols. These have to be dissolved, and the naphthols precipitated with an acid. Now, since an excess of caustic soda is always used in the fusion process, also an excess of acid is required, firstly, to neutralise the free alkali; secondly, to decompose the sodium naphthol salt; and, thirdly, to decompose, with evolution of sulphurous acid, the sodium sulphites which are the result of the fusion of the  $\alpha$ - and  $\beta$ -naphthalene sulphonic acids with the caustic soda; it will be plain that there is here room for economic improvements. Such an improvement Messrs. Levinstein & Co. have with great ingenuity effected. It is embodied in Eng. Pat. 2300, 1883, and consists in heating the mixture of excess of caustic soda and sulphonic acid in the fusing process very gradually, when, at a certain temperature, two layers of fluid are formed. The top layer consists of crude sodium naphtholate, which is decanted, whilst the lower stratum is a mixture of caustic soda and sodium sulphite. This lower layer is collected and dissolved in water, and then concentrated, when the sulphite precipitates, settling down to form a layer resembling red sand. The mother-liquid is evaporated further, and is then used over again. The reddish-looking sulphite is recrystallised, when a pure commercial sodium sulphite is obtained.

50.  $\alpha$ -NAPHTHYLAMINE SULPHONIC ACID, ETC.—In the manufacture of the azo-reds and scarlets, the naphthols are not always used as such, for if a colour were produced by diazotising an amido com-

pound like naphthylamine, for example, and a naphthol, it would turn out to be an insoluble colour. It is thus necessary, in order to obtain a dyestuff possessing the requisite conditions of solubility, that either or both the above-named materials shall be first sulphonated, naphthylamine- and naphthol-sulphonic acids being respectively obtained. The use of such sulphonated materials means the production of a sulphonated colouring matter, which, again, means a soluble colouring matter, and the degree of solubility being conditioned by the extent of the sulphonation (i.e., the number of sulphonic acid (—SO<sub>3</sub>H) groups introduced into the molecule of the dye-compound), the manufacturer can, by using sulphonated materials, which are known compounds, regulate and graduate, as it were, the solubility of his dyestuffs in an intelligent manner. It is not found desirable or beneficial to exceed certain tolerably definite bounds in the sulphonating process, and, indeed, various grades of the same dye are obtained according to the degree of sulphonation, these different grades having quite special uses, and hence, frequently, quite special values. These are general rules, and mainly hold good for all the varieties of coal-tar dyes.

Now the methods of converting  $\alpha$ -naphthylamine into naphthylamine sulphonic acid were well known many years ago, but this conversion was only effected by means of fuming sulphuric acid. Messrs. LEVINSTEIN & Co. claim to be the first to replace this more expensive agent by the less expensive ordinary sulphuric acid; and since 1881 this firm has manufactured colours from  $\alpha$ -naphthylamine-sulphonic acid and  $\beta$ -naphthylamine-sulphonic acid, produced by the aid of common "vitriol." In the specimens No. 83, marked "Roccellin," is a compound produced by bringing together diazonaphthalene-sulphonic acid and an alkaline solution of  $\beta$ -naphthol. The diazonaphthalene-sulphonic acid is obtained by diazotising the  $\alpha$ -naphthylamine-sulphonic acid (or naphthionic acid), thus:—

The reaction by which the colouring matter itself is formed must then be as follows:—

The scarlet No. 84, marked A, represents a specimen of the colour produced by bringing together diazonaphthalene-sulphonic acid obtained from the  $\beta$ -naphthylamine-sulphonic acid, and  $\beta$ -naphthol. Instead of sulphonating the naphthylamine or basic compounds, the phenol may be sulphonated, and this idea is realised in Eng. Pat. 623, 1879. The object of this patent is to obtain protection for the manufacture of  $\beta$ -naphtholdisulphonic acids, for their combination with certain aromatic bases, such as xylidine, cumidine, etc., and for the purification and separation of the colours thus obtained. Now, besides combining sulphonated amido-bases with naphthols and amido-bases with sulphonated naphthols, colours may be prepared by the combination of both sulphonated bases and sulphonated naphthols. This firm has discovered a new way of preparing a special mono-sulphonic acid and a tri-sulphonic acid of  $\beta$ -naphthol, and with these such doubly sulphonated azo-colours have been prepared and patented (see

Eng. Pat. 706, 1883.). To form an idea of the comparatively enormous quantities in which the azo-scarlets are used, this firm turns out of its works about four tons per week, and it is further extending its production.

58, 59, 60, 61 AND 62. CALCIUM NITROSO- $\alpha$ -NAPHTHOL SULPHONATE AND NAPHTHOL YELLOW.—This "Naphthol Yellow" is a fine yellow dye for the special mode of manufacturing which Messrs. Levinstein & Co. claim greater simplicity, a better yield and cheaper production. "NAPHTHOL YELLOW" is the alkaline or alkaline-earthly salt of the dinitronaphthol-sulphonic acid ( $C_{10}H_7(NO_2)_2OHSO_3H$ ). This formula, however, only gives the idea or pattern of one variety of the naphthol yellow basis. An interesting preparation exhibited by this firm is the free naphthol-yellow sulphonic acid. This firm also claims new methods of producing nitroso- $\alpha$ -naphthol-mono- and di-sulphonic acids, with the oxidation with nitric acid and conversion into "naphthol yellow" (Eng. Pat. 5692, 1882). This dyestuff is said to have almost replaced picric acid; besides being four times cheaper, it is faster, and being an acid colour it is far more useful for compound colours, where acids are used.

63, 64, 65 AND 66. SALTS OF SPECIALLY-PREPARED  $\beta$ -NAPHTHOL-SULPHONIC ACIDS.—Eng. Pat. 706, 1883.

68. SODIUM ANTHRAQUINONE MONO-SULPHONATE.—This firm has found a very simple way of obtaining nearly the theoretical yield of the mono-sulphonic acid, of which the above is the sodium salt. A mixture of molecular weights of fuming sulphuric acid and anthraquinone is heated in closed autoclaves under pressure. (Eng. Pat. 2299, 1883; and also this Journal, ii. [5], 222.)

78. PRINTING SCARLET.—The features of novelty in the preparation of this azo-scarlet are to be found in Eng. Pat. 706, 1883.

79 AND 80. XYLIDINE AND CUMIDINE SCARLETS.—In the preparation of the scarlets the naphthol is sulphated instead of the amido-compound. (See Eng. Pat. 623, 1879.)

81 AND 82. VERMILLIONS 2B. and xB.—(See Eng. Pat. 706, 1883.)

83. ROCCELLIN.—Special method of production and improved manufacture, as already indicated when referring to 50.

85 AND 86. MALACHITE AND BRILLIANT GREENS.—Prepared from specimens 38 and 39 by the new method of condensation.

87. SYNTHETIC ROSANILINE.—Under this head Messrs. Levinstein claim improvements in the methods of producing the pararosaniline.

88, 89, 90 AND 91. PURPLE I., AND BLUES I., II. AND III.—Blue III. is the well-known "Blackley Blue," the beautiful deep shade, with inclination to violet, of which is well exhibited in the dyed skein of silk encircling the specimen tube. This colouring matter is largely used by paper makers both in Europe and America, as well as by woollen manufacturers. It was discovered in the works of Messrs. Levinstein at Blackley. As regards its chemical composition it is the sodium salt of the disulphonic acid of a diphenylated tolylated rosaniline. Since its introduction into the trade some sixteen years ago, it has largely substituted, not only ultramarine in the tinting of newspaper, but also Prussian blue used for dyeing shop and other packing papers. In conjunction with logwood and bichromate of potassium it

is also extensively used for dyeing light and heavy woollen goods, producing fine heavy blue shades comparatively fast, and far cheaper and brighter than the corresponding indigo shades. Messrs. Levinstein state that since its first appearance their firm has produced over 1000 tons, representing a value of nearly one million sterling. "Blackley Blue" has been thought and indeed stated to belong to the indulinis, but, as above shown, this is far from being the case.

## ANILINE AND OTHER COLOURS AND INTERMEDIATE DERIVATIVES, ETC.,

EXHIBITED BY THE BADISCHE ANILIN- UND SODA-FABRIK OF LUDWIGSHAFEN A. RH. AND STUTTGART (Group. XIV. No. 2654).

This company, with works in Ludwigshafen, Stuttgart, Neuville sur Saône and Butirki, near Moscow, and with which the name of Heinrich Caro will be always connected, have brought together in one case specimens of their products and materials. The collection, and especially its arrangement, are striking evidences of artistic skill and scientific research. In these works, under the directorship of H. Caro, assisted by a large staff of chemists and engineers, great results have been achieved.\* At the commencement of the catalogue of specimens issued by the Badische Anilin- und Soda-Fabrik, quite a study of itself, we find the following remarks from the pen of Dr. Caro, which form a concise introduction to the collection:—

"Our exhibits at the International Inventions Exhibition are intended to illustrate—both from a manufacturing and scientific point of view—a series of inventions relating to the manufacture of coal-tar products.

"Some of the chemicals—the commercial or scientific names of which will be found in the subjoined list—have been discovered by our chemists, others were the result of scientific research, whilst we have more or less successfully tried to render them commercially available.

"Our claims to the ownership of these inventions are substantiated by due reference to the chemical literature, and to the numbers and dates of our respective patents.

"The exhibits are arranged in nine different groups, the members of which are, as nearly as space would permit, placed in vertical columns. Each group is again subdivided into several inventions."

But the most fitting introduction to a study—not a mere inspection—of this beautiful collection would be a previous study of the admirable Address of Dr. Perkin closing the 1884-85 session of the Society of Chemical Industry (see this Journal, iv. [7], pages 427 to 438).

In the following tabulated list I have given the divisions in which the collection is arranged and catalogued with subdivisions; but in tabulating these I have re-arranged them in a more condensed form, so as to furnish what I believe will be a very useful table of reference, serving as an index to the literature, patents, and nomenclature of the dyes. The names of the individual specimens would make a long list, and the most interesting of them have been referred to by Dr. Perkin in his address, *loc. cit.* Hence it would be unnecessary to reprint them all, especially as the literature and patent list are fully given.

\* See President's Address, this Journal, iv. [7], page 437.

## TABULATED LIST OF DYES, Etc., DISCOVERED AND MANUFACTURED BY THE BADISCHE ANILIN- UND SODA-FABRIK.

(ARRANGED BY WATSON SMITH.)

GROUPS OF SUBSTANCES REPRESENTED, WITH OTHER SUBDIVISIONS.	LITERATURE.	PATENTS.	EX. No.	SPECIAL DETAILS OF EXHIBITS, ETC.

(from 223 and beta-Naphthol Disulphonic Acid).

(To be Continued.)

## Journal and Patent Literature.

### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

*On the Construction of Chimneys.* L. Ramdohr. Chem. Zeit. 9, 903.

The author recommends the construction of chimneys with equal inside width from the base to the top. There are two ways of building such chimneys—viz. (1) dressing the bricks in nearly every course of the brickwork, which plan involves a great deal of troublesome work and waste of material, and is therefore not advisable; or (2) building the chimney in several steps, and giving the top end of each step the normal width intended. The height of these steps should not exceed 5.5 metres. As regards the calculation for the inside width of the chimney, it is essential that its narrowest section be nearly equal to the sum of the air spaces left between the fire-bars. This width must even be increased for low chimneys, whereas it may be a little diminished for high ones. For small boilers or furnaces, the chimney need not be higher than 16m.; for large furnaces a height of 35m. is sufficient, if the chimney be not far from the fire; but if the distance be considerable the height must be increased to 50–60m., whereas the width may be diminished to from  $\frac{2}{3}$  to  $\frac{1}{2}$  of the calculated width. The flues leading to the chimney should at least be as wide as the sum of the air spaces between the bars. For the base well-burnt bricks are better than quarry stones. The cap has an inclination of 30° to the outside. The thickness of the brick-work at the top should in no case be less than 20cm.—S. H.

*A New Syphon.* Chem. Zeit. 9, 907.

BODE and WIMPF have designed a new kind of syphon, which is of great use for syphoning off acid, caustic or poisonous liquids. Its special feature is due to the fact that it is not set by suction, but by blowing so that the liquid to be syphoned off can never get into the mouth. Fig. 1 represents the construction. The tube D is surrounded by a wider one C, closed at the top, and provided

with a ball valve B at the end E. On putting the apparatus into a liquid the ball valve is raised, and the tubes C and D are filled to the height of the surrounding liquid. If now air be blown into the tube H, the valve is closed, and the liquid being driven from C into D and F sets the

syphon to work. The blowing is then discontinued and H closed. If it be desired to interrupt the flow, it is only necessary to blow again a little stronger through H. The valve B is now pressed into its seat, and no liquor being able to enter the syphon, it empties itself. The syphon need never be removed from the liquid, either at the start or at the end. C. Gerhard, of Bonn, and the Moncheberg Pottery, are prepared to supply the syphon to the trade. It can be made of glass, earthenware, ebonite, indiarubber, and metal. It is also intended to fit Woulff's bottles with this syphoning arrangement, as shown in Fig. 2, for drawing off acids in the course of the manufacture.—S. H.

*Improved Anti-incrustation Composition for Steam Boilers.* A. M. Clark. From Van Baerle & Co. Eng. Pat. 11,518, August 21, 1884.

THE composition consists of silicate of soda or polish, with or without the addition of alkali in any form.

—H. J.

### II.—FUEL, GAS, AND LIGHT.

*Improvements in Coke-Ovens.* Dingl. Polyt. J. 256, 359.

SACHSE (Ger. Pat. Add. 30,021, June 18, 1884) now gives his horizontal coke-oven a rectangular cross section

throughout, the walls are perpendicular, and the top is not built vaulted, but consists of plates of iron lined with refractory clay laid upon the upright walls. Spaces

between the walls and plates, or between contiguous plates, are luted with clay. The advantages of this new system are, that immediately after the introduction of

the charge it can be stamped down, and also that any part of the oven may be made accessible from above, either during work or rest.

The arrangement adopted by Lürmann (Ger. Pat. 29,557, June 14, 1884, Add. to 18,633) for compressing coal in coking it in horizontal ovens, is illustrated in

Figs. 1, 2, and 3. As shown in Figs. 1 and 2, the roof is made somewhat higher in part to allow free passage for the gases evolved. The compression is obtained by means of *nn*. The arrangement shown in Fig. 3 is

may be either fixed or movable. In the latter case the size of the gas passage is regulated by the distance to which *op* is inserted.

To increase the yield of by-products from the distilla-

fig 5.

fig. 6.

fig. 7.

fig 8.

fig 9

adopted when it is desirable not to make any alteration in the roof. A passage for the gases is maintained or obtained by means of the iron arrangement *op*, which

tion gases of coke-ovens, Brunck covers the material under treatment with a layer of small coke, lime, or the like, and also makes an addition of lime to the charge to

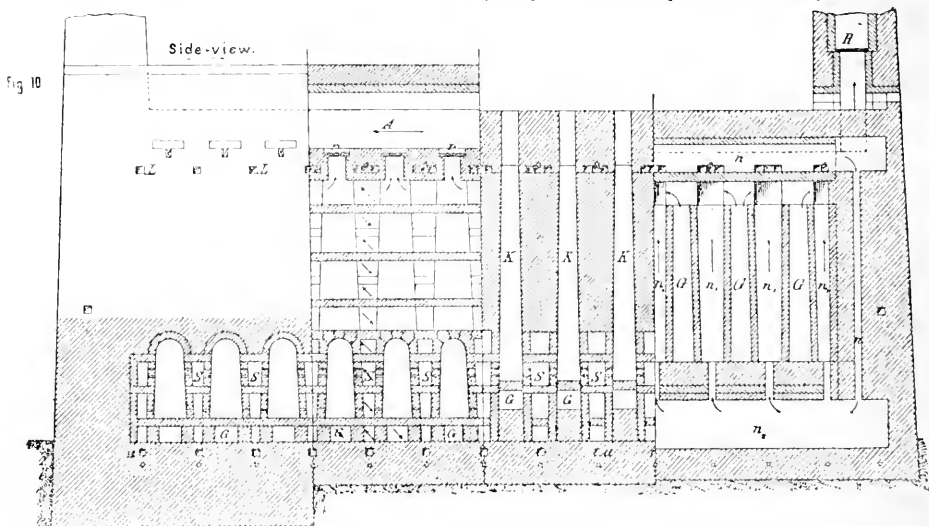

increase the yield of ammonia (Ger. Pat. Add. 29,018, Dec. 21, 1883). The arrangement of the oven is shown in Fig. 4.

In order to increase the durability of coke-ovens with horizontal gas canals, Brzezowski (Ger. Pat. 29,228, March 12, 1884) collects the gases at two different points in the upper part of the chamber, and by thus dividing the stream of gas is enabled to reduce the sectional area of the gas passages. Figs. 5 and 6 are sectional views, Fig. 7 is the plan of the arrangement and construction. The distillation gases pass from the chambers *a* through horizontal channels *c* at each end of the upper part of the chambers, into the channels *k, k*, disposed horizontally one above the other. Above the gas channels are air passages *v*, connected with the outer air by the tubes *r*. Air is supplied by means of *r* into the gas passages *k* and *k*, the draught caused by the chimney in connection with the main gas canal *k* being quite sufficient to produce the in-curent of air. The distillation gases are thus inflamed as soon as they pass from *a*. By the partition wall *m* being built from above, and not extending the whole depth of the gas passages, the necessity for a double main is obviated.

beneath the cover of the chamber or near the fire door at the lowest part of the hearth.—W. D. B.

*Report of Experiments in the König Coal Mine, on the action of Shot-firing on Coal-dust and Firedamp.* Chem. Zeit. 9, 641.

The experiments have, so far, had the following practical results:—(1.) In the presence of coal-dust, which occurs in mines in the neighbourhood of the concussion, the normal flame length of a shot is always more or less extended. (2) *a*. In the complete absence of firedamp the length of the flame is a limited one, and does not exceed, however far the dust extends, 6 to 15 metres, for most kinds of dust, provided that clay is used, and the walls of the bore do not give off gas with the explosion; 9 to 21 metres, if coal-dust is used as covering, or the walls of the bore, with the action of the blast, give off dust and gas. *b*. There are also certain kinds of coal-dust which are ignited by shot-firing, and when once ignited burn on and give not only flame of great length, but also the phenomena of an explosion, when no firedamp is actually present. (3) *a*. By the presence of small quantities of firedamp all the

In Bauer's upright coke-oven, illustrated by Figs. 8, 9, 10 (Ger. Pat. 28,530, February 26, 1884), the distillation products proceeding from the coking chamber *K* proceed through a double series of slits near the bottom of the chamber into the passage *S*, and there meet air which enters at *a*, and is warmed before mixing with the distillation gases in *S*. The mixed air and gas in a state of combustion is drawn from the lower part of *S* through the channel *z* into the passage *G* beneath the hearth of the chamber, proceeds through the vertical portion of *G* upwards, and at the top, just beneath the cover of the chamber, mixes with air introduced in regulated amount at *L*, and heated by passing through the horizontal passage *n*, downwards into *n*, and thence into the upright passages *n* situated between the gas passages *G* mentioned above. At the top of *n*, are slits through which the hot air passes into *k*, there to meet the stream of burning gases from *G*. Near this point a small number of slits in the wall of *K* allow a further amount of the distillation gas to mix with the gases from *G*, and the hot air from *c*; the direction now taken by the current is shown by the arrows. The draught is regulated by registers *r* at the entry into the outlet *A*, and further by the chimney register *R*. The gases may be collected to be worked for tar and ammonia, either just

effects of combustion are intensified; nevertheless those kinds of coal-dust which alone give flames of a limited length, produce with firedamp up to 3 per cent. only a moderate lengthening of the flame, but not by any means an expansion throughout the length of the dust present. *b*. If, however, the percentage of firedamp is 4 per cent. or more, these kinds of dust give an unlimited transfer of flame, which otherwise would not be the case. *c*. Those kinds of dust, which of themselves conduct the flame unlimitedly, give with less than 3 per cent. of gas, real explosions. (4.) By means of coal-dust isolated regions containing firedamp even at great distances may become connected with the scene of the shot-firing, and will produce an explosion, even though no fire-damp has been originally present at that spot.—J. B. C.

*The Gaseous Products of the Combustion of Coal.* A. Scheurer-Kestner. Bull. Mulhouse, 1885, 328.

THIS is a reply to the criticisms of F. Fischer contained in a recent article (*Polyt. J.* 251, 323). The author reasserts the statements made by him in 1868, in regard to the trustworthiness of analyses of these products after having been collected over water, as representing the actual result of the combustion of the coal.

In regard to the influence of the supply of air upon the combustion, the author corrects certain misrepresentations, by restating his former conclusions, that to obtain the maximum effect from a coal, about one-third of the air supplied should remain unused.—C. F. C.

*On the Reduction of Carbon Dioxide to Carbon Monoxide, by means of Carbon.* A. Naumann and C. Pistor. Ber. 18, 1647-1657.

WATER-GAS, which is formed by passing steam over incandescent coal, does not only contain carbon monoxide and hydrogen, but also carbon dioxide, often in very considerable quantities. The reaction expressed by the equation,  $H_2O + C = CO + H_2$  is, in fact, only a desirable maximum which can never be fully attained. The authors attempted to find out how far the completeness of the reaction depends on the temperature. For this purpose a combustion-tube filled with purified charcoal was heated in a combustion furnace while dry and pure carbon dioxide was passing through it. For measuring the temperature a number of small glass tubes filled with salts or metal wires of known fusing point was uniformly divided amongst the charcoal in the combustion-tube, and according as one salt was fused at the end of an operation and another was not fused, the temperature was considered to lie between these limits. The analysis of the gas which escaped at the end of the tube was performed according to Bunsen's method. The results of the experiments will be seen from the following table:—

*Obtaining Sulphur from Furnace Gases.* Emil Hanisch and Max Schroeder, Neumühl-Hamborn, Prussia. Eng. Pat. 6404, May 26, 1885.

THE sulphur dioxide, after separation from the accompanying gases, by absorption in a water-tower with subsequent boiling of the aqueous solution, is led first through a vertical cylinder containing carbonaceous material, heated externally by producer gas, whence a mixture of sulphur vapour and unchanged sulphur dioxide with the oxides, sulphide, and oxy-sulphide of carbon is obtained. This mixture is then passed through an externally heated cylinder, filled loosely with fire-brick; here a mutual reaction occurs resulting in sulphur (in the gaseous state) and carbon dioxide—

Carbon monoxide may be substituted for carbon—

To effect the reaction with this gas half of the carbon dioxide produced in the reaction is returned and passed through the first cylinder, where it becomes converted into the mon-oxide, afterwards meeting with the sulphur dioxide which, in this case, is introduced into the channel between the two cylinders, the reaction taking place solely in the second of these. The sulphur vapour is condensed and collected in suitable chambers.

—W. G. M.

*On Explosions caused by Dust.* C. Engler. Chem. Ind. 8, 171.

OWING to repeated explosions in the lamp-black works of the Black Forest, the author investigated the causes of

*Heat of Combustion of Rouchamp Coal.* A. Scheurer-Kestner. Bull. Mulhouse, 1885, 333.

THE author's previous results on this subject have been criticised by Bunte and Stohmann. With the view to end the controversy on the point at issue between them, the author appeals to recent numerical results which entirely confirm the preceding. The mean composition of the coal, ash free, and dried at 110° was: C, 89.09; H, 5.09; N, 1.30; O, 4.52 per cent., the heat of combustion for 1grm. 9130cal. Calculating from the composition of the coal—the calculation including a deduction for the hydrogen burnt at the expense of the oxygen of the coal, according to Dulong—the number of calories is 8761, the difference being 369, or 4.25 per cent. The author upholds therefore the statements on this subject made by himself and his collaborateur, Mennier-Dollfus, in 1868-1870.—C. F. C.

such accidents. These may be produced by igniting a mixture of (1) combustible gases with air; (2) fine particles of coal or soot with air; and (3) combustible gases and soot with air. The conditions under which combustible gases explode with air have been clearly defined by Bunsen, Winkler, and Wagner. On the second point the author found that a thick cloud of common coal soot produced in an apparatus devised for that purpose can neither be ignited by a "naked" light nor by the induction spark of a powerful Ruhmkorff. Clouds of flour, sulphur, naphthalene, or colophonium ignite at once very vigorously, especially the last with explosive force. Soot being in a hot state in the soot-chambers, a cloud of soot and charcoal, 300° C. hot, was produced in the apparatus, but on introducing a light no transmission of the flame could be observed. It therefore appears that explosive effects are only produced by those substances which on heating give off combustible gases.

Hilt arrived at the same conclusion when investigating explosions in coal-pits caused by coal-dust. A series of experiments was also made on the nature of air mixed with coal or soot particles and combustible gases.

	Vols. per cent. illuminating gas and coal-dust.	
Air, containing 12.3 ignites with violent explosion	10.2	"
" " " " " "	9	"
" " " " " "	8	"
" " " " " "	7	ignites quickly without explosive force
" " " " " "	5.6	"
" " " " " "	3.5	"
" " " " " "	2.4	does not ignite

Further experiments showed that air containing 7.5 per cent. illuminating gas and no coal-dust cannot be ignited under the same conditions, and it is therefore evident that a gas mixture, which is harmless by itself, burns with an explosive force when mixed with coal-dust. The same experiments made with marsh gas gave an equal result.—S. H.

*Improvements in the Treatment of Gas and in the Materials and Apparatus employed therein.* F. Leslie and J. A. Wanklyn, London.

This invention relates to the carrying on of a process described by the above patentees in their Provisional Specification 419, January 12, 1885, which consists in separating gas into two qualities for heating and lighting. This process depends upon the fact that the former is lighter and passes more readily through a partition of porous material. It is now stated that this separation can be much more easily effected in the presence of an oily or fatty substance. The apparatus consists of a cylinder with closed ends, having a division of wire gauze, upon which rests the porous material employed. Below the gauze two pipes enter the cylinder; one admits coal gas in its ordinary condition, and the other allows the heavy illuminating gas to pass away. Above the gauze is another exit pipe to carry off the light heating gas which has made its way through the porous material. For this last, linseed meal is recommended, but any crushed oily seed will answer, as will also fragments of stearic acid, tallow, pieces of cork, bark, or such like, coated with oil or lard.—A. R. D.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

*A New Lutidine.* A. Ladenburg and C. F. Roth. Ber. 18, 1590

FROM that fraction of bases obtained from Dippel's oil boiling at  $174-176^\circ$ , a third lutidine has been obtained by precipitation with  $\text{PbCl}_2$ . The platinum double salt forms a voluminous precipitate of a dark orange colour, which easily decomposes. On recrystallisation it is obtained in needles or pointed plates of a characteristic bronze colour. The hydrochloride of the base is obtained from the platinum salt by means of  $\text{H}_2\text{S}$ , and with potash the free base is separated. It is an oil distillable with steam and possessing the penetrating smell of lutidine (B. P.  $174-176^\circ$ ).—J. B. C.

*The Decomposition of the Terpenes by Heat.* Berthelot. Ann. Chim. Phys. (6), 5, 136.

TILDEN'S experiments confirm the views long held by the author—viz., that the terpenes do not belong to the aromatic series, but are formed by polymerisation of the double anylene,  $\text{C}_8\text{H}_8$ .—J. B. C.

*Valuation of Ozokerite.* Lach. Chem. Zeit. 9, 905.

ONE HUNDRED grms. ozokerite are treated with 20 grms. fuming sulphuric acid in a tared basin. The mixture is heated from  $170$  to  $180^\circ$ , and continuously stirred until all sulphur dioxide has escaped. On reweighing the difference presents the yield of volatile products—

viz., petroleum and water. Another quantity of ozokerite is mixed with 10 per cent. of decolourising powder (residues from the manufacture of prussiates), previously dried at  $140^\circ \text{C}$ . A tenth part of the mixture is weighed off and put into a small cylindrical filter, closed at the bottom, whose weight is known, when dried at  $130^\circ \text{C}$ . The contents are then extracted with benzene in a small extracting apparatus. The filter is dried at  $130^\circ \text{C}$ , and reweighed, and from the loss the percentage of wax can be calculated. By evaporating the benzene solution and drying the residue at  $180^\circ \text{C}$ , this result may be verified, while the melting point of the wax can also be ascertained.—S. H.

*Improvements in Separating Solid Paraffin from Oils.* G. T. Bailely, Midealder. Eng. Pat. 11,987, September 4, 1884.

THIS invention relates to apparatus for cooling and crystallising paraffin oils in a state of repose, and has reference also to the breaking up of the solidified mass, and feeding the same to the apparatus used for separating the solid portions of the paraffin from the liquid portions. The apparatus consists of a narrow vertical cell whose outer walls are exposed to the cooling influence of the air; in the lower part a rotating screw is arranged horizontally and longitudinally, which by its action breaks up the solidified mass in the cell and discharges it continuously into pipes leading to a filter-press.—D. B.

*An Improved Process and Apparatus for Extracting Benzene from the Gases evolved in Sealed or Closed Coke-Ovens.* John Coates, London. Eng. Pat. 11,202, May 1, 1885.

AFTER passing through the ammonia scrubbers the gases are drawn through one or more rectangular washers, made perfectly gas-tight, and containing tubes or plates so disposed as to cause the gas to pass through the washing liquid, which is preferably an oil having an affinity for benzene. From the washers the gas passes up a scrubber consisting of a tower packed with boards, coke, tiles, or other suitable material down which the absorbing oil is allowed to trickle. The oil is drawn off and the benzene distilled from it by any known process.—A. R. D.

### IV.—COLOURING MATTERS AND DYES.

*Dioxyppyronequinone.* H. Reinherz, Ger. Pat. 31,091, July 16, 1884; and Dingl. Polyt. J. 256, 323.

AFTER heating one part pyrenequinone with 4–5 parts concentrated sulphuric acid at a temperature of  $180-210^\circ$  for 2–3 hours, the disulphonic acid is obtained. On purifying somewhat with calcium or lead salts, and heating with potassium or sodium lye, or fusing with solid caustic alkali, the potassium or sodium salt respectively of dioxyppyronequinone is obtained, the red coloured aqueous solution of which gives coloured precipitates with lead acetate and metallic chlorides. Hydrochloric acid precipitates the dioxy-compound as a reddish-brown powder, which can be purified by recrystallising from alcohol. The alkaline salts of the bisulphonic acid are almost colourless, and are somewhat difficultly soluble in water; the solutions, however, are red in colour, and can be used for dyeing. Dioxyppyronequinone can also be obtained by treating one molecule pyrenequinone with two molecules bromine in a closed vessel at  $90-115^\circ$  for  $2\frac{1}{2}$  hours, and then heating the light-red dibrom-pyrenequinone with an alkali.—J. T.

*Preparation of Rosaniline Dyes.* E. Erlenmeyer. Ger. Pat. 30,357, February 21, 1884; and Dingl. Polyt. J. 256, 324-325.

THE author recommends the preparation of these dyes by the oxidation of certain compounds of methylated amines with primary, secondary and tertiary aromatic amines. Pararosaniline, for example, is to be prepared

by heating 120 parts dimethylaniline, 465 parts aniline, and 920 parts of 75 per cent. arsenic acid, or 123 parts methyl-violet, 501 parts aniline and 558 parts arsenic acid, at 189° C., with agitation, and maintaining this temperature until a test becomes solid on cooling. The mass is boiled in water, the extract is heated with common salt equal in amount to the portion treated with water, and the bluish-green hydrochloride is precipitated with common salt. Or, 180 parts dimethylaniline, 300 aniline hydrochloride, 555 nitro-benzene, and 15 iron-filings; or, again, 205 parts methyl-violet, 582 aniline chlorhydrate, 555 nitro-benzene, and 15 iron-filings, are heated very gradually to 180° with stirring, and maintained at this temperature until a cooled test becomes solid; the mass is then boiled, with the addition of some hydrochloric acid, and the filtered extract is salted out. Corresponding violet and blue dyes, as in the case of methyl-violet by the copper chloride process, can be prepared by oxidising dimethylaniline in combination with diphenylamine, etc., by oxidising with copper chloride. Also the action of a zinc chloride on the compound of methylphenylnitroso-amine, with dimethylamine and analogous compounds, produces violet and blue dyes.—J. T.

**Formation of Quinones from Paramethylated Amines.** E. Noelting and T. Baumann. Bull. Mulhouse, 1885, 305.

THE authors find that quinones are formed in the oxidation of the paramethylated amines by chromic acid, provided the latter is added in sufficient quantity. The following are the proportions of the reagents employed in the authors' experiments:—Base 5, water 500, chromic acid 15, sulphuric acid (60° B.) 25:—

*Paratoluidine* gave traces only of the quinone. *Metaxylidine*,  $C_8H_9.NH_2.CH_3$  (1, 2, 4), yielded toluoquinone,  $C_8H_6O.O.CH_3$  (1, 2, 4) (m. p. 70°), in small quantity. *Orthoxylidine* (1, 3, 4) yielded a quinone, but the quantity obtained (from 4grms.) was too minute for identification. *Mesidine*,  $CaH_2.NH_2$  (Me<sub>2</sub>) (1, 2, 4, 6), yielded metaxylquinone,  $C_8H_6O.O.CH_3$  (1, 2, 4, 6), melting at 72°. The yield in this case was large, 5grms. of the base giving 2grms. of the quinone. *Pseudocumidine*,  $C_8H_9.NH_2$  (Me<sub>3</sub>) (1, 2, 4, 5), yielded the corresponding quinone. A quantity equal to 20 per cent. of the weight of the original base was obtained in the pure state (m. p. 123°); a further quantity which remained dissolved in the mother-liquor was converted into the hydroquinone (m. p. 210°) which was isolated (comp. J. Prakt. Chem. 23, 429). *Isoduridine*,  $C_8H_9.NH_2$  (Me<sub>4</sub>) (1, 2, 3, 4, 6), under the same treatment, yielded a cumoquinone which was converted into the corresponding hydroquinone (m. p. 169°) by the action of sulphurous acid upon the aqueous distillate from the mixed products of oxidation. The quinone was subsequently obtained by oxidising the hydroquinone. It is liquid at the ordinary temperature of the air, crystallising in yellow needles at 11°.—C. F. C.

**Some Derivatives of Pseudocumidine.** E. Noelting and T. Baumann. Bull. Mulhouse, 1885, 309.

THE authors having previously shown that a crystalline cumidine is formed by the action of methyl-alcohol upon the hydrochlorate of both para- and orthoxylidine, and that its constitutional formula is, therefore,  $C_8H_9.NH_2$  (Me<sub>3</sub>) (1, 3, 4, 6), have now established the identity of this base with that obtained by Schäper (Zeit. Chem. 1867, p. 12) by amidating pseudocymene (comp. Hofmann, Berl. Ber. 15, 2895). In the course of their researches the authors have prepared the following derivatives:—

*Acetocumidine*: White needles, soluble in alcohol, slightly in water, m. p. 161°. *Diazoacetocumidine* was obtained by diazotating the base, and treating the product with cumidine in acetic acid solution. It crystallises in transparent tables (m. p. 130°). *Amidoacetocumidine* was obtained by heating the diazo product (20 pts.), with cumidine (40 pts.), and cumidine hydrochlorate (13 pts.), at 80°. From the product, after distilling away the excess of cumidine, the amidoazo compound was dissolved out by means of ether, and precipitated by

hydrochloric acid from its ethereal solution. The free base crystallises from its solution in alcohol, in orange-coloured plates (m. p. 138°). By reduction with stannous chloride it is converted into a mixture of cumidine and cumylenediamine, from which the latter is easily isolated. It crystallises in white needles, m. p. 91°.

An *amidotetramethylbenzene* was formed by heating the hydrochloride of cumidine with methyl-alcohol at 200–300°. It was obtained as a liquid boiling at 245–250°, crystallising at –10°. The hydrochloride crystallises in white needles. Mesidine similarly treated yielded an identical amidotetramethylbenzene. The base in question was, moreover, found to be identical with that recently isolated by Hofmann (Ber. 17, 1912) from amongst the by-products of the transformation of xylylene into cumidine. It is hence to be regarded as a derivation of isodurene, and may be designated isoduridine.

—C. F. C.

*The Use of Poisonous Colours.* Chem. Zeit. 47, 832.

AT the meeting of the Verein zur Wahrung der Interessen der Chemischen Industrie Deutschlands held on April 25, the report of the commission appointed to consider the use of poisonous colouring materials was adopted. The commission defined poisonous colouring materials to be all those colours or colour preparations which contain:—A. Antimony, arsenic, lead, chromium (with the exception of pure chromium oxide), copper, mercury, cinnabar, gamboge, and picric acid; B. Barium (but not barium sulphate), heavy spar, cadmium, zinc, and tin. The use of all these for colouring foods or food stuffs is forbidden. Those enumerated under section A should be so packed for transit as to render the loss of any of the poisonous substances impossible, and, with the exception of lead chromate, are not to be used for colouring toys. The use of arsenic for wall papers is forbidden. Wall-paints containing copper and arsenic are to be discontinued. The sale of articles coloured with poisonous materials as above defined is to be made illegal. The report has been forwarded to the German Government.—S. R.

**Evaluation of Indigos.** (Abstract of a paper read before the Society of Dyers and Colourists.) Ch. Rawson. Jour. Soc. Dyers and Colourists, 1885, 74.

THE principal colouring matter in indigo is indigotin, in addition to which indigo red, indigo brown, indigo gluten, and mineral matters are present. The different shades obtained in the dye-bath are due to the indigotin and indigo red present; the other bodies producing little or no effect. The methods of analysis may be classed under the following heads:—

I. By oxidation of sulphindigotic acid.

II. By loss on sublimation.

III. By reduction to indigo white in an alkaline solution.

**I. Oxidation of Sulphindigotic Acid.**—To obtain a solution of sulphindigotic acid, 1grm. of finely-powdered indigo is intimately mixed in a small mortar with its own weight of ground glass. The mixture is gradually and carefully added during constant stirring with a glass rod to 20cc. of concentrated  $H_2SO_4$  (sp. gr. 1.845) contained in a cylindrical porcelain crucible (cap. 13oz.); the mortar is rinsed out with a little powdered glass, which is added to the contents of the crucible, and the whole is exposed in a steam-oven for a period of one hour to a temperature of 90° C. The sulphindigotic acid thus formed is diluted with water and made up to a litre. The solution must be filtered, in order to separate certain insoluble impurities, which otherwise would interfere with the subsequent operations. 50cc. of the clear solu-

tion are measured into a porcelain dish, to which are added 250cc. of distilled water. To this diluted liquid a solution of permanganate of potash (0.5 grm. per litre) is gradually run in from a burette until the liquid, which at first takes a greenish tint, changes to a light yellow, the sulphindigotic acid being converted by oxidation into a yellow body named sulphiatic acid. According to the equation—

It would appear that indigo-red acts upon "permanganate" in the same way as indigotin, whereas indigo-brown is precipitated from its solution in strong  $H_2SO_4$  on diluting, and does not affect the result; but indigo-gluten and the mineral portion strongly decolorise "permanganate." As indigo-red cannot be regarded as an impurity, the inaccuracy in the analysis may be chiefly ascribed to the gluten and mineral impurities. To eliminate this source of error, the author makes use of the property of sodium sulphindigotate, being almost insoluble in solutions of common salt. The 50cc. of the filtered solution of indigo, instead of being directly titrated with permanganate, are mixed in a small flask with 50cc. of water and 32grm. of common salt. The liquid, which is almost saturated with the salt, is allowed to stand for two hours, when it is filtered, and the precipitate washed with about 50cc. of a solution of salt (sp. gr. 1.2). The precipitated sulphindigotate of soda is dissolved in hot water, the solution is cooled, mixed with 1cc. sulphuric acid and diluted to 300cc. The liquid is then titrated with potassium permanganate as before. A small correction is necessary, owing to the slight solubility of the sodium sulphindigotate in the salt solution. For 0.05grm. of the indigo sample 0.0008grm. must be added to the amount of indigotin found.

The potassium ferricyanide method of Allgren is not recommended by the author, the results obtained being too high.

**Hyposulphite Method.**—This process, which was recommended by A. Müller (*American Chemist*, v. p. 128), depends upon the fact, that a solution of sodium hypsulphite (not thiosulphate) reduces sulphindigotic acid quantitatively to disulpho-leucindigotic acid. A flask of 100cc. capacity is loosely filled with twisted sheet zinc, which is covered with a solution of sodium bisulphite (sp. gr. 1.30). The flask is corked and allowed to stand for about an hour. The liquid is now decanted, and well mixed in a large flask or bottle with five litres of distilled water, containing in suspension about 50grm. of recently-slaked lime. The vessel is closed to prevent access of air, and, after allowing insoluble matters to subside, the clear liquid is syphoned off into a convenient stone bottle, and about 100cc. of petroleum oil poured on the surface of the liquid to prevent oxidation. The bottle is fitted with a cork with two tubes, one of which is in the form of a syphon, and is used to fill the burette; the other tube, which only just passes through the cork, is connected with a supply of coal-gas. A further precaution is to cover the bottle with a sheet of black paper. The solution may be standardised either by pure indigotin or by an ammoniacal solution of copper sulphate, using in the latter case indigo-carmin as indicator. The copper solution is prepared by dissolving 1.994grm. (equal to 1grm. indigotin) of the crystallised salt,  $CuSO_4 \cdot 5H_2O$ , in a litre of water containing 100cc. strong ammonia (sp. gr. .880); 50cc. of this solution are measured into a wide-mouthed flask (capacity 200cc.) boiled to expel air and allowed to cool. The flask is provided with a caoutchouc stopper, perforated with four holes, into two of which are fitted two Mohr's burettes, one containing the hypsulphite solution, and the other the indigo-carmin. The two other apertures serve for the entrance and exit of a current of hydrogen or coal-gas. The burette containing the "hypsulphite" is furnished with a perforated cork, through which passes a glass tube connected with a supply of coal-gas; and at the lower extremity a glass tube is joined to it, which is in connection with the bottle filled with sodium hypsulphite. By this means the

burette can be refilled without fear of oxidising the hypsulphite solution. The flask containing the 50cc. of copper sulphate is attached to the caoutchouc stopper, and the air is expelled by a current of coal-gas, which should first pass through U-tubes containing ferrous hydrate. The solution of "hypsulphite" is now gradually run in until the liquid becomes nearly colourless, when a few drops of indigo-carmin are added from the other burette, and, finally, a further quantity of hypsulphite, until the solution assumes a peculiar brownish-red colour. The quantity of hypsulphite used to decolorise the few drops of indigo-carmin solution is very small, but by determining the strength of the two liquids the amount thus consumed can be easily calculated, and then deducted from the number of cc. of copper sulphate solution. 50cc. of copper sulphate are equivalent to .45 indigotin, so that supposing 25cc. of sodium hypsulphite have been required for the titration, each cc. of the hypsulphite will correspond to .002 indigotin. The preparation of the sulphindigotic acid solution is the same as that already given. The measured quantity to be analysed is boiled to expel air and allowed to cool. The flask is then attached to the burettes, and after driving out the air by a current of coal-gas, the hypsulphite solution is gradually added during constant agitation. The advantage of this method is that neither indigo-gluten, indigo-brown, nor indigo-red have any appreciable effect upon the estimation of the indigotin. The only substance which affects the result is iron in the ferric state; but it is only in the lower classes of indigo that iron is present to any appreciable extent, and in those cases it exists, or is subsequently reduced to the ferrous state.

**II. Sublimation.**—The method proposed by C. T. Lee (*Chem. News*, August 1, 1884), *loc. cit.*

According to the author, great accuracy in the results by this method cannot be ensured. He finds that indigo-gluten, indigo-brown, and indigo-red are all more or less affected by this method, and that pure indigotin leaves a residue occasionally amounting to 10 per cent. As a rule, inferior qualities of indigo yield results by this process which are too high, whilst, on the other hand, indigos rich in indigotin give results undoubtedly too low.

**III. Reduction of Indigotin in an Alkaline Solution.**—Of all these processes the two recommended by the author are that of Crace-Calvert, by means of ferrous sulphate and sodium hydrate, and that introduced by himself, by means of sodium hypsulphite and lime. The latter, he considers, gives the best results of any process hitherto published. This process is as follows: One gramme of finely-powdered indigo is ground into a thin paste with water, and introduced into a flask with 500cc. to 600cc. of lime water. The flask is furnished with an indiarubber stopper, which has four perforations, in one of which is inserted a syphon closed by a pinch-cock, and in another is fixed a funnel provided with a stop-cock; the other two apertures serve for the entrance and exit of a current of coal-gas. The flask is connected with a supply of coal-gas, and the contents heated to about 80° C.; 100cc. to 150cc. of a solution of sodium hypsulphite are now introduced by means of the funnel, and the mixture, which in a few minutes takes a yellow tint, is kept near the boiling point for half-an-hour. After allowing the insoluble matters in the flask to subside, 500cc. are syphoned off, and the remaining liquid accurately measured. The sodium hypsulphite used was five times the strength of the solution previously described. The 500cc. are poured into a flask, and by means of an aspirator a current of air is drawn through the liquid for about twenty minutes. The excess of hypsulphite is thus oxidised to sulphite, and the indigo-white to indigo-blue. An excess of hydrochloric acid is now added to dissolve any carbonate of lime which the precipitate may contain. The precipitate is washed upon a weighed filter with hot water, dried at 100°, and weighed. The weight thus obtained is indigotin and indigo-red. If it is desired to determine the amount of each of these, the filter with its contents is placed in an extraction apparatus, and the indigo-red dissolved by means of alcohol.—J. B. C.

*Valuation of Indigo.* Ch. Rawson. Jour. Soc. Dyers and Colourists, 1885, 211.

THE author criticises a paper by Dr. Rau (*Amer. Chem. J.* 1885, p. 7) on a modification of Fritzsche's method for the determination of indigo according to which the sample of indigo is reduced by grape sugar and sodium hydrate in an aqueous alcoholic solution. As the author was led to expect from the solubility of indigo-red in alcohol, the reduced indigo when decanted and precipitated by a current of air consists of pure indigotin, indigo-red remaining in solution. The estimation of indigotin is not in itself sufficient to determine the value of a sample of indigo.—J. B. C.

*Condensation of Chloral-hydrate with Tertiary Amines.* P. Boessneck. Ber. 18, 1516.

THE author has repeated the researches of E. and O. Fischer on the condensation of chloral with dimethyl-aniline, with the following results. The condensation was effected in presence of  $ZnCl_2$ , the product dissolved in dilute HCl, and the bases separated with ammonia. The condensation products which become semi-solid upon standing are treated with ether, which dissolves dimethylaniline and another base to be referred to, whereas the methyl derivative of pentaphenylethane discovered by O. Fischer remains undissolved.

The ethereal solution containing the new base is evaporated, and the oily residue treated with steam to eliminate the free dimethylaniline. A black half-solid substance remains, which with an excess of HCl changes to a crystalline mass—the hydrochloride of the base. By filtration and washing with alcohol the crystals are obtained colourless, and by recrystallisation from water, chemically pure, about 25 per cent. of the hydrochloride is obtained on the original quantity of chloralhydrate. The free base separates on addition of alkalis in an oily form; but rapidly becomes crystalline (m. p. 111°). By heating with alkalis, the smell of chloroform is at once apparent. From this fact and the results of analysis the substance is supposed to possess the following constitutional formula:  $Cl_3 \equiv C - C.OH.H_2C_6H_5.N(CH_3)_2$ , to which the author gives the name of dimethylamido-phenyl-oxy-trichlorethane. Further experiments have shown that by modifying the method of preparation—i.e., by allowing the action to proceed in the cold, the formation of the pentaphenylethane derivatives is avoided, and a larger yield of the new base obtained.

As observed, the action of boiling alkalis produce decomposition with formation of chloroform. If the operation be conducted in a flask connected with a condenser, and steam passed into the alkaline liquid, chloroform is found to collect in the receiver, at the same time a colourless substance distils and crystallises in the condenser. From the melting point and properties the authors consider it to be dimethylamidobenzaldehyde, decomposition occurring as follows:

*Reduction Products of the Nitroazo Compounds and Azonitrolic Acids.* T. v. Janovsky. Monatsh. Chem. 1885, 455.

THE present paper is a continuation of former researches (this Journal, 1885, 397), with a view to fixing the constitution of the nitrolic acids derived from nitroazo bodies. From the analysis two formulæ are possible— $C_6H_5N = NC_6H_4N(OH) - (HO)NC_6H_4N = NC_6H_5$  and  $C_6H_5N = NC_6H_3 - NOH$ .

The position of the group  $-N.OH$  is determined by that of the nitro-group in the original substance. On reduction the nitrolic acid gives an amidoazobenzene identical with that obtained from diazoamidoazobenzene. The red oil obtained as by-product in the preparation of nitroazobenzene is dimetadinitroazobenzene yielding on reduction *m*-phenylenediamine.

By partial reduction of *m*-dinitroazobenzene, a semi-solid nitrolic acid is formed, which dissolves in alkalis on heating with a violet blue colour. The analysis indicates the presence of only one "nitro" group. If the boiling alcoholic solution be reduced with ammonium sulphhydrate until alkalis no longer give a blue colouration, but a deep green, the solution has a gold-brown colour, the product formed being *m*-diamidoazobenzene—

This compound is therefore a symmetrical isomeride of chrysoidine. It dyes wool and silk a yellow colour. By nitrating the red oil with excess of fuming nitric acid two nitro-products are formed, one being soluble, the other insoluble in glacial acetic acid.

By partial reduction of *p*-dinitroazobenzene a nitro-nitrolic acid is obtained (this Journal, 1885, 397), which on further reduction with ammonium sulphide in alcoholic solution yields di-*p*-diamidoazobenzene. This is not identical with diphenin (di-*p*-amidohydrazobenzene). Nitrate of silver added to a solution of a salt of this base gives a yellow-brown precipitate, which dissolves in hot water and crystallises out on cooling. This silver reaction appears to be common to all amidoazobenzenes. This body colours silk yellow, and is the second isomeride of chrysoidine, having the formula—

With cold fuming nitric acid, mononitroazobenzene yields a trinitro product (m. p. 180°), and the same compound may be prepared from azobenzene and *p*-dinitroazobenzene. A second trinitro compound is obtained by acting on *p*-dinitroazobenzene in the cold with fuming nitric acid (m. p. 169°), which explodes on heating above its melting point. The formulæ of these two bodies will probably be,  $NO_2.C_6H_3 = NC_6H_3(NO_2)_2 (3:4)$  and  $NO_2.C_6H_2 = NC_6H_2(NO_2)_2 (2:4)$ .

By decomposition *p*-phenylenediamine and triamidoazobenzene are formed. Triamidoazobenzene gives a nitrolic acid on reduction. These nitrolic acids are fundamentally different from those of the fatty series, and also differ from the hydroxamic and hydroxamic acids, which are prepared with hydroxylamine. The name nitrolic acid has been retained on account of the group  $-N.OH$  which is present. From these considerations, and from the fact that the analyses of these compounds indicate a quantity of hydrogen less than that required in the first formula given, the author considers the following to represent the constitution of this class of bodies,  $C_6H_5N = \dot{N}C_6H_5 = \dot{N}.OH$ .—J. B. C.

*Improvements in Producing Yellow Colouring Matter suitable for Dyeing and Printing.* W. W. Grieve, Glasgow. From the "Farbenfabriken vormals Friedrich Bayer & Co.," Elberfeld, Germany. Eng. Pat. 9606, July 1, 1884.

THIS invention is a development of the specification, 9162, June 19, 1884, and consists in substituting tetrazoditolyl or tetrazodixyl for the tetrazodiphenyl described in the previous provisional specification. The tolyl and xyllyl bases are prepared from nitrotoluene or nitroxylylene by a process analogous to that employed in making benzidine from nitrobenzene. The colouring matter is produced by combining the tetrazo-compounds with salicylic acid.—R. M.

*Improvements in the Preparation of Purple Colouring Matter suitable for Dyeing and Printing.* J. H. Johnson, Lincoln's Inn Fields. From H. Caro, Mannheim, Germany. Eng. Pat. 11,030, August 7, 1884.

THIS invention is an improvement upon the patent No. 4428, September 15, 1883, in which it was stated that zinc chloride was inferior to aluminium chloride as a condensing agent in effecting condensation between carbon oxychloride and dimethylaniline or analogous tertiary bases. The inventor now shows that by a modification of the original process zinc chloride can be equally well employed, and as an example the following

liquid is drawn back through the material, and returns by way of the pipe *c* into the reservoir *a*. The specifica-

FIG. 2.

tion contains other drawings showing slight unimportant modifications of the above.—E. J. B.

*Improvements in the Manufacture of Fibrous Material from Wood for Surgical and other Purposes.* Henry Harris Lake. From Josef Odelga. Eng. Pat. 2957, March 6, 1885.

THE inventor claims the preparation and use of the long thread fibrous material obtained by scraping strips or blocks of wood, which material is similar to linen lint, and may be used as lint for surgical purposes, or as filling material, and may be spun into yarn, and in the form of spun yarn be used in the manufacture of woven fabrics, cord, braided articles, netting, embroidery, and knitted goods.

—E. J. B.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

*Note on Printing Blue Grounds.* M. O. Breuer. Bull. Mulhouse, p. 532, 1884.

DIFFICULTIES experienced in printing blue grounds with Alkali blue 5B. have suggested the method described, which was successfully used for years for printing violet. The addition of 15 per cent. of ammonia caused complaints respecting uneven grounds to cease. The blue made with Alkali blue 5B., and treated in this manner, was in itself an improvement, but perfection was only attained by proceeding as follows:—The blue 5B. was first decomposed by an acid, and dissolved in ammonia. The following are the formulae:—

*For the blue—*

Alkali blue 5B. ....	1,000	grams.
Water.....	10,000	"

Dissolve and precipitate with—

100 grams of HCl at 21° B $\acute{e}$ , decant and filter:

The result is 10,000 grams of blue paste.

*Printing colour—*

Blue paste as above .....	2,000	grams.
Ammonia .....	350	"
Glycerine .....	500	"
Dry gum senegal.....	1,100	"

*Reduction—*

Gum water .....	1,000	grams.
Ammonia .....	35	"
Glycerine .....	75	"

Print on wool mordanted with tin, damp before steaming, steam 60 minutes and wash. These remarks bear out a fact known some time already, and which perhaps might repay study—viz., that the addition of ammonia improves all printing colours made with aniline colours properly so called, as well as those popularly so called. Almost all are improved thereby, even those which ought not to be affected at all, such as, e.g., the ponceaux K, 2 R, and 3 R, which are all salts and not acids. It has also been noticed that in printing light blue grounds on silk, the addition of ammonia to aniline colours has been of another advantage. It was found thereby possible to

avoid the presence in light blue grounds of little light and sometimes even white spots with which previously the grounds were sown, and which were simply due to calcareous soap, resulting from careless soaping. Ammonia proved to be a solvent for the substances producing these marks.—H. A. R.

*Chrome Discharge of Indigo Blue.* A. Scheurer. Bull. Mulhouse, 1885, 316.

THE process of fixing an alumina mordant simultaneously with the discharge of a dyed indigo blue, by means of a mixture of aluminium chloride and potassium bichromate, printed upon the cloth and steamed, is attended with the disadvantage that in the after-process of dyeing with alizarin the shades produced are lacking in brightness. Better results are obtained by substituting aluminium oxalate for the chloride, in which case an acid (oxalic) requires to be added. In comparing the alizarin shade produced upon an original and a discharged white (indigo), each of which had been printed with this mixture and steamed, those upon the former were found to be considerably brighter. A probable explanation of the inferior colour upon the discharged ground is the retention of a chromic oxide in combination with a product of oxidation of the (discharged) indigo.—C. F. C.

*Use of Oxalate of Antimony in Printing.* E. Jacquet. Bull. Mulhouse, 1885, 318.

THE author recommends a mixture of basic antimony oxalate and ammonium oxalate as a substitute for tartar emetic in the fixation of tannin, and, therefore, of those colours which require the tannin mordant—e.g., methylene blue. The basic salt is prepared from the antimony-potassium oxalate by precipitation with ammonia, and is added in the form of paste together with twice its weight of ammonium oxalate, to the mixture of colouring matter, tannin, etc., in the usual proportions. After steaming the goods are cleared in the usual way, but with the addition of chalk to the bath in order to neutralise the oxalic acid.—C. F. C.

*Development of Aniline Black.* C. Zurcher. Bull. Mulhouse, 1885, 319.

THE tardy development of aniline black upon the fabric from the usual printing mixtures, at temperatures between -13° and +13°, the author refers to a separation of the aniline salt from the liquor, which appears from his observations to be especially favoured by certain conditions of humidity and of movement of the surrounding atmosphere.—C. F. C.

*Starch as a Substitute for China Clay in Printing.* O. Breuer. Bull. Mulhouse, 1885, 322.

THE author finds that starch, made into a paste with water in the cold, is a perfect substitute for China clay for printing in reserve for indigo blue, and for many other purposes, especially for printing upon silk. It may be used in quantities of from 250 to 400 grammes per litre of thickening, without causing any undue hardening of the fabric.—C. F. C.

*A Reducing Vat for Indigo and Blue-Black.* C. Collin and L. Benoist. Ger. Pat. 30,449, Feb. 29, 1884.

IN order to avoid detrimental fermentations in preparing the vat, the inventors propose to employ a completely fermentescible food material, and a pure ferment. For a vat of 8000 litres, 16kilos. of flour or starch are boiled for a few minutes in water containing 1.6kilo. of sodium carbonate. The starch paste is transferred to the vat, and Skilos. of glucose, 5.3Skilos. of soda, and 1kilo. of magnesia are added. Magnesia is better adapted for the neutralisation of the lactic butyric and other acids formed than lime. With this vat, the amount of alkali necessary to combine with the above-named acids and to form the indigotic salt may be calculated with fair accuracy. As, however, the alkalinity

of the vat at the commencement would be too high if the total amount of alkali were to be added at once, there is added upon the first day only one half of the soda required to neutralise the acids formed, in addition, of course, to the alkali required for the formation of the indigotic salt. This is calculated to be 230grm. of soda for 1kilo. of indigo. Whilst the vat is being worked, an addition of 2kilos. of starch paste and 2kilos. of glucose (daily) will suffice for 100kilos. of wool dyed per diem. With pure indigo, this method gives 40 per cent. better results, with mixed indigo and blue-black 65 per cent. better results, than the old reduction plan. The ferment, *desmabacterium hydrogenciferum*, is obtained pure by the following cultivation process:—100grm. of potato cuttings are allowed to digest for some time in 500cc. of water, at 40° to 44° C. The liquid soon becomes peopled with micro-organisms, amongst which is the *desmabacterium*. A flask is now filled with 1.5grm. phosphate of soda, 3grm. tartrate of ammonia, 5grm. of glucose, 5grm. of soluble starch, 3grm. of sodium carbonate, 0.5 grm. of lime, and 1litre of water. The flask is provided with a doubly-bent tube, which dips into a large evaporating basin containing 200cc. of water. The contents of the flask and basin are boiled for twenty minutes to effect sterilisation, and also to expel air, and then 50 to 60cc. of the liquid containing the *desmabacteria* are introduced into the basin, the boiling being at the same moment discontinued. The contents of the basin are slowly sucked into the flask, and when this has cooled down sufficiently for the hand to touch it without inconvenience, the bent tube is dipped under mercury, and the whole maintained for four or five days at a temperature of 35° to 40° C. At the end of this period, the *desmabacterium* will be in full activity, and in a pure condition; the liquid is then to be absorbed by wood flour sterilised at 150° in the proportion of three parts of the flour to two of liquid. The moist wood flour is dried at 40° to 45°, and the ferment thus obtained preserved in well-closed bottles. Of this prepared ferment, 50grm. suffice for a vat of 12cbm. contents.

—W. D. B.

*Improved Apparatus for Dyeing.* W. D. Thornton, Bradford. Eng. Pat. 10,042, July 11, 1884.

THE object of this invention is to dye wool in the silver, loose, and also when spun into yarn; also cotton in various stages of manufacture, in less time than hitherto. The fibres to be dyed are placed in an airtight vessel, a vacuum is created inside the vessel, and the dye-liquor admitted by opening a valve. Owing to the vacuum previously present, penetration is rapidly completed, and the dyeing rendered uniform. The liquor is finally drawn off by an ejector, which can be done in much less time than possible by gravity alone.

—H. A. R.

*Improvements in the Application of Chloride of Lime for Bleaching Purposes.* George Lunge, Zürich. Eng. Pat. 11,333, August 16, 1884.

HYDROCHLORIC, sulphuric or oxalic acids, when used as a means of liberating chlorine, do so as free chlorine, which injures fibres, machinery and health of workmen. Carbonic acid liberates hypochlorous acids instead of free Cl, but its gaseous form is not convenient. It is proposed to employ acetic acid, or another weak organic acid of an analogous nature. A very small quantity is sufficient, as it acts over and over again. The reactions taking place are the following:—

No free acid is thus ever present, which is a great advantage, especially with short fabrics. The acetic acid may be either added to the bleaching liquor at first, or the acid used along with the bath subsequent to soaking in bleach liquor. It is claimed that less bleaching powder is required, and that the water courses are less fouled.—H. A. R.

*Improvements in Dyeing Cotton Yarns and Fabrics.* F. A. Gatty, Accrington. Eng. Pat. 11,456, August 20, 1884.

THIS invention consists in an improved method of dyeing certain fast and permanent colours from olive to brown, by means of the oxides of chromium and iron in varying proportions, according to the shade required. For an olive shade, the inventor takes five gallons of chrome alum solution at 10° Tw., and 1 gallon of  $\text{FeSO}_4$  at 1½ lb. per gallon, or else an equivalent quantity of another soluble iron salt. For brown, the quantity of iron is increased according to shade, and the goods are then squeezed in a suitable manner. The next process is a passage through soda solution at 4° Tw. or more, and at a temperature of 140° to 150° F. approximately. The subsequent treatment of the dyed goods presents nothing unusual.—H. A. R.

## VII.—ACIDS, ALKALIS, AND SALTS.

*Preparation of Stannic Chloride.* L. A. Czimatis (Ger. Pat. 31,550, October 22, 1884). Dingl. Polyt. J. 256, 332.

ON heating a mixture of stannic oxide and magnesium chloride, or calcium chloride, stannic chloride distils over, and may be condensed. The mass obtained by mixing a solution of stannic oxide in hydrochloric acid with the chloride of an alkali metal, or of an alkaline earthy metal, after evaporation, can be similarly treated.—J. T.

*Combination of Oxalic Acid with Alumina.* C. Koechlin and L. Mathieu-Plessy. Bull. Mulhouse, 1885, 304.

OXALIC acid in combination with alumina is not immediately precipitated by lime salts. The authors have endeavoured, but without success, to take advantage of this property in the employment of the latter as mordants. Their researches, however, established the following relationships of affinity:—(1) Tribasic aluminic sulphate (hydrated) dissolves in a solution of neutral ammonium oxalate; (2) hydrated aluminic oxide likewise; (3) cryolite is attacked by a solution of oxalic acid at high temperature (150°).—C. F. C.

*Use of Kœrting's Apparatus for Facilitating the Passage of Gases from Pyrites Burners to the Lead Chambers.* A. Scheurer-Kestner. Bull. Mulhouse, 1885, 348. (Sealed Packet, October, 1877.)

THE author's experiments on this subject commenced at Thann in 1876. After many modifications, a thoroughly satisfactory and economical arrangement of the apparatus has been devised, whereby the steam to supply the lead chambers is intercepted and caused to work the blower. It is found that the steam from 1814kg. water, employed in this way, will produce sufficient draught for the combustion of 7000kg. pyrites of 45 per cent. sulphur.—C. F. C.

*The Italian Tartar Industry.* G. Kaemmer. Chem. Zeit. 9, 939 and 1012.

THE greater proportion of the Italian tartar is obtained from the marc and lees, and sold as half-refined. Cream of tartar is manufactured in Italy, to a very small extent in the south, but somewhat more largely in Piedmont, Tuscany, Lombardy, and generally speaking Upper Italy. The manufacture of tartar—Cremore di St. Antimo—is carried on largely in the south, and has concentrated around St. Antimo, Trani, Barri, and Messina. The lees are collected in the provinces, dried on the spot, and forwarded home, where they are ground in common horizontal mills, boiled in copper boilers, holding about 1200 litres, with from 10 to 12 times their weight of water, and the whole allowed to stand for 5 or 6 days, taking care to prevent the crystals which form at the surface from falling to the bottom. The liquor and crystals are removed from the insoluble portion, and this

is boiled with sulphuric or hydrochloric acid, and potash added subsequently in a thoroughly empirical manner, to effect the conversion of the tartrate of lime into acid tartrate of potash. This second crop of bitartrate is of less purity than that obtained by the first crystallisation, and is mixed therewith. The costs of working, owing to the crudeness of the apparatus, are very small, about 28-34 marks per 100kilos. of tartar. The loss of tartaric acid varies from 8 to 15 per cent., and the above estimate of the cost takes no account of the price of the lees. Well-arranged factories, working with a loss of 4 to 6 per cent. at most, and turning the nitrogenous residues to account, are able to manufacture a better product at a cost of 8 to 12 marks per 100kilos. of tartar. The importance of the Italian tartar industry is seen from the fact that in Southern Italy alone the number of boilers amounts to between 3000 and 3500, corresponding to a production annually of 6,000, 000kilos. of tartar from lees that is more than 10,000,000 marks. The composition of this tartar is upon an average:—

69.87	per cent.	tartaric acid as potassium bitartrate
4.06	"	" " " as calcium tartrate
Total, 73.93	"	" " " corresponding to
94.60	"	" " " of its salts

The remaining 5.4 per cent. consists of moisture, organic matter, sand (as much as 1 per cent.), iron, alumina, copper, phosphates, and magnesia. The manufacture of *Cremore di Vinaccia*, directly from the marc of the red grape, is carried on in a more scientific manner and with greater profit than that of *Cremore di St. Antimo*, since the alcohol obtained is a considerable source of profit. The author estimates the total annual value of this product at 5,000,000 marks, and places the average composition as 60 to 72 per cent. of tartaric acid as potassium bitartrate, 3 to 10 per cent. as tartrate of lime, recent analyses having shown 85.01 per cent. of bitartrate, 7.81 of calcium tartrate. The remainder consists for the most part of moisture, sand and organic matters; of iron, phosphates, copper, and alumina, there are less than in the *Cremore di St. Antimo*. The method of testing, almost universal still for trade purposes, consists in boiling 50grm. of the finely-powdered sample with one litre of water for 6 to 10 minutes, pouring the clear solution into a dish and allowing it to remain at rest for 12 hours. The crystals are then collected, dried and weighed; the weight found multiplied 2 and increased by 10 to correct for solubility, is taken as the percentage of potassium bitartrate. *Cremore di St. Antimo* is sold upon a basis of 90 per cent., *Cremore di Vinaccia* upon that of 85 per cent. The manufacture of cream of tartar or refined tartar is not carried on upon a large scale as compared with that of crude tartar. The total production can scarcely be more than 600,000kilos. with a value of 1,500,000 marks; the export is almost exclusively to England. The production of tartaric acid is much hampered by the high price of sulphuric and hydrochloric acids, but amounts to between 200,000 and 250,000kilos. per annum of about three-quarter million marks in value. The greater proportion of this is consumed at home, the remainder exported to England. It is computed that the total value of the Italian wine residues amounts to between 26 and 30 million marks per annum, or 1 mark per hectolitre of wine; by improved methods of working this amount might readily be increased by one-half or even doubled.—W. D. B.

*New Applications of the Nitrometer.* G. Lunge. Chem. Ind. 8, 161-171.

THE author at first criticises Allen's paper on the same subject, read before the Birmingham Section of this Society on 4th March, 1885. According to Allen, sulphuric acid has "a notable solvent power for nitric oxide," and hence a source of error is introduced, which must not be ignored, but Lunge proves this statement to be wrong (*Ber.* 18, 1391). He also points out here that the nitrometer is an excellent contrivance for determining the solubility of gases in certain liquids under variable pressure and temperature. Another new application of the same apparatus is for

reducing volumes of gas to normal pressure and temperature. Lunge also modified Allen's apparatus for the estimation of urea in urine. A small 50cc. beaker fitted with a perforated indiarubber cork is connected by a small piece of strong indiarubber tubing with the nose of the three-way tap of the nitrometer, which is filled with mercury (Allen fills his instrument with a saturated solution of sodium or magnesium sulphate). The beaker, which should be of strong glass, contains a small glass or ebonite tube, provided with a loop of platinum wire (*Fig. 1*) to facilitate its insertion and withdrawal. Or,

FIG. 1.

better still, the beaker may be replaced by a small bottle, containing a tube fused to the bottom (*Fig. 2*). The whole must be light enough to be hung on the nitrometer-tap. The same apparatus can, of course, take the place of Knop's azotometer, Scheibler's carbonic acid apparatus, or be used for the assay of commercial peroxide of hydrogen. In the latter case the sample to be tested is filled into the inner tube, while permanganate solution, strongly acidified with sulphuric acid, is placed into the bottle proper. On mixing, oxygen is readily given off, and the quantity of the same is measured in

FIG. 2.

the nitrometer. A very interesting and novel application depending on the same principle and the same reaction is for titrating standard solutions without weighing or measuring a substance of known composition. Supposing a potassium permanganate solution has to be tested for its strength. A certain measured quantity of permanganate is acidified with sulphuric acid, and decomposed with an excess of hydrogen peroxide of unknown strength. The complete decolourisation shows whether an excess was present. If now the volume of oxygen given off be measured in the nitrometer the strength of the permanganate solution can be easily

calculated. It is shown by experiments that this method is very accurate as well as quick. For testing the strength of standard acids (sulphuric, hydrochloric acid, etc.), a measured quantity is treated with an excess of sodium or calcium carbonate, and after reading off the volume of carbonic acid evolved, the strength of the acids can be computed. These examples can be increased by many more. Suffice it to say, that the nitrometer may be used for analytical purposes in all cases where a certain quantity of gas is produced, which after measuring allows of the decomposed substance being calculated. Of course, the gas must not be soluble in the liquid employed for decomposing, nor must it attack mercury. Bleaching powder solution acts on the hydrogen peroxide like permanganate. By means of bleaching powder solution in excess, the strength of hydrogen peroxide can therefore be estimated, and *vice versa*. Potassium ferricyanide in alkaline solution liberates the oxygen of peroxide of hydrogen, and can therefore be analysed in the same manner. The nitrometer can further serve in analytical operations for absorbing gases. The determination of indigotin and indigo-red in commercial indigo by reduction to indigo-white and measuring the amount of oxygen absorbed, belongs to this class of

measuring tube. After shaking, the percentage of carbonic dioxide can be read off. Then some concentrated pyrogallic acid solution is added, and the oxygen estimated. If analyses of gases have to be performed where reagents must be applied which act on each other, the nitrometer is combined with several of Hempel's gas-pipettes. For the analysis of gases dissolved in water, etc., the small beaker in Fig. 1 is filled with the liquid in question, and after inserting the stopper the liquid is raised to the boil, and the heating continued until all gases are driven out. By lowering the reservoir tube the expulsion of gases is greatly facilitated by suction. When the volume does not increase, the beaker is disconnected by turning the tap, the nitrometer allowed to cool, and the gases are ready for being analysed.—S. H.

*On the Inflammability of Vegetable Matter by Nitric Acid.* R. Hass. Chem. Ind. 8, 173.

A CARBOY filled with common nitric acid, 36° B. (1.325), strong, and packed up in the usual manner in a wicker basket with straw, was said to have taken fire spontaneously. The author, therefore, made some experi-

No. of Experiment.	Concentration of Nitric Acid.		Packing Material consisting of	Box or Wicker Basket.	Size of the same: Cubic contents.	Time from the moment of wetting packing material with the acid until it took fire.

operations. Another very convenient application is for absorbing gases evolved in manufacturing processes, because of the nitrometer combining the advantages of Bunte's and Hempel's gas burettes with the possibility of manipulating the gases over mercury. If it be required to test fire-gases for carbonic dioxide and oxygen, which is all that is necessary in most cases, the gases are aspirated into the nitrometer-tube, and after cutting off the further supply of the gases, potassium hydrate solution is introduced through the cup into the

ments in order to find out up to what lowest strength nitric acid is liable to cause spontaneous combustion. The above table renders the details and results of these experiments.—S. H.

*On the Limit of Combination between the Bicarbonates of Magnesium and Potassium.* R. Engel. Compt. Rend. 100, 1224-1227.

FROM previous experiments of the author, potassium and magnesium bicarbonate combine to form sesquicarbonate

$\text{MgCO}_3 \cdot \text{HRCO}_3 + 4\text{H}_2\text{O}$ , with elimination of  $\text{CO}_2$ . He has further determined the condition of equilibrium by the mutual action of the bicarbonates—(1) under different pressures of  $\text{CO}_2$  (by which the magnesium carbonate is held in solution); (2) under equal pressure, but varying proportions of the two bicarbonates. The experiments show from (1) the decomposition of the double salt at equal temperatures increases with the pressure of  $\text{CO}_2$ ; and from (2), the relation  $y = \sqrt{2a-x}$  when  $x$  and  $y$  are respectively the amount of sulphuric acid necessary to neutralise potassium or magnesium carbonate held in 10cc. of the solution, and  $a$  a constant ( $=6.25$ ).—J. B. C.

*Determination of the Value of Acetate of Lime.* A. A. Blair. Amer. Chem. J. 7, 26-31.

THE solution of acetate of lime is precipitated with a weighed quantity of sodium carbonate, and the excess of alkali titrated in an aliquot portion of the filtrate with normal acid, using phenolphthalein as indicator. If the solution of the acetate is brown in colour, it is filtered through animal charcoal before the addition of the sodium carbonate.—S. R.

*Iron Vessel for holding Acids.* E. Pohl, Dortmund. Ger. Pat. 30,188, January 3, 1884.

THIS vessel, which is to serve for the storage and transport of nitric acid, etc., consists of a drum lined with asbestos cloth, made impermeable by soaking in a bath of paraffin, stearin or wax.—F. M.

*Method for the Preparation of the Anhydrides of Organic Acids.* Chemische Fabrik vormals Hoffmann und Schötenack, Ludwigshafen. Ger. Pat. 29,669, April 9, 1884.

A CURRENT of carbonyl-chloride is passed over anhydrous sodium acetate heated to  $140^\circ$ . The distillate is purified by fractional distillation, 15 parts of it yielding about 10 parts of fairly pure acetic anhydride. Particular care must be taken not to heat the sodium acetate beyond  $140^\circ$ , as otherwise considerable quantities of acetone would be formed, which can scarcely be completely separated from the anhydride. Propionic and butyric anhydrides may be prepared in a similar manner, the anhydrous salts, however, requiring a temperature of  $170^\circ$  and  $200^\circ$  respectively, for their decomposition. In both cases chlorides are formed besides the anhydrides, evidently in consequence of a secondary reaction expressed by the equation  $(\text{C}_2\text{H}_3\text{CO})_2\text{O} + \text{COCl}_2 = \text{CO}_2 + 2\text{C}_2\text{H}_3\text{COCl}$ . The chlorides are converted into anhydrides by the well-known methods. Benzoic anhydride can likewise be prepared by this method, the sodium benzoate being heated to  $360^\circ$  while exposed to the action of the carbonyl-chloride. The greater part of the product formed in this case consists of benzoyl-chloride.—F. M.

*An Improved Process and Apparatus for the Continuous Production of Carbonic Acid.* E. Capitaine, London. From H. Herbertz. Eng. Pat. 8617, June 5, 1884.

THIS improved process comprises the production of carbonic acid free from air as the main product, and of carbonic acid mixed with air as a by-product. Five cylindrical vessels arranged one above the other, provided each with a stirring apparatus, and capable of being heated with steam or by a fire, serve for the reception of the bicarbonate of soda or of potash. The first cylinder is provided with a hopper, by which the finely-ground material is fed in, and the cylinders are connected with each other by tubes at alternate ends, so that the bicarbonate passes along the whole length of the apparatus. The first and fourth cylinders are fitted with domes and gas-escape pipes, by which the carbonic acid is led to cooling worms for the abstraction of its heat and some of its moisture, and then through purifying vessels containing sulphuric acid, and finally to gasometers. The gas from the fourth cylinder is free from air.—W. D. B.

*Improvements in the Method of and in Apparatus for Extracting Sulphur and Sulphurous Acid from Pyrites.* Arthur Charles Henderson, Middlesex. From Léon Labois, Paris. Eng. Pat. 9761, July 4, 1884.

THE arrangements preferred by the patentee for this purpose consist of a retort connected with a condensing chamber and separately heated, placed immediately above a roasting furnace of the Malétré type, in such manner that the heated residue from the former may be immediately raked into the latter through a valved channel temporarily placed against the mouth of the retort. A large percentage of elementary sulphur may be thus distilled off, the residual sulphur being roasted into sulphur dioxide in the second stage and utilised as desired. By a slight modification the ore in the first case charged into and removed from the retort through the door, may be introduced through a hopper placed in its roof, and be raked into the calciner through a cavity in the floor, this channel being effectually closed during distillation by the previous charge. If the situation of the works will not permit of the erection of the distilling furnace immediately above the calciner, the half-treated ore must be conveyed rapidly, while still hot, in a hopper truck from the one furnace to the other. The retort and calciner may be constructed in one, but in order thus to insure satisfactory results the air introduced for the calcination must be heated, preferably by regeneration of the heat from the escaping gases.—W. G. M.

*Improvements in the Manufacture of Precipitated Phosphate of Alumina and the Mixed Precipitates of Phosphate of Alumina and Sulphate of Lime.* W. A. Hills. Eng. Pat. 10,267, July 17, 1884.

RAW or calcined natural phosphate of alumina is treated with sulphuric acid in the usual way; the resultant solution is separated from the insoluble residue, and the phosphate of alumina is precipitated by diluting the solution with water, preferably hot, or by blowing steam through it until the same result is attained. The inventor finds that sufficient dilution with pure water will cause the precipitation of the alumina salt from the acid solution, but water containing an alkali in solution may also be used if desired, or in some cases chloride of sodium or potassium, or chloride of lime may be added for the purpose of causing a readier precipitation. By the addition of solution of salts of lime produced by the lixiviation of "tank waste," a mixed precipitate of phosphate of alumina and sulphate of lime is obtained.—H. J.

*Utilisation of Waste Calcium Chloride.* C. T. Richardson. Eng. Pat. 10,418, July 21, 1884.

THE process, which is primarily designed to effect the utilisation of the calcium chloride produced as a waste product in the Weldon process, the ammonia-soda process, etc., consists in treating the purified solution with solution of sulphate of ammonia in the proportion requisite for the conversion of the whole of the calcium chloride into sulphate. The precipitated lime salt is then separated by filtration, and the ammonium chloride solution concentrated and crystallised in the usual manner.—H. J.

*Improvements in making Granulated Crystalline Carbonate of Soda, and in Apparatus therefor.* J. Mactear. Eng. Pat. 10,651, July 28, 1884.

THE invention relates to the manufacture of carbonate of soda (soda crystals) in a granulated crystalline form, and is an improvement upon the inventor's patent, No. 1714, of 1875. The process consists essentially in dissolving soda ash in water, and subjecting the solution during crystallisation to the combined action of cooling and scraping or agitation in a long shallow trough having a passage for cooling water beneath it, and provided with a number of scrapers fixed to a frame which receives longitudinal movements from a rotating shaft, and which is lifted during its return movement by bell-cranks operated on by a rotating cam.—H. J.

*Improved Process for Obtaining or Recovering Manganese Oxide from Manganese Sulphate produced in obtaining Chlorine.* J. Mactear. Eng. Pat. 10,813, July 31, 1884.

A SOLUTION of manganese sulphate is mixed with sufficient magnesium chloride to be equivalent to the sulphate, and to any free sulphuric acid in the solution. The mixture is evaporated out of contact from air, whereupon hydrochloric acid is copiously evolved, and may be condensed and utilised. In this way there is formed a mixture of manganese oxide and magnesium sulphate, from which the latter can be removed by washing with water. The manganese oxide can be subsequently raised to a state of higher oxidation for use in obtaining chlorine. The magnesium sulphate may be crystallised, and sold as such, or it may be reconverted into magnesium chloride for use again in the process.

—S. H.

*Improvements in the Manufacture of Chlorine and Hydrochloric Acid.* W. Weldon. Eng. Pat. 11,035, August 7, 1884.

THIS invention consists in heating solid hydrated magnesium chloride to a low temperature, so as to drive off a large portion of its water without driving off more than a small part of its chlorine. After having been partially dehydrated, the solid magnesium chloride is intimately mixed with magnesia and the mixture heated in a current of air. The chlorine is thereby driven off, partly in the free state and partly as hydrochloric acid. Instead of partially dehydrating the magnesium chloride before adding magnesia, the latter may be intimately mixed previously. In this case, if it be desired to obtain as much as possible of the chlorine in the free state, the mixture should at first be dehydrated by heating it at a low temperature, and should be then heated to a higher temperature in a current of air.—S. H.

*Improvements in Manufacturing Chlorine from Hydrochloric Acid.* W. Weldon. Eng. Pat. 11,036, August 7, 1884.

THE invention relates to neutralising with magnesia the hydrochloric acid from which it is desired to manufacture chlorine, and then treating the magnesium chloride so obtained for the separation of free chlorine from it. This is best done by evaporating the solution of magnesium chloride and adding magnesia to it. The solid magnesium oxychloride thus obtained is heated to a low temperature to drive off a portion of its water, and then to a high temperature in a current of air.

—S. H.

*Obtaining Large-grained Salt.* Brandes, Lippe. Ger. Pat. 31,751, August 26, 1884.

IN order to obtain a larger amount than hitherto of coarse-grained salt from brine, the latter is drawn off as soon as the coarse grains have completely formed, and worked for fine grained salt in a second pan. Hitherto a portion of the large-grained salt has been allowed to remain in the pans, to be collected subsequently as a second-quality product.—W. D. B.

*Improvements in Packages for containing Caustic Soda.* J. Clare. Eng. Pat. 12,159, September 9, 1884.

THE improvement consists in the method of closing the orifice in the head of the caustic-soda drum by means of a lid with folded edges, so arranged as to slide within the edges of the orifice, also folded to correspond.

—H. J.

*Improvements in the Utilisation of Alkali Waste from the Leblanc Process in the Manufacture of Carbonate of Soda with Production of Sulphuretted Hydrogen.* E. W. Parnell and J. Simpson, Liverpool. Eng. Pat. 331, January 12, 1885.

THE object of this invention is to dispense with the use of lime for the liberation of ammonia from ammonium

chloride in the ammonia-soda process, by employing alkali waste from the Leblanc process for this purpose, and also to produce sulphuretted hydrogen in a condition available for the manufacture of sulphur or its compounds. A mixture of alkali waste is heated with a solution of ammonium chloride in a closed vessel, when ammonium sulphide will be given off with the steam. This vapour is absorbed in water, and employed for the manufacture of carbonate of soda, by being conducted into a solution of sodium chloride, together with carbonic dioxide, in the same manner as free ammonia is employed in the ordinary manufacture of carbonate of soda by the ammonia process. Ultimately the sulphur which passes into the absorbing plant is liberated in combination with hydrogen, and may, after washing with an acid solution to absorb any trace of ammonia, be burnt or dealt with by any of the known methods.

—S. H.

*Improvements in the Manufacture of Chromates and Bichromates.* J. J. Hood. Eng. Pat. 3895, March 26, 1885.

THE chrome ore is first heated with potassium salts, and with or without lime, in the usual manner, lixiviated, and the resulting potassium chromate solution concentrated.

IN order to produce sodium chromates, the above-described solution is treated with sufficient sulphate of soda to convert all the potassium and calcium salts present into sulphates, and the mixture concentrated, when the potassium sulphate crystallises out, and may be used for decomposing a fresh quantity of ore; the saturated solution of sodium chromate is then treated with the quantity of sulphuric acid necessary to combine with half the sodium present, and the sodium sulphate separated by crystallisation. The solution of sodium bichromate is then further concentrated and crystallised, or evaporated to dryness and fused.

TO prepare the ammonium chromates, a hot, strong solution of ammonium sulphate is added to a hot, strong solution of potassium chromate, and the whole allowed to cool, when the bulk of the potassium sulphate formed crystallises out. The residual liquid, which still contains some potassic sulphate, may be used for making either ammonium chromate or bichromate; for the first salt, the liquid is evaporated at a gentle heat, with addition of ammonium hydrate if necessary; during the concentration the potassium sulphate crystallises out and is removed, and the ammonium chromate is eventually allowed to crystallise. To form ammonium bichromate, the liquid is simply boiled down, the potassic sulphate taken out as it separates, and the solution crystallised; the ammonia gas given off during the operation being collected by suitable means.

OR the ammonium salts are prepared from sodium chromate, and ammonium sulphate or chloride, with addition of hydrochloric or sulphuric acid in sufficient quantity to form sodium bichromate, whereby losses of ammonia are avoided. Other chromates and bichromates may be prepared from sodium chromate.—H. J.

*Improvements in Apparatus for the Production of Sulphuric Acid.* William Spence. From J. Thys, of Baku, Russia. Eng. Pat. 9317, June 23, 1884.

THE apparatus under this invention is intended to increase the production of sulphuric-acid chambers, and consists in the adaptation to such chambers of one or more columns of lead, which support leaden frames and sheets of lead pierced with holes alternately. Sulphurous acid, nitrous gases, and steam pass through the holes of the plates and impinge on the parts not perforated, whereby a multiplied contact is brought about which effects a better oxidation of the sulphurous acid.—S. H.

*Improvements in the Manufacture of Anhydrous Sulphuric Acid.* Henry Edward Newton. From A. Nobel and G. Fehrenbach, Paris. Eng. Pat. 10,860, August 1, 1884.

AN air-tight cylinder of acid-proof material  $\alpha$  is filled with fragments of glacial phosphoric acid, and sur-

rounded with a sand-bath *c*, which permits of its being heated to a high temperature. On passing vapours of monohydrated or highly concentrated sulphuric acid through the pipe *g*, sulphuric anhydride is formed, and distils over through *b*, whilst at the same time the glacial phosphoric acid absorbs the water contained in

the sulphuric acid, as well as a certain quantity of sulphuric acid, liquefies and flows off through *d*. From time to time a fresh supply of phosphoric acid is introduced through *A*. The residual liquid phosphoric acid, containing water and sulphuric acid, can be recovered by distilling off the sulphuric acid after adding some more water.—S. H.

*Improvements in Apparatus for Concentrating Sulphuric Acid.* P. Jensen, London. From A. Kux. Eng. Pat. 8803, June 10, 1884.

This apparatus (see Figs. 1 and 2) consists of an upper dome-shaped part *a* connected with a lower

FIG. 1.

dome-shaped part *b*, by a system of tubes, through which the dilute acid circulates. The tube sys-

FIG. 2.

tem is enclosed in a cylinder, through which steam is passed by the inlet *f* and outlet *g*. It is a special

feature of apparatus constructed according to this invention that the steam does not pass through lead pipes, but outwardly surrounds a pipe system, through which the acid circulates. If a pipe becomes leaky, it can be stopped with a leaden plug; if it collapses, the apparatus still continues to work. The dilute sulphuric acid enters at *h*, and is heated in the tubes. Aqueous vapour passes away at *k*, a spray *l* fixing any acid mechanically carried over. A tube *d*, which is not heated, assists the circulation of the acid between *a* and *b*. The concentrated acid is drawn off at *i*. This apparatus is especially suitable for the concentration of the dilute acid from vacuum ice-making machines.—W. D. B.

*An Improved Method and Apparatus for Recovering the Nitrous Products in the Manufacture of Sulphuric Acid.* C. D. Abel. From the Société Anonyme de Javel, Paris. Eng. Pat. 10,571, August 1, 1884.

THE recovery of nitrons compounds in the manufacture of sulphuric acid by the employment of Gay-Lussac towers is unsatisfactory, because by these means there is not effected that intimate mixture of the gases which is necessary for the formation of nitrons acid that is absorbed by sulphuric acid. This invention relates to a method for effecting the required intimate mixture without resistance to the flow of the fluids. At the top of a tower, lined with lead, are placed several sets of apparatus delivering showers of concentrated sulphuric acid about 60° B., which descend on to a stratum of coke about a foot deep laid on a grating raised about a yard above the bottom of the tower. The gas enters under this grating, rises up through the showers of sulphuric acid, and is led by a pipe from the top down to the bottom of the Gay-Lussac tower.—S. H.

*Apparatus for Concentrating Sulphuric Acid.* A. J. Boulton, London. From M. Willett, U.S.A. Eng. Pat. 9362, June 24, 1884.

THE objects of this invention are to allow the acid to be rapidly and easily heated, to condense the vapours evolved at some distance away from the surface of the acid—thus obviating any cooling action at the surface of the acid,—to render possible the employment of light, and rolled instead of hammered platinum, and to reduce fuel consumption, size of apparatus, and loss of platinum. The boilers consist of platinum tubes about three feet in length and six inches in diameter, preferably arranged in a series at descending levels above an inclined furnace shaft. The tubes are supported by a number of iron plates set vertically at right angles to the length, and shaped to conform to the curve, of the boilers. The ends of the boilers project beyond the outside supporting plates, so that the solder-jointing of the ends is not exposed to the action of the fire. Plates of iron or other suitable material running lengthwise between the tubes prevent the portion of the boilers above the therein-contained acid from coming in contact with the flames or hot gases from the furnace. The boilers have gas openings at their tops in the centre, by which the vapours are conveyed to water arms, and thence to condensers. The connection of the boilers in series is effected by platinum tubes at alternate ends, each containing a slip-joint, this arrangement being rendered possible by the gradation of levels. These connecting tubes are so arranged that the first or highest boiler containing the weakest acid, and exposed to the least degree of heat, has a film of liquid not more than an inch and a-half deep; whilst the last or lowest boiler holding the strongest acid, and exposed to the greatest heat, from its position in front of the furnace, contains acid to the depth of two inches and a-half. The position of the connecting tubes is such that the acid from the surface of an upper or preceding boiler is carried to the bottom of that next below it. The capacity of production is stated to be from eighteen to twenty-two pounds per square inch, the loss of platinum six-tenths of a milligram per ton of oil of vitriol obtained.—W. D. B.

*Improvements in Stills for Concentrating Sulphuric Acid.*  
C. Bartsch. Eng. Pat. 6127, May 19, 1885.

A STILL for concentrating sulphuric acid which may be readily opened for inspection, and shall be less liable to fouling than the ordinary platinum still in use, is the subject of this invention. A in Fig. 1 is a trough of platinum, semi-circular in cross-section, and B is a flange secured to A near its top, and extending around its periphery, thus leaving a gutter C. D is a cover which rests in the gutter; E is the inlet pipe for the acid, and is placed near the top; F is an outlet for escaping fumes; G is an overflow pipe; H is the main outlet, leading into an equalising jar, whence the acid flows into convenient receptacles. The equalising jar consists of an inner and outer jar, between which a stream of cold water is passed. It is so placed that its outlet shall be level with the height at which the acid is desired to be kept in the still.

Before commencing to distil, the gutter C is filled with any liquid so as to form a hydraulic lute, and the equalising jar is filled with acid up to the level of its outlet. The acid to be concentrated is then allowed to flow slowly into the still through E. The main outlet is connected with the still at the point where the end-rise commences from the bottom, and thus will carry off acid from the very lowest portion of the still, whereby only that of the greatest specific gravity and consequent concentration flows off. The flow of the acid at the bottom outlet also carries off into equalising jar deposits of lead and iron sulphide contained in the acid and precipitated in the course of concentration, which would otherwise burn fast to the bottom of the still, and crack the bottom, owing to unequal expansion.—S. H.

## VIII.—GLASS, POTTERY, AND EARTHENWARE.

*Remarks on the Calculation of Mixings for the Manufacture of Glass.* E. Tschenschur. Dingl. Polyt. J. 256, 75.

NOTWITHSTANDING the many publications which appeared in the last decade on the chemical constitution and composition of glass, we are still in want of a practical method which allows of easily calculating the mixtures of raw materials for glass making. Although we know that many kinds of glass consist of a double compound of an alkali trisilicate and earth trisilicate, the proportion of both remains still to be settled. According to Benrath, this proportion should only vary from 1:1 to 5:7 for the best glasses, but R. Weber has lately shown that considerably greater variations may occur without detriment to the quality of the glass. The author has attempted to find out a relation between alkali, earth and silica for the different kinds of glass. If in the analysis of any glass  $x\text{AO}^*$  expresses the alkali,  $y\text{EO}^*$  the earth, and  $z\text{SiO}_2$  the silica, all in equivalents, the composition of glass will be represented by the formula  $x\text{AO} + y\text{EO} + z\text{SiO}_2$ , where  $x, y, z$  may be figures variable between certain limits, according to the quality of the glass. For the normal composition of glass, these coefficients would have the value  $x=y=1; z=3$  ( $x+y=6$ ). But the formula  $z=3$

( $x+y$ ) would only be right if  $x=y$ —that is to say, if the glass contains equal equivalents of alkalis and earths, the amount of silica should be six times as much. This formula is now compared with some analyses of glass, published by R. Weber, which has been found in practice to possess the physical qualities required. In these analyses there was—

$x$	$y$	$z$	$3(x+y)$	$\left(\frac{x^2}{y} + y\right)$
0.6	1	4.0	4.8	4.1
0.6	1	4.2	4.8	4.1
0.85	1	5.3	5.64	4.8
0.9	1	5.3	5.7	5.4
0.9	1	5.2	5.7	5.4
0.6	1	4.4	4.8	4.1
0.6	1	3.8	4.8	4.1
2.0	1	12.5	9.0	15.0
1.5	1	9.6	7.5	9.75
1.5	1	8.8	7.5	9.75
0.85	1	5.2	5.55	5.20
0.33	1	3.5	3.99	3.33

The first three columns represent the equivalent of alkali, earth and silica really found in the samples; the fourth column shows the figures which should have been expected if the amount of silica corresponded with  $3(x+y)$ , whereas the fifth column is calculated from another formula which was substituted for  $3(x+y)$ . As already mentioned above,  $z$  could only be equal to  $3(x+y)$  if  $x$  be equal to  $y$ , but this was not the case in the samples tested. We also see that  $z$  is lower than  $3(x+y)$  if  $x$  be smaller than 1, and *vice versa*. The

substituted formula  $3\left(\frac{x^2}{y} + y\right)$  agrees much more

closely to the results found by analysis, and we should now write our normal formula for the composition of glass,

$x\text{AO} + y\text{EO} + 3\left(\frac{x^2}{y} + y\right)\text{SiO}_2$ . We can further conclude

from the analyses that if  $y=1$ ,  $x$  may vary from 0.6 to 1.0 for sheet-glass, from 1.5 to 2.0 for Bohemian flint-glass, and from 0.8 to 1.5 for white bottle-glass. Assuming these variations, we obtain the following formulas for the composition of sheet-glass ( $R=K$  or  $\text{Na}$ ).

1.  $(0.6\text{R}_2\text{O} + 1.\text{CaO})4.1\text{SiO}_2$
2.  $(0.7\text{R}_2\text{O} + 1.\text{CaO})4.5\text{SiO}_2$
3.  $(0.8\text{R}_2\text{O} + 1.\text{CaO})4.9\text{SiO}_2$
4.  $(0.9\text{R}_2\text{O} + 1.\text{CaO})5.4\text{SiO}_2$
5.  $(1.0\text{R}_2\text{O} + 1.\text{CaO})6.0\text{SiO}_2$

From these formulae we can calculate the following percentage compositions for the two kinds of sheet-glass:—

Potash-Lime Glass.		Soda-Lime Glass.	
1a. $0.6 \times 47.1 = 28.26 = 15.7 \text{ K}_2\text{O}$		1b. $0.6 \times 31 = 18.6 = 11.0 \text{ Na}_2\text{O}$	
$1.0 \times 28.0 = 28.0 = 15.6 \text{ CaO}$		$1.0 \times 28 = 28.0 = 16.5 \text{ CaO}$	
$4.1 \times 30.0 = 123.0 = 68.7 \text{ SiO}_2$		$4.1 \times 30 = 123.0 = 72.5 \text{ SiO}_2$	
179.26 100.0		169.6 100.0	
2a. $0.7 \times 47.1 = 32.97 = 16.8 \text{ K}_2\text{O}$		2b. $0.7 \times 31 = 21.7 = 11.7 \text{ Na}_2\text{O}$	
$1.0 \times 28.0 = 28.00 = 14.3 \text{ CaO}$		$1.0 \times 28 = 28.0 = 15.2 \text{ CaO}$	
$4.5 \times 30.0 = 135.00 = 68.9 \text{ SiO}_2$		$4.5 \times 30 = 135.0 = 73.1 \text{ SiO}_2$	
195.97 100.0		184.7 100.0	
3a. $0.8 \times 47.1 = 37.68 = 17.7 \text{ K}_2\text{O}$		3b. $0.8 \times 31 = 24.8 = 12.4 \text{ Na}_2\text{O}$	
$1.0 \times 28.0 = 28.00 = 13.2 \text{ CaO}$		$1.0 \times 28 = 28.0 = 14.0 \text{ CaO}$	
$4.9 \times 30.0 = 147.00 = 69.1 \text{ SiO}_2$		$4.9 \times 30 = 147.0 = 73.6 \text{ SiO}_2$	
212.68 100.0		199.8 100.0	
4a. $0.9 \times 47.1 = 42.29 = 18.2 \text{ K}_2\text{O}$		4b. $0.9 \times 31 = 27.9 = 12.8 \text{ Na}_2\text{O}$	
$1.0 \times 28.0 = 28.00 = 12.1 \text{ CaO}$		$1.0 \times 28 = 28.0 = 12.8 \text{ CaO}$	
$5.4 \times 30.0 = 162.00 = 69.7 \text{ SiO}_2$		$5.4 \times 30 = 162.0 = 74.4 \text{ SiO}_2$	
232.29 100.0		217.9 100.0	
5a. $1.0 \times 47.1 = 47.1 = 18.4 \text{ K}_2\text{O}$		5b. $1.0 \times 31 = 31.0 = 13.0 \text{ Na}_2\text{O}$	
$1.0 \times 28.0 = 28.00 = 11.0 \text{ CaO}$		$1.0 \times 28 = 28.0 = 11.7 \text{ CaO}$	
$6.0 \times 30.0 = 180.00 = 70.6 \text{ SiO}_2$		$6.0 \times 30 = 180.0 = 75.3 \text{ SiO}_2$	
255.1 100.0		239.0 100.0	

We will now illustrate the application of these formulae for the production of sheet-glass of medium

\* AO=alkali oxide; EO=earth oxide.

fusibility. Supposing there are the following raw materials:—

Niesselstein sand of 99%  $\text{SiO}_2$   
Ammonia soda ash of 98%  $\text{CO}_3\text{Na}_2(57\cdot3\% \text{Na}_2\text{O})$   
Refined salt cake of 96%  $\text{SO}_4\text{Na}_2(42\% \text{Na}_2\text{O})$   
Ground Calc-spar of 97%  $\text{CaCO}_3(54\cdot3\% \text{CaO})$

According to formula 4b, we should have to take for a suitable mixing—

(12·8 × 100) : 57·3 = 22·3kg. soda ash  
(12·8 × 100) : 54·3 = 23·6kg. calc-spar  
(74·4 × 100) : 99 = 74·2kg. sand;

or in using salt cake, (12·8 × 100) : 42 = 30·5kg. salt cake.

Just in the same manner we can apply the other formulas for the production of glass, more or less fusible, just as required. The mixtures for cast plate-glass formerly contained far more alkali than they do at present. Whereas Henrivaux's analysis of an old plate-glass from St. Gobain showed

$\text{SiO}_2$  ..... 77·1%  
 $\text{CaO}$  ..... 6·0  
 $\text{Na}_2\text{O}$  ..... 16·2  
 $\text{Fe}_2\text{O}_3$  and  $\text{Al}_2\text{O}_3$  ..... 0·7

corresponding to the proportion of equivalents 12·2 : 1·0 : 2·5, new plate-glasses have the following composition:—

Or, expressed in equivalents of silica, lead oxide and potash—

35 : 10 : 0·33 : 17 : 10 : 0·8 : 51 : 10 : 0·7 : 63 : 10 : 1·0

whereas the normal formula would require

33 : 10 : 0·3 : 19 : 10 : 0·8 : 47 : 10 : 0·7 : 60 : 10 : 1·0

There are also published analyses of flint-glass containing more and less silica than required by the normal formula. This shows that the easy fusibility of lead silicate allows of employing more silica than corresponding with the formula. But if less silica be employed, the glass will not be very durable. Indeed, it appears that these glasses are only specially prepared for optical purposes where a great refractive power is the principal aim. For cheapness' sake, a portion of lead oxide is often replaced by lime or baryta, or a mixture of either, and in this case the amount of silica agrees with our normal formula, as shown by Nelise and Schür's analyses of Mastroch half-crystal glass:—

$\text{SiO}_2$  ..... 61·9 ..... 65·5 ..... 57·5  
 $\text{PbO}$  ..... 16·0 ..... 16·0 ..... 25·4  
 $\text{CaO}$  ..... 4·5 ..... 9·1 ..... 4·1  
 $\text{BaO}$  ..... 6·3 ..... — ..... —  
 $\text{K}_2\text{O}$  ..... 11·3 ..... — ..... 11·9  
 $\text{Na}_2\text{O}$  ..... — ..... 9·4 ..... 1·1

$\text{SiO}_2 : \text{PbO} + \text{CaO} + \text{BaO} : \text{Alkali} = 51 : 1 : 0·6 ; 17 : 1 : 0·7 ; 50 : 1 : 0·7$

Calculated on our formula— 41 : 1 : 0·6 ; 13 : 1 : 0·7 ; 45 : 1 : 0·7

	From St. Gobain (Henrivaux).	From Mauthuon (Henrivaux).	From Germany (Henrivaux).	From St. Gobain (Pclouze).	From Aix-la- Chapelle (Jaekel).
$\text{SiO}_2$ .....	72·1	69·3	70·27	72·1	72·31
$\text{CaO}$ .....	15·7	15·8	15·86	15·5	14·96
$\text{Na}_2\text{O}$ .....	12·2	13·4	13·66	12·4	11·42
Or expressed in equivalents ....	43 : 1 : 0·7	41 : 1 : 0·6	41 : 1 : 0·6	43 : 1 : 0·6	45 : 1 : 0·7

These very well agree with our normal formula, which would require thus:—

417 : 1 : 0·7 ; 408 : 1 : 0·6 ; 408 : 1 : 0·6 ; 408 : 1 : 0·6 ; 417 : 1 : 0·7

For white bottle glass, the proportion of the equivalents between lime and alkali should lie between 1 : 0·8 and 1 : 1·6, corresponding with the following percentage composition:—

Soda-Glass.		Potash-Glass.	
$\text{SiO}_2$ .....	from 74 to 79·5	.....	from 69·5 to 74·8
$\text{CaO}$ .....	„ 14 „ 7·6	.....	„ 13·0 „ 7·2
$\text{Na}_2\text{O}$ .....	„ 12 „ 12·9	.....	„ 17·5 „ 18·0

whereas for crystal glass (grinding glass), the proportion of lime and alkali should lie between 1 and 2, or, expressed in percentage—

$\text{SiO}_2$  ..... 78·6%  
 $\text{CaO}$  ..... 5·0  
Alkali ..... 16·4

Numerous analyses of good flint-glass also prove the applicability of our normal formula, thus:—

Of late years the demand for a glass combining cheapness and durability caused glass-makers to produce glass containing as much silica as possible. The amount of lead oxide had thus to be reduced, and this was replaced by potash, in order to guard against any appearance of a yellowish colour. But the quality grows inferior at the same time, a decrease of lead being accompanied by loss of weight, brilliancy, refractive and diverse power. In using 90% pearl-ash, normal mixtures are thus:—

Sand ..... 100 ..... 100 ..... 100 ..... 100  
Red lead..... 108 ..... 81 ..... 74 ..... 58

$\text{K}_2\text{O}$ .....	6·8	12·5	9·1	13·51
$\text{Fe}_2\text{O}_3$ + $\text{Al}_2\text{O}_3$ .....	0·82	0·5	2·0	—
$\text{MgO}$ .....	0·36	—	—	—
	100·46	99·7	100·2	99·81

Our normal formula is not applicable for the composition of green bottle-glass. Cheapness is here the first consideration, and therefore expensive alkalis must only be very economically used. Green bottle-glass can, indeed, be considered as a lime silicate, often containing alumina and magnesia silicate. On account of the absence of an alkali, the composition approaches that of a bisilicate. A higher amount of silicate cannot be attained without making the glass so difficult to fuse as to make it quite impossible to work it in our furnaces. As a matter of fact, the glass-maker finds it often necessary to add a little iron as a flux to avoid devitrification. French bottle-glass, of latest make, had the following composition, according to Henrivaux:—

	Cognac.	Bordeaux.	Champagne.
SiO <sub>2</sub> .....	62.54	61.75	61.30
Al <sub>2</sub> O <sub>3</sub> .....	4.42	7.10	4.44
Fe <sub>2</sub> O <sub>3</sub> .....	1.34	2.70	1.85
CaO.....	20.47	19.60	17.95
MgO.....	5.41	4.55	6.18
Na <sub>2</sub> O.....	4.73	4.10	6.16
MnO.....	4.73	0.11	6.16
K <sub>2</sub> O.....	0.94	0.11	1.13
SiO <sub>4</sub> H <sub>2</sub> .....	0.10	0.09	0.17
	99.95	100.00	99.98

Proportion of equivalents—

2.0 : 1.0 : 0.1    2.0 : 1.0 : 0.1    2.0 : 1.0 : 0.2

Supposing the following raw materials have to be used for bottle-glass making:—

Gneiss, composed thus—

	Sand of 90% SiO <sub>2</sub> ; 5% Fe <sub>2</sub> O <sub>3</sub> and 5% Al <sub>2</sub> O <sub>3</sub> and limestone of 91% CaCO <sub>3</sub> ; 5% SiO <sub>2</sub> and 4% Al <sub>2</sub> O <sub>3</sub> + Fe <sub>2</sub> O <sub>3</sub> .
SiO <sub>2</sub> .....	64.17%
Al <sub>2</sub> O <sub>3</sub> .....	13.87
FeO.....	6.40
CaO.....	2.74
MgO.....	2.21
K <sub>2</sub> O + Na <sub>2</sub> O.....	7.63
H <sub>2</sub> O.....	1.01
	98.03

a suitable mixing would be 100 parts gneiss, 70 parts limestone, and 60 parts sand.

Parts	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	CaO	MgO	K <sub>2</sub> O + Na <sub>2</sub> O	TL
100 gneiss contain ..	64.17	13.87	6.10	2.74	2.21	7.63	97.02
70 limestone ..	3.00	2.40	—	35.70	—	—	41.10
60 sand ..	54.00	3.00	3.00	—	—	—	60.00
	121.17	19.27	9.10	38.41	2.21	7.63	198.12

The bottle-glass obtained would therefore have the following composition—

	%	Equivalents.
SiO <sub>2</sub> .....	61.2	= 2.04
Al <sub>2</sub> O <sub>3</sub> .....	9.6	= 0.18
Fe <sub>2</sub> O <sub>3</sub> .....	4.7	= 0.11
CaO.....	19.4	= 0.69
MgO.....	1.1	= 0.05
Alkali.....	4.0	= 0.10
	100.0	

which corresponds well with Henrivaux's analyses of French Cognac and Bordeaux bottle-glass.

We may therefore say that whereas in the composition of green bottle-glass the formation of a bisilicate is all that can be aimed at, for all other kinds of glass with  $x$  equivalents of alkali and  $y$  equivalents of earths we can arrive at the amount of silica  $z$  in equivalents by applying the formula  $z = 3\left(\frac{x^2}{y} + y\right)$ .—S. H.

*Contributions to a Knowledge of Opal or Cryolite Glass.*  
C. Weinreb. Dingl. Polyt. J. 256, 361.

OXIDE of tin, which doubtless formed a difficultly-fusible tin enamel, was first employed for the above variety of glass; this was replaced later on by calcium phosphate from the ashes of bone and guano—the majority of

mineral phosphates such as phosphorites and apatite are too rich in iron for the purpose, the product being known as bone-glass. In 1860, in North America, an opal glass was prepared by the use of eryolite, Al<sub>2</sub>F<sub>6</sub>·6NaF, and since that date this material has been employed almost exclusively. Seeing that the price of eryolite has risen greatly, a substitute for eryolite is desirable. It is then first necessary to determine on what circumstances or materials the production of milk-glass depends. In 1869 Benrath examined American eryolite glass, and finding no fluorine, advanced the opinion that the opalification was due to a separation of alumina, and designated this phenomenon "devitrification"; he also concluded that the whole of the fluorine had been volatilised as silicon fluoride. In the same year, a cryolite glass from the same source was examined by Williams, who found that it contained fluorine, and ascribed the opalification to a formation of silicon fluoride of sodium, which dissolved in the molten glass, but separated on cooling. The statements of these two observers, as to the presence of fluorine, being so contradictory, the author analysed an Austrian eryolite glass, with the following results:—SiO<sub>2</sub>, 78.00; Al<sub>2</sub>O<sub>3</sub>, 3.12; Fe<sub>2</sub>O<sub>3</sub>, trace; MnO, trace; CaO, 3.87; Na<sub>2</sub>O, 9.46; K<sub>2</sub>O, 4.55; F, 3.77; total, 102.57; less O corresponding to F, 1.59 = 100.98. From these numbers the proportions of the materials of the charge may be calculated with approximation to have been—SiO<sub>2</sub>, 100; Al<sub>2</sub>F<sub>6</sub>·6NaF, 15.91; Na<sub>2</sub>CO<sub>3</sub>, 8.13; K<sub>2</sub>CO<sub>3</sub>, 7.91; CaCO<sub>3</sub>, 8.55. The amount of alumina found is a measure of the eryolite added, and from the proportions respectively which alumina bears to fluorine in eryolite and in the glass, it appears that during the melting, 4.11 parts of fluorine per 100 of SiO<sub>2</sub> are volatilised as a silicon fluoride. With a view of determining whether the formation of milk-glass is due to (1) alumina, (2) fluorine, or (3) alumina in conjunction with fluorine, the author has made synthetical experiments recorded in detail. The results show conclusively that only in conjunction with fluorine has alumina the power of causing "devitrification," this depending, apparently, upon the formation of aluminium fluoride which dissolves in the molten mass, but separates out in a most minute state of subdivision on cooling. If milk-glass manufacturers desire to dispense with the use of eryolite, recourse must be had to materials rich respectively in alumina and fluorine; in regard to the first there is little difficulty, as kaolin and felspar, free from iron, are readily obtained; in respect of the second, there is practically no choice but to employ fluor-spar, which it will be necessary to convert into an alkaline fluoride by fusion with sodium carbonate, since too much lime would be introduced into the glass were the fluor-spar directly added. The author has found by experiment that the yield of alkaline fluoride is much greater if an equal weight of silica be added before fusing with sodium carbonate. The melt is lixiviated, the solution consisting of alkaline fluoride and silicate is evaporated to dryness, and the dry residue added directly to the charge.—W. D. B.

## X.—METALLURGY, MINING, Etc.

### PROGRESS IN METALLURGY.

*Zinc Extraction.* Dingl. Polyt. J. 256, 317-321.

L. KLEEMAN'S modification of his condenser for zinc distillation is described; the object of the modification being to prevent escape of zinc vapours at the front of the furnace. (Ger. Pat. 28,596, December 14, 1883.)

*Bessenerising Copper Ore and Matte.* J. Garnier. Ger. Pat. 30,418, July 3, 1884.

A modified Bessener converter for the above process. The lining is to be made either of siliceous material, or of materials which are not attacked by silica or bases, such as chrome iron ore, calcium sulphate, zinc silicate, calcium phosphate, &c. When an acid lining is employed, it is to be so thin that a layer of slag or matte may be chilled upon it by cooling the exterior of the vessel with an air or water-jacket.

*Furnace for Smelting or Fusing Metals.* J. Quaglio, J. Pintsch and A. Lentz. Ger. Pat. 29,551, March 9, 1884. (See this Journal, vol. iii. p. 639.)

The arrangement consists of two shaft furnaces placed near together, and connected at the top and bottom by flues, in the latter of which are placed suitable valves to control the gaseous currents. The gases from one shaft are passed into the top of the other, and down through a mass of ignited fuel, and then into a gas-holder for distribution as required. The shafts are charged with fuel and ore, and the liquid products are removed in the usual way.

*Fusion of Zinc Alloys.* G. Selve. Ger. Pat. 29,535, June 21, 1883.

The patentee proposes the furnace shown in Figs. 1 and 2 for the preparation of zinc alloys. Crucibles T project through the roof of the furnace, and stand on refractory stands F. The crucible is somewhat smaller than the hole in the roof, so that the two are not in contact. The sole slopes on all sides towards the middle, so that when a crucible leans, the spilt metal can be tapped off at S. In the preparation of brass, for example, after the requisite amount of copper is fused, the whole

FIG. 2

of the zinc is quickly added, and so much scrap brass as will make the contents pasty. By this means cold layers of metal are formed in the upper part of the crucible. Since the crucibles project from the furnace this reduced temperature at the surface of the metal is easily maintained by the addition from time to time of scrap. By this means very little loss of zinc results. On drawing the crucible and stirring up the contents a uniform alloy is produced.—J. T.

*Coating Iron and Steel with Copper and its Alloys.* J. J. Taylor. Wolverhampton. Eng. Pat. 10,886, August 2, 1884.

The articles are pickled as if for galvanising, and are then immersed in a hot solution of one pound borax to four gallons water. The articles are dried and immersed in the copper or copper alloy bath; the flux employed through which to enter the articles consists of borax. Common salt is added from time to time to thin this flux. The flux employed over the part of the bath where the articles are withdrawn after being coated, consists preferably of glass, though borax, alone or with glass, may be employed.—J. T.

*Improvements in the Method of and in Apparatus for Extracting Gold and Silver from their Ores by Amalgamation.* H. M. Whitehead, London. Eng. Pat. 11,701, August 27, 1884.

The amalgamator consists of a series of air-tight chambers, each containing a vertical partition reaching from the top to within a short distance of the bottom, and having its lower edge toothed. One-half of one terminal chamber is connected with an exhaustor, and the reverse half of the other terminal is in communication with an ore-feeding channel. A door is arranged at the lowest part of each chamber for the removal of amalgam, and a gauge glass is fitted to each pair of compartments. When required for use, mercury is poured into each chamber until the row of teeth is just covered, the exhaust is let on, and the ore fed in at the other end. The ore (dry or with water) is thus carried by suction beneath the division; and, therefore, through the mercury in each successive compartment until it passes away through the exhaust outlet. Flouring is to be prevented by the use of sodium amalgam or otherwise.—W. G. M.

*An Improved Method of Extracting Copper, Nickel, Cobalt, Silver or Gold from their Ores.* Lorentz Albert Groth, K. G. V., London. From C. G. Dahlerus, Demain, France. Eng. Pat. 5642, May 7, 1885.

The ore is to be roasted, mixed with chloride of lime or similar substances, and dilute acid: the resulting solutions of the metals is then precipitated in the usual way.

—W. G. M.

*Improvements in Method of and Apparatus for Reducing Ores.* J. K. Griffin, Brooklyn, U.S.A. Eng. Pat. 6124, May 19, 1885.

The ore is fed through a hopper into a rotating distributor, having openings in its periphery for the discharge of the ore, and contained in an outer shell also revolving, but at a higher speed and in an opposite direction. The ore, thus fed in, becomes packed by the action of the centrifugal force against the inner wall of the shell until the accumulation has reached to the circumference of the distributor, then for the first time the pulverisation commences by the mutual attrition of the particles of ore. As fast as the substance is reduced to the required degree of fineness, the powder is carried

away by currents of air introduced through channels in the distributor, and is collected in suitable receivers. The degree of fineness obtainable will vary (inversely) with the velocity of the air current. For certain ores it is preferable that the shell only rotate, the distributor remaining fixed. Experiment has shown that velocities of 150 to 200 revolutions per minute, in opposite directions, suffice to crush hard rock, such as quartz, to an impalpable powder in satisfactory quantities, and without injury to the machine, and without admixture of foreign substances.—W. G. M.

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

*Measurement of Frictions of Lubricating Oils.* C. J. H. Woodbury. Bull. Mulhouse, 323, 1885.

THIS is a report by M. Scheurer-Kestner upon a paper bearing the above title, recently communicated to the Société Industrielle. The subject has been investigated by the dynamical method, and by means of an apparatus consisting essentially of a couple of discs with plane opposing surfaces, the lower of which is rotated by the direct application of power, the upper tending to be drawn into rotation by contact; this tendency is resisted and its quantity registered by means of a dynamometrical suspension. The oil to be tested is supplied continuously through a tube passing through the upper disc, which also contains an annular hollow through which a stream of water is made to circulate, when the experiments are to be made at constant temperatures. The quantitative expressions for the friction are obtained ultimately in terms of the dynamometer readings and the weight of the upper disc, and the results are given in three tables appended to the original paper. In the first are contained the results of varying the temperature from 40° to 100° F., and the downward pressure upon the upper disc from 1 to 40 lb. per square inch. An inspection of the diagram, by which the numbers are graphically represented, shows that the force tending to rotate the upper disc does not increase proportionately to the pressure; this is due to the influence of the cohesion of the oil itself, in consequence of which it participates in the rotation. The second table gives the value of the coefficients of friction for the same series of experiments, calculated by means of an equation deduced from a

consideration of the special conditions of the apparatus, and of the phenomena to be investigated. In general terms, the introduction of the third lubricating substance, between the opposing surfaces, approximates the molecular problems involved to those of the flow of liquids from minute orifices. The coefficient of friction is seen from this table to diminish with increase of pressure, and of fluidity of the oil. The practical limit of fluidity is the necessity of preventing contact of the opposed surfaces. In the third table the effect of varying the temperature is shown by the numerical results obtained with a very fluid mineral oil, the pressure on the upper disc being kept constant at 33lb. per square inch. The maximum of useful effect was reached at 82° F. In conclusion, the author discusses the subject generally, showing to what extent purely scientific methods may be made to contribute to the elucidation of the very practical question of the value of lubricants.

—C. F. C.

*Test of Mineral Lubricating Oils.* P. Falke. Chem. Zeit. 9, 906.

MINERAL lubricating oils are often adulterated by the addition of cheap oils. The following tests may serve for ascertaining their purity:—(1) Colour. The oil must be perfectly clear, and as light as possible. It should not be turbid, which may be caused by the presence of water or other substances. If the oil be turbid by water, it froths on heating, whereas a turbidity produced by solid matters, such as paraffin, disappears on warming, and reappears on cooling. The characteristic feature of all mineral oils is their blue fluorescence. (2) Smell. The smell must be as little perceptible as possible, and should not increase on warming the oil. It mostly smells like petroleum. (3) Behaviour on shaking with water. If three parts of oil be shaken with one part of water in a test tube, warmed, and allowed to stand in a water-bath for some time, no emulsion must appear between water and oil, but the latter should stand clear above the water, which should opalesce only very faintly, and be perfectly neutral. (4) Behaviour to caustic soda. The oil should not be attacked by a caustic lye of 1.40 sp. gr., neither in the cold nor on warming. Saponification is a certain evidence of the presence of animal or vegetable fat. (5) Behaviour to sulphuric acid. On mixing the oil with sulphuric acid of 1.60 sp. gr. it must not be coloured brown, but yellow at the most; otherwise resins have not been carefully removed. (6) Behaviour to nitric acid. On mixing oil with nitric acid of 1.45 sp. gr. a rise of temperature takes place, which should not exceed a certain limit. (7) Specific gravity. Although the specific gravity of oils suitable for lubricating purposes varies from 0.875 to 0.950, only a very small latitude (0.003 at the most) is permitted in contracts. It is invariably taken at 15° C. (8) Behaviour on exposure to the air and heat. Spread in a thin layer and exposed to the air for some time, its consistency must not change, nor should it become acid on being heated continuously above 150°. Heated in open vessels it should not give off combustible vapours, except at a high temperature, which is usually specified in contracts. Its flashing point should be ascertained in Abel's apparatus. (9) Behaviour at a low temperature. It should bear a low temperature without losing its lubricating power, nor should it become solid even at a very great cold, but it should rather assume the appearance of an ointment. (10) Test for consistency. This determination is most important. The velocity of efflux of pure rapeseed oil is taken as a standard, and that of the mineral oil compared with it. 100cc. of the sample are allowed to flow out of a burette with tap, while the time which is required is noted down. In conclusion, the author urges the desirability of having a uniform mode of testing.—S. H.

*An Improved Process for the Extraction of Oil and the Production of Meal from Flax and other Seeds.* H. H. Lake. From C. G. B. Casero, of St. Etienne, France. Eng. Pat. 11,403, August 18, 1884.

INSTEAD of, as usual, heating and then pressing the whole bulk of the linseed, the patentee reduces it to

coarse powder, and separates the meal by sifting into two parts about equal in weight. The part which goes through the sifters contains nearly the whole of the oil, which may be thus expressed without torrefaction. A purer oil is the result, and there is far less tendency to form an emulsion, as the mucilage remains in the portions which do not go through the sifter, which also thus form a novel linseed meal.—W. L. C.

*A New Method of and Apparatus for Making Emulsions for different Purposes.* C. J. P. de Laval. Eng. Pat. 12,562, September 18, 1884.

EMULSIONS of fats and oils, both for food purposes and as lubricants, are prepared by forcing liquid fat or oil, under high pressure, into liquids at lower pressure, in finely-divided streams, through minute apertures. The apparatus consists essentially of two reservoirs and a force pump, the outlet of which is a heavily-loaded valve, adjustable by a fine-threaded screw. Drawings are given.—W. L. C.

*Improvements in Apparatus for Lard Refining, Cooling, and Filling.* C. F. Hodges and W. Christy. Eng. Pat. 12,720, September 23, 1884.

THE apparatus, which is figured, consists of (1) a refining tank provided with a steam-jacket and mechanical stirrers; (2) a cooling tank provided with dashers or stirrers, and circulating pipes for hot water or steam; (3) filling apparatus with clips and nozzles, mechanically operated.—W. L. C.

## XII.—PAINTS, VARNISHES, AND RESINS.

*The Darkening of Oil Colours.* R. Kayser. "Mittheilungen des bayerischen Gewerbemuseums," 1885, p. 21.

THE author's observations confirm the statement that if a varnish boiled with litharge be rubbed up with cinnabar, a formation of sulphide of lead gradually results. In oil painting only varnish prepared with borate of manganese should be employed, for the author ascribes the darkening of oil-colours to this gradual formation of lead sulphide.—W. D. B.

## XIII.—TANNING, LEATHER, GLUE, AND SIZE.

*Adulteration of Leather.* R. Kayser. Chem. Zeit. 56, 1001.

STARCH sugar is added frequently to increase the weight, as leather is eight or ten times as dear as this adulterant, and the sophistication cannot be detected without chemical investigation. On examination of different samples of leather, the author finds grape-sugar present in quantities varying from 2.7 to 7.6 per cent.—S. R.

## XV.—SUGAR, GUMS, STARCHES, Etc.

*Sugar Beet Farming.* Dingl. Polyt. J. 256, 374.

WREDE places the cost of sugar beet growing in the province of Hanover at 2.5 marks per double centner, inclusive of leaves and cuttings. How much of the cost of production is to be subtracted on account of these two last items is doubtful.

Each shows that beets grown in the shade are inferior to those in the open.

By cultivation experiments on nine different estates, Maereker has found that on an average the highest sugar contents per beet—viz., 14.9 percent.—was obtained with Dippé's Improved White, but the best total yield of sugar with Klein-Wanzlebener Original crossed with Vilmorin Klein-Wanzlebener.

The importance of cultivating varieties as rich in sugar as possible is shown by the following results:—

	Variety rich in Sugar.	Variety poor in Sugar.	Difference.
Yield per morgen....	18centnr.	192centnr.	-8
Sugar in the beet....	11.3	12.5	+1.2
Degree Brix .....	18.5	16.8	+1.7
Sugar in the juice ..	15.9	11.0	+4.9
Quotient .....	85.9	83.3	+2.6
Sugar per morgen ..	26.31	24.0	+2.31

—W. D. B.

*Some Reactions of the Glucosides Helicin and Gluco-vanillin.* F. Tiemann and A. Kees. Ber. **18**, 1657-1665.

IN studying the formation of such glucosides as these in the plant, the authors endeavour to obtain light as to the physiological processes in the vegetable organism giving rise to them. Therefore a trustworthy test for these glucosides would be of extreme value. The authors claim the introduction of the phenylhydrazine and hydroxylamine derivatives for this purpose, which give characteristic reactions. They are prepared with great facility; the former derivatives by gently heating either helicin or glucovanillin with phenylhydrazine hydrochloride—the new hydrazines separate on cooling; the latter derivatives by heating in molecular proportions a slightly alkaline alcoholic solution of either of the glucosides with hydroxylamine. When the reaction is complete the mixture is neutralised, evaporated to dryness, and extracted with absolute alcohol. *Helicin phenylhydrazine*,  $C_6H_5(CH.N.HC_6H_5)(OC_6H_4O_2)[1:2]$ , is soluble in alcohol, ether and hot water, almost insoluble in cold water, and insoluble in benzene. It is deposited from its aqueous solutions in white, scarcely crystalline masses, which turn brown without apparent decomposition when dried in the air. The dry substance melts at  $187^\circ$ . It does not reduce Fehling solution. The hot aqueous solution is yellow, by prolonged boiling the colour becomes paler, and the substance undergoes partial decomposition. Emulsion resolves it into the hydrazine of salicyl aldehyde, identical with that of Fischer (Ber. 17, 575) and Rössing (*Ibid.* 3004), and glucose identified by the Fehling- and by Fischer's hydrazine-reaction. *Glucovanillin phenylhydrazine*,

crystallises from its solution in boiling water, is readily soluble in alcohol, sparingly in cold water, and almost insoluble in benzene and ether. It is coloured brown in the air, and when dry melts at  $195^\circ$ . It produces a green precipitate in, but does not reduce Fehling solution. With emulsion it yields glucose and *vanillin phenylhydrazine*,  $C_6H_5(CH.N.HC_6H_5)(OC_6H_4O_2)(OH)[1:3:4]$ , which forms greyish-white leaflets (m.p.  $105^\circ$ ) with silver lustre, and when moist become discoloured in the air. The crystals are readily soluble in alcohol, ether, and benzene, but very sparingly in water and light petroleum. *Helicin aldoxim*,  $C_6H_5(CH.NOH)(OC_6H_4O_2)[1:2]$ , crystallises in fine white needles (m.p.  $190^\circ$ ) with 1 mol.  $H_2O$ , which loses at  $100^\circ$ . It is insoluble in ether, but slightly soluble in alcohol, moderately so in water, whilst it dissolves readily in both acids and alkalis, but is partially precipitated from concentrated acid solutions by ammonia. It gives no characteristic colour reaction with concentrated sulphuric acid. It is powerfully levorotatory. Emulsion converts it into glucose and *salicyl aldoxim* (see Lach, Ber. 17, 1753). *Glucovanillin aldoxim*,  $C_6H_5(CH.NOH)(OC_6H_4O_2)(OC_6H_4O_2)[1:3:4]$ , forms light yellow needles (m.p.  $152^\circ$ ) with 1 mol.  $H_2O$ , which is driven off at  $100^\circ$ . It is less soluble in water and alcohol than helicin aldoxim, but behaves in a similar manner to that substance with the other reagents, and the polariscope. With emulsion it yields glucose and

*vanillin aldoxim* (comp. Lach., *Ibid.* 1786). In all the above reactions the aldehyde group of the glucosides is attached, and the authors could not induce action between ether phenylhydrazine or hydroxylamine, and the glucose nucleus of these and many other glucosides—*e.g.*, salicin, coniferin, etc.; in this they resemble the kind of sugars termed by Scheibler "Biosen," which do not react until they are inverted.—D. A. L.

*Constitution and some Properties of Raffinose.* C. Scheibler. Ber. **18**, 1779-1786.

THE author confirms the identity of raffinose with "plus-sugar" and "gossypose" (see this Journal, iv. 411). Loiseau found fifteen per cent. of water in raffinose, and attributed to it the composition indicated by the formula  $C_{18}H_{32}O_{16} + 5H_2O$ . Ritthausen, on the other hand, found only 13.64 per cent. water in his sugar from cotton seed, and concluded it was  $C_{18}H_{32}O_{16} + 3H_2O$ . These different results are due to the difficulty attached to drying raffinose; heated at  $85^\circ$  to  $90^\circ$  below its melting point, it loses only 13.64 per cent. of water; when it is heated higher, even at a little above  $100^\circ$ , it begins to caramelise, and becomes to a certain extent inverted; raffinose is hence much more susceptible to change than raw sugar, which does not caramelise under  $160^\circ$ . By drying this sugar, as far as possible (until the loss = 13% water), over sulphuric acid, and then in a water-bath the author is able to confirm Loiseau's view of the composition of raffinose. The author finds its specific rotation is  $D = +103.9$  to  $104$ , or  $\frac{1}{\sqrt{v}} = 114.6$ . By treatment with acid at  $17-18^\circ C$ . its rotatory power diminished at first rapidly, later on slowly, and after ten days was constant at  $+52.3$ . At higher temperatures this change takes place quicker; at  $60^\circ$ , for example, the specific rotation is reduced to  $+53.2$  in three hours, and to  $46.7$  in sixteen hours; the solution then becomes yellow, and the colour increases as the heating is continued. The author suggests that the rapid reduction in this rotation is due to inversion, whilst the slower decrease is perhaps the result of a subsequent change in the product of inversion. This point is being investigated with phenylhydrazine, and otherwise. From these properties of raffinose, and as it is found associated with a betain both in cotton seed (*loc. cit.*) and in beet, the author infers that it is present in the original beet. Its easy inversion and caramelising, and its high specific rotation, go far to explain the reduction in polarisation and partial inversion of beet-juice during the winter storage of roots in heaps. Roots of high rotatory power suffer much quicker and to a greater extent than other roots; these roots are supposed to be poor in juice because they yield less sugar than their rotatory power indicates. It is now evident that this supposition is not correct, but, in fact, these roots contain a large percentage of raffinose, which would account for the high rotatory power, for the bad-keeping properties, etc. The behaviour of many sugar residues suggests the presence of raffinose. The identity of raffinose and melitose is not yet confirmed. Raffinose containing  $C_{18}$  would be classed, according to the author, as a "Trios" sugar.—D. A. L.

## XVI.—BREWING, WINES, SPIRITS, Etc.

*Extracts from the Report of the Meeting of the Brewery Institute in Berlin.* Chem. Zeit. **9**, 638.

DR. HAYDUCK explained the value of hops in their effect upon the keeping power of beer. The antiseptic action of hops in beer fermentation is perceptible even in the proportion of 0.25 hops to 500 of the wort. The effect of 1–15 parts of hops on the different bacteria is approximately the same. It follows that the antiseptic principle of hops is with difficulty soluble. Hops of the same kind act in the same way even when the extraction has gone on a longer or shorter time. Different kinds of hops, however, act very differently. The less valuable, but

fresh hops, including wild hops, are not inferior in their action on the fungus to the better qualities. Sulphuring hops does not improve matters. Hop-extracts of commerce were found to be useless. Hayduck considers the resins in the hops, of which he isolated two kinds, to be the anti-septic agents in the case of all bacteria. The bitter principle cannot be separated from the resin. The disappearance of the bitter principle in the course of fermentation by separation of the resin and oxidation has been fully confirmed. Preserved hops are also efficient in their action. In the discussion which followed, the feeling of practical brewers was against economy in the use of hops. They supported, however, the new method of boiling hops, which effects a certain economy. In considering the action of the pure-cultivation yeast obtained from the single cell, opinions were divided. In certain instances the results were excellent; in others, again, the fermentation was arrested, and a peculiar taste was imparted to the beer. Dellbrück suggested that probably a higher temperature would produce a yeast freer from bacteria—that is to say, the isolation of the pure yeast. The method of Hayduck for regenerating the yeast by treatment with sugar solution of hops at a high temperature was strongly supported by the result of actual experiment. For washing the yeast, very cold water was recommended.

Dr. Francke spoke on the subject of the barley of the present year. He laid stress upon the troublesome treatment of kiln-drying in the use of stored malt of different sorts. According to Nervack, a stored malt is more moist, and forms, therefore, on grinding, a coarser material for the mash, which favours, therefore, the process of cleansing. To obtain a better quality of barley, it was proposed that the results of experiments with the barley of a certain district, together with the analysis, be communicated to the Agricultural Society before seed-ordering, in order to be in a position to choose a better brewing barley for seed.

Attention was called to the use of manures, as in many cases artificial manuring with Chili saltpetre and kainite was found injurious. Balcke suggested the use of kilns constructed with air ventilation, to prevent browning of the moist malt. Zimmer's centrifugal apparatus promises an extended use. The discoverer hopes to prevent frothing of the colder worts by changing the exit of the worts from the centrifugal. The cause of the red-colouring of white beer is supposed to be due to the presence of spherical bacteria. Different views were held on the subject of brewing-water. The efficiency of hard water was generally admitted. It was recommended to boil the water, and let settle before use, even with iron and calcium carbonate present.—J. B. C.

#### *The Valuation of Pressed Yeast.* W. Gintl. Ber. der Oesterr. Chem. Gesellschaft, 1885, p. 2.

THE comparative efficiency of different samples of yeast is best arrived at by comparative fermentation experiments, but when it is necessary to obtain absolute expressions, it is not sufficient, in addition to the usual microscopic and qualitative tests, to ascertain the amount of true yeast material present—it is also necessary to determine the proportion which the yeast bears to the starch. The author has found by analysis that an increase in the starch contents usually causes an increase within a certain limit—in the percentage of true yeast material, the diminution being in the water. The starch, however, by abstracting water from the yeast-cells causes a considerable proportion of these to shrink and wither, without absolutely killing them; so that the increased percentage of yeast material caused by the addition of starch results in a decreased efficiency; the fermentation is more feeble at the commencement, but more vigorous later on, when the proportion of starch to yeast is larger than when the reverse is the case. The addition of starch is not considered desirable by the author; it does not result in increased efficiency, and it is but a replacement of water, which costs nothing, by a comparatively costly material.—W. D. B.

#### *Process for Preventing Subsidiary Fermentations in Substances employed in the various Manufactures based on Fermentation.* C. D. Abel. From Dr. C. Meyer, Uerdingen, Germany. Eng. Pat. 5439, May 2, 1884.

THIS patent aims at removing from distillers' fermentations, micro-organisms, which would act injuriously upon the fermentation process and upon the quality of the product. The removal is effected by adding a voluminous body to the mash and filtering; this completely removes bacteria. The voluminous bodies used are:—

1. Freshly precipitated hydroxides, such as aluminium hydroxide.
2. Insoluble amorphous combinations, as phosphate of iron.
3. Silicic acid precipitated from its combinations.
4. Albumen, starch paste, etc.

The process can also be used for preparing an artificial ferment free from lactic acid-bacteria. The advantages claimed for the process are: Improved saccharification, pure fermentation, high yield of alcohol, reliable working, and complete utilisation of the starch in the malt.

—G. H. M.

#### *Improvements in the Mode or Process of and Apparatus for Generating Carbonic Acid Gas, to be used in the Aeration of Drought Ale and other Beverages.* W. H. How, Ungar. Eng. Pat. 10,109, July 14, 1884.

THIS apparatus consists of an outer vessel containing a solution of a carbonate or bi-carbonate, and a small narrow-necked vessel filled with sulphuric acid made into a paste by absorption with alum, covered with a tubulated bell-jar, and placed on the bottom of the outer vessel. The bell-jar is provided with stopcocks, and when these are opened the solution enters the bell and flows in upon the absorbed acid. The evolved carbonic acid bubbles through the solution, and is thus washed. When the apparatus is not required for use, the acid vessel is either closed by an automatic or other valve, or the stopcocks are closed, and the solution expelled from the bell by the accumulated carbonic acid.—W. D. B.

#### *Improvements relating to the Extraction from Grapes or Raisins of various Substances, and to the Use or Application of the same for Colouring or other Purposes.* E. H. Newby. From E. Thiebaud, Montdidier, France. Eng. Pat. 10,100, July 24, 1884.

THIS is a process for extracting the colouring matter from grapes or raisins, and from the residue in the manufacture of wine, by means of digesting with hot dilute alkali, and precipitating the colouring matter from the filtered solution with dilute hydrochloric acid. The precipitate is then purified by digestion with ammonia solution at 30° C. for some days. The colouring matter goes into solution, and can be obtained by distilling off the ammonia. The extracted substance may be used as a dye, or a pigment, or for colouring wines and articles of confectionery. It has tanning properties, and is a fast colour. In place of alkalis, the following substances may be used for extracting the colouring matter: Alcohols, ethers, turpentine, wood-spirit, carbon disulphide, acids, glycerine, or the wine itself.—G. H. M.

#### *Process and Apparatus for Purification of Alcohol.* C. D. Abel. From J. A. F. Bang and M. C. A. Rudin, both of Paris. Eng. Pat. 10,870, Aug. 1, 1884.

THIS invention relates to a method and apparatus for purifying crude alcohol in order to obtain, by one single process of distillation, the total amount of ethylic alcohol free from essential oils and aldehyde. This is done by removing these latter with a solvent from the alcohol at 50° B. The solvent used is what is known as essence of petroleum, purified by shaking with strong sulphuric acid. The essential oils and aldehyde dissolve in this on agitation; whilst the hydrocarbon itself is insoluble in alcohol of 50° B. The hydrocarbon can be regenerated

by treatment with strong sulphuric acid. After treatment with the petroleum spirit, the alcohol is rectified as usual. A plan of the apparatus used is appended.

—G. H. M.

*Improvements in Beverages resembling Beer, and in the Process of Manufacturing the same.* Thomas Etty, Liverpool. Eng. Pat. 11,297, August 15, 1884.

This is a process for manufacturing non-intoxicating beverages resembling beer from pearl-barley, malt, hops, sugar, and flavouring by boiling with water, and fermenting the liquid obtained with barm.—G. H. M.

*Improvements in the Manufacture of Champagne or Sparkling Wines.* J. C. Mewburn. From The Société Anonyme "La Vinicole." Eng. Pat. 12,105, September 6, 1884.

This invention consists in manufacturing sparkling wines by fermenting a mixture of wine and condensed must in a closed vessel, under pressure, at a temperature of 25° C. for twenty to twenty-five days. The wine is then transferred to another vessel, under a pressure of about six atmospheres, cooled, clarified and bottled, still under pressure. It is claimed that this yields a perfect wine in flavour and keeping power, and avoids the expense and loss incurred in the ordinary process of preparing sparkling wines. The amount of condensed must used varies from five to fifteen per cent., depending upon the nature of the wine employed.—G. H. M.

## XVIII.—ELECTRO-CHEMISTRY.

*Alloy for Electrical Conductors.* H. H. Lake, London. From T. Shaw, Newark, New Jersey, U.S.A. Eng. Pat. 10,932, August 5, 1884.

The object of this invention is to produce an alloy of aluminium, copper and phosphorus. The conductivity of this alloy is greater than that of iron, steel or phosphor-bronze. Alloys of copper containing from less than one per cent. to more than five per cent. of aluminium, and from one-twentieth to one per cent. of phosphorus, are employed. The amount of tensile strength required will regulate the proportions within the above limits. The copper is first melted, and the aluminium is added, a small quantity at a time, with a flux of palm oil, stirring well all the time with a pine stick; the phosphorus is then added, with stirring, and the alloy is poured into chill moulds.—J. T.

*Elements for Voltaic Batteries.* D. G. Fitzgerald and T. J. Jones, London. Eng. Pat. 1831 (September 23, 1884), 1885.

In place of zinc the inventors employ as the positive element, lead, which is readily reducible from most of its compounds; as the negative element they employ a conductor (preferably of lead or carbon), coated or maintained in contact with lead peroxide. They claim (a) the use, for the purpose of electrolytically obtaining in bulk material for the elements of voltaic batteries, of a paste composed of equivalents of sulphate of lead and magnesia, or of lead sulphate, and an alkali; (b) the production of a negative element by subjecting a lead plate to electrolytic action as an anode in a solution of magnesium sulphate, in conjunction with a cathode, consisting of a number of superposed trays, containing a lead compound, to be reduced to the metallic form; (c) the treatment of lead sulphate obtained as the spent material in the working of lead primary batteries, with an alkaline solution, prior to reconvertng such sulphate into peroxide by electrolysis; (d) the construction of electrolytic converting tanks or troughs, in which both the electrodes are constituted by a number of sets of superposed trays (preferably of lead), containing the materials to be acted upon electrolytically.—J. T.

## XIX.—PAPER, PASTEBOARD, Etc.

*Gas-fired Digester for use in the Manufacture of Paper Pulp from Wood, Straw, &c.* T. A. Reid, Liverpool. Eng. Pat. 9774, July 5, 1884.

This invention relates to a gas-fired digester arranged with a peculiar system of flues, whereby the digester can be fired with safety, economy, and directly. For details of construction, drawings and method of preparing wood pulp by the alkaline soda process with this apparatus, see original specification.—H. A. R.

*Process and Apparatus for the Manufacture of Cellulose and Glucose from Wood and other Vegetable Products.* Adolph Behr, Coethen, Germany. Eng. Pat. 9797, July 5, 1884.

LITHERTO cellulose has been prepared for technical purposes from wood by extracting all other substances from the wood by means of sodium hydrate. By the process described in above specification, the wood is treated by other reagents than sodium hydrate, and in such a way as to produce pure cellulose, and at the same time to convert into glucose as much as possible of the admixtures, consisting chiefly of carbohydrates. The wood shavings are dried by steam, then digested thoroughly with hot oil of turpentine or fusel oil, washed with steam, treated with dilute sulphuric acid, and again washed; the pure cellulose obtained may be either bleached at once, or dried and stored. The glucose and glucose-forming bodies are contained in the dilute sulphuric acid and in the condensed steam which was used for driving off the turpentine or fusel oil, and the glucose from these solutions is worked up by suitable means.

—A. J. K.

*Manufacture of Artificial Ivory.* L. P. Merriam, Homerton. Eng. Pat. 10,765, July 30, 1884.

The object of this invention is to produce a grained effect similar to real ivory, by means of xylonite, pyroxyline, celluloid or other equivalent material. The materials are reduced to sheets of different colours or shades, and placed in the machine known to xylonite-makers as a stulling machine—i.e., a cylinder and piston arrangement worked by hydraulic pressure or otherwise,—the machine being heated by steam to soften the material under operation. From this machine the material issues in rods or strips, which are again compacted into solid blocks by pressure. It is claimed that imitation ivory made by this process is more like the genuine article than that made in the ordinary way.—H. A. R.

*Improvements in the Preparation of Safety Papers for Cigarettes, &c.* J. Jameson, Newcastle. Eng. Pat. 11,087, August 9, 1884.

The object of this invention is the production of a safety paper, which shall indicate by a change in appearance any chemical or mechanical attempts at erasure or alteration. The inventor forms upon the paper a more or less intricate design, discoverable by reflected light, owing to a difference in the amount of glazing on the two surfaces. The design may be produced by pressure from plates or rollers, so as to slightly emboss the surfaces, or by extra application of size, forming thereby the said design, or else by the printing on of a soluble film. Another means is to highly glaze the whole surface first and then form the design by damp printing. The inventor may also use any convenient soluble chemical (e.g., iodide of potassium), which by its reaction (e.g., with mercuric chloride) will show whether the paper has been subjected to any sponging with a view to remove ink, such as what is known as "school-room ink," which contains no mordant.—H. A. R.

*Utilisation of the Sodium Sulphide Liquors from the Manufacture of Cellulose.* Oesterreichischer Verein für Chemische und Metallurgische Production. Ger. Pat. October 14, 1884.

The waste liquors resulting from the preparation of cellulose by the sodium sulphide treatment, are worked

up to black ash by evaporation and subsequent furnacing with lime and coal. Sodium sulphide lye is obtained by boiling this black ash in water, or even by heating the dilute waste liquors under a pressure of about three atmospheres.—W. D. B.

*Improvements in the Treatment of Dry Absorbent Bodies for Manufacturing various Useful Materials.* E. Paul Louvet, Paris. Eng. Pat. 2979, March 6, 1885.

INVENTOR brings into contact with coal-, wood-, or petroleum-tar, products composed of cellulose, such as cardboard, paper, rope, string, thread, stuffs, canvas, dry paper pulp, etc. The vessel containing the mixture is hermetically closed, and by creating a vacuum the tar is forced into the pores of the cellulose. Pressure is then applied to the material. After being moulded into sheets, the material is placed between stones, and freed from tar-oils by heat and pressure. The resulting substance is termed "cozoline." It is impermeable, uninflam- mable, acid-proof, unputrefiable, and capable of numerous applications—viz., for impermeable roofing, "cuir bouilli" or papier-mâché products, barrels and pipes for acids and gases, etc.—H. A. R.

*Improvements in the Manufacture of Fire and Water-proof Boards or Paper from Asbestos.* W. E. Heys, Manchester. From E. Ludewig, of Frankfort-a-O., Germany. Eng. Pat. 4151, April 2, 1885.

THIS invention relates to the manufacture of non-hygroscopic asbestos boards or papers. American or other soft fibrous asbestos, to the amount of 20-25% of the weight of the dry finished board, is taken and mixed with 25-35% of powdered aluminium sulphate. When well mixed the mass is impregnated with a 50% solution of zinc chloride in water. After washing with water, the mass is treated with ammonia, and after another washing with water, an addition is made of a 10% solution of resin soap, mixed with an equal amount of sulphate of alumina. To the pulp thus prepared in the rag-engine, inventor adds above 35% flour of ordinary or "green" asbestos stone. Finally, 5 to 8% of barium sulphate is added, and when diluted with water as required, the pulp may be employed for either machine- or hand-made paper. It is proposed to prepare a material suitable for roofing purposes, by covering on both sides ordinary tarred roofing paper or felt with asbestos paper prepared as above.—H. A. R.

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

*The Production and Use of Hydrogen Peroxide.* W. Lindner. Chem. Zeit. 9, 940 and 976.

THE introduction into commerce of a peroxide of barium of 70 to 75 per cent. rendered it possible to prepare hydrogen peroxide for about one-quarter the cost of the English product, the purity and stability being equal. In 1878 experiments were made on the bleaching of lawn and ivory with encouraging results. The preparation of hydrogen peroxide is best effected by the old peroxide of barium method. The peroxide must be as pure as possible, very finely divided by sieving with a considerable quantity of water, and freed from barium hydrate by washing. The decomposition of the peroxide of barium may be effected by means of hydrofluoric, hydrofluosilicic or phosphoric acid, but best by one of the two latter. Oxalic acid gives a good yield, but the product is not stable. The introduction of the paste peroxide of barium into the dilute acid must be very gradual, the temperature must not rise above 20° C., and the liquid must be maintained in constant agitation. When the neutralisation of the solution is sufficiently approximated the liquid is separated from the sediment—after adding a little phosphoric acid when the decomposition was effected by hydrofluosilicic acid,—and freed from dissolved baryta by the addition of a little sodium sulphate. The most stable peroxide of hydrogen is that which has been prepared with phosphoric acid, and

contains a small proportion of that acid in the free state; the addition, however, of phosphate of soda to a peroxide of hydrogen containing free acid, other than phosphoric, is found to increase the stability. The strength of a solution of peroxide of hydrogen is best determined by titration with solution of permanganate containing 7 grains.  $\text{KMnO}_4$  per litre. A convenient plan giving results within 0.1 per cent. in about three minutes is to take 2cc. of peroxide in a graduated tube holding 35cc., add five to six drops of hydrochloric acid, and then the standard permanganate solution, gradually, and with thorough agitation, until the contents of the tube are of a red or brownish colour; the quantity of solution added is now read off, 5cc. representing 1.0 per cent. of  $\text{H}_2\text{O}_2$ . When really stable, hydrogen peroxide can be stored in pitched barrels, tin cans, either varnished with amber varnish or plain, as well as in glass bottles; and it has been found that, avoiding high temperatures and the action of light, the deterioration on storing for three months does not amount to so much as 0.1 per cent. For the bleaching of ivory and other compact materials, it is only necessary to immerse the pieces in the acid solution till sufficiently white, the tint being observed in a sample after drying. For bleaching fibrous substances such as hair, it is advisable either to employ an ammoniacal solution of the peroxide, or else first immerse the material in the usual acid solution, allow the excess of liquid to drain away, and place the thus moistened substance in an ammoniacal atmosphere; this latter plan is specially applicable to Tussan silk, which must not lose its lustre. The employment of hydrogen peroxide as a discharge in printing is recommended by Schmid. For household purposes the peroxide may be safely used to remove from white goods stains of ink, wine, fruit juice, and the like, the best plan being to moisten the spots with the peroxide and add a few drops of ammonium chloride solution. Ornaments of bone and ivory yellow with age are readily whitened in a few days; fabrics yellow with age are also readily and safely restored with the peroxide. Pean and Bally recommend the peroxide for the disinfection of wounds, Pommer and Ebbl for the regulation of the fermentation of beer, wine, must, and worts; Krandauer, however, believes that a foreign taste is thus imparted to the liquor.—W. D. B.

*On Narcaine.* A. Claus. Ber. 18, 1569.

*Narcaine-ethylbromide*  $\text{C}_{22}\text{H}_{29}\text{NO}_6\text{Br}$ —Br. is obtained by heating narcaine with a slight excess of ethylbromide with back-flow condenser, or in a closed tube in the steam-bath.

*Narcaine-ethylchloride* is obtained from the corresponding bromide by decomposition with silver chloride. It forms well-characterised platinum and mercury double chlorides.

*Narcaine-ethylnitrate* and *oxalate* can likewise be prepared from the bromide by double decomposition with the analogous silver salts.

*Narcaine-methyliodide*, chloride and nitrate are prepared similarly to the ethyl derivatives. The platinum double salt of the methyl-chloride separates out as a crystalline powder, by treating an aqueous solution of the iodide with  $\text{HCl}$ . It is slightly soluble in water.

By boiling the above haloid derivatives of narcaine with alkali, hydrazid is formed, and a tertiary base is produced with the alcohol radical. In this way methyl-narcaine  $\text{C}_{22}\text{H}_{29}(\text{CH}_3)\text{NO}_3$  has been prepared from narcaine-methyliodide. The bases obtained in this way dissolve in dilute acids, and are reprecipitated with an alkali. They differ in this way from the quaternary ammonium bases—e.g., narcaine-methylhydroxyl, the salts of which are not decomposed with ammonia. Benzyl-narcaine has been obtained from narcaine-benzylchloride by boiling with potash solution.

By the oxidation of narcaine with potassium permanganate a new base of the formula  $\text{C}_{27}\text{H}_{35}\text{NO}_{10}$  has been prepared.—J. B. C.

*Papaverine.* A. Claus and E. Hüetlin. Ber. 18, 1576.

To prepare the haloid alcohol radical additional products of papaverine, the best method is to heat the substances

together in a closed tube on the water-bath. The compound of ethylbromide and papaverine is readily obtained in this way; whereas, those with methyl- and ethyl-iodide and benzyl-chloride require heating 18-20 hours. The authors have prepared papaverine-methyl and -ethyl-iodide ethyl-bromide, chloride, and nitrate and benzyl-chloride of the general formula,  $C_{21}H_{21}NO_4 \cdot RX$ .

—J. B. C.

*Benzoyl-ecgonine.* W. Merck. Ber. 18, 1594.

A CRYSTALLINE by-product in the preparation of cocaine was heated with concentrated HCl in a closed tube to 100°. The acid liquid was poured off from the crystalline product formed, and both portions separately tested. The crystalline portion was found to be benzoic acid, the acid liquid on shaking out with ether gave a crystalline substance, from which, on treating with moist silver oxide, a base separated having the characteristic properties of ecgonine. The analysis of the original substance and its products of decomposition indicate the following constitutional formula:  $-C_9H_{11}NO_3 - C_7H_6O$ .

—J. B. C.

*The Constitution of Cocaine.* G. Calmels and E. Gossin. Compt. Rend. 100, 1143-46.

THE authors obtain by decomposition of cocaine hydrochloride with crystallised bariumhydrate and water at a temperature of 120°, the same products, which Lossen (*Ann.* 133, 351) prepared—viz., methyl-alcohol, benzoic acid and a crystalline substance (A) which, with HCl, yields benzoic acid and ecgonine. From the latter, by heating or evaporating the solution of its platinum double salt, the modified salt  $(C_9H_{11}NO_3)_2PtCl_2$  is formed easily soluble in water. The alkali compounds of ecgonine crystallise with difficulty, and are decomposed with  $CO_2$ . The barium salt has the formula—

The compound (A) gives, on distillation, an oil which passes over mostly at 210-230°, a crystalline hydrochloride and an orange platinum double salt. It is an isotropine which decomposes on distillation with baryta into ethylamine, and an oil free from nitrogen (similar to tropine, which yields methylamine). These compounds are derived from ethyltetrahydropyridine—

isotropine being the methoxy derivative, ecgonine a carboxylated isotropine, and cocaine  $C_{17}H_{21}NO_4$ , the benzoyl-methyl ether of ecgonine.—J. B. C.

## XXI.—EXPLOSIVES, MATCHES, Etc.

*Progress in the Manufacture, Application and Knowledge of Explosives.* Dingl. Polyt. J. 256, 408.

SOME experiments with "kinetite," a gelatinous mixture prepared according to Petry and Fallenstein's patent\* (Ger. Pat. 31,786, June 18, 1884), are recorded in the *Berg- und Hutten-Männischen Zeitung*, 1885, p. 65. As compared both with gunpowder and dynamite, the results were very unfavourable; moreover, kinetite labours under the disadvantage of requiring a very powerful initial detonation.

Favier (Ger. Pat. 31,411, May 27, 1884) proposes to prepare a non-hygroscopic powder by mixing paraffin, resin or nitronaphthalene with hygroscopic nitrates, such as those of soda and ammonia. Apart from the somewhat uncertain degree of security against absorption of moisture thus attained, this composition labours under the great disadvantage of requiring an initial detonation provided by about 20 per cent. of gun-cotton or dynamite placed in the perforation of the compressed cartridge.

In the Transactions of the Technical Society of the Pacific Coast, 1884, i. 5, Jensen discusses the causes of

accidents in the manufacture of highly-explosive substances.

In consequence of certain representations which have been made in reference to the fraudulent conveyance of powder and sporting ammunition, a series of experiments has been carried out by the French Committee on Explosive Substances, to determine how far the conveyance of ammunition is to be considered attended with danger. The report of the committee is published in *Bulletin d'Encouragement*, 1885, vol. xii. p. 26. The committee arrived at the conclusions that with the varieties of ammunition mentioned below there was complete security against the detonation *en masse* of a package being caused by the explosion of one of its contents: Caps in tin-plate boxes, charged with 65 per cent. silver fulminate, 35 per cent. potassium nitrate; caps loaded with Gaupillat's mixture, packed in paste-board boxes; Flobert's caps containing 2 parts silver fulminate, 1 part of potassium nitrate, 1 part of sulphide of antimony, in tin boxes; caps for central fire cartridges in paste-board boxes; Gaupillat's cartridges of small calibre in paste-board boxes; revolver cartridges of both systems, sporting cartridges, and metallic rifle cartridges of all kinds. Flobert's and revolver cartridges may safely be sent express in boxes of not more than 5 kilos., caps in boxes of not more than 2 kilos. gross weight. The committee is also of opinion that detonators should not be regarded as safety ammunition.

Experiments carried out by Berthelot and others, as to velocity with which the detonation of various explosives is propagated, are recorded in the *Revue Industrielle*, 1885, p. 188. The explosives were contained in thin metal tubes of from 1 to 2 mm. internal diameter, and from 100 to 200 mm. long. The determinations were made partly with the aid of Schert's and Le Boulenger's chronographs and partly with Subert's velocimeter. The velocity of propagation was found to increase with the diameter of the charge, with the density of the explosive, and to be influenced by the composition, but not by the shape of the tubes. In tubes of 3 mm. diameter nitro-glycerine refused to detonate at 12°, detonated only partially at 14°, and required to attain to a temperature of 18° before it could be completely exploded under these circumstances. The following numbers give in meters per second the mean velocities of propagation of detonation of different explosives:—

Compressed gun-cotton in lead tubes 5200, in tin tubes, 5916. Granulated gun-cotton, 4770. Starch powder, 4885. Nitromannite, 6908. Nitrogyresine, 1078. No. 1 dynamite from Vonges, 2668. Pancastite, 4685. The velocity is less at the commencement than later on, and it was found that, measured at intervals of 25 meters, the velocity of propagation in compressed gun-cotton varied in a length of 100 m. from 4661 to 5986 m. per second.—W. D. B.

*Improvements in Presses or Apparatus for the Manufacture of Compressed Gunpowder.* H. H. Lake, London. From H. Gruson. Eng. Pat. 7108, May 1, 1884.

THE improved form of press which is here patented differs from presses heretofore constructed, in that the table containing the matrices moves with the lower set of plungers, the upper set of plungers being motionless.

—W. D. B.

*An Improved Explosive Compound.* Thomas Wilkins, Peckham. From T. Petry and O. Fallenstein. Eng. Pat. 10,986, August 6, 1884.

A GELATINOUS mass is obtained by dissolving gun-cotton in nitro-benzene or other nitro compound of the aromatic group of coal-tar derivatives, and finely powdered chlorate or nitrate of potassium or other base, together with sulphur, free or combined as sulphide, added to the jelly. The powdered salts are first well mixed and kneaded with the jelly till a homogeneous mass is obtained.

\* See Abstract, second column of this page.

The sulphur or sulphide is then introduced, and the whole well worked up. The best proportions are :

- 16 to 21 of the aromatic nitro compound.  
 3 „ 1 of gun-cotton or other form of nitro-cellulose.  
 82½ „ 75 of chlorates and nitrates.  
 1 „ 3 of sulphur or sulphide.

The resultant explosive is of a plastic nature, and may readily be formed into cartridges.—W. D. B.

*Improvements in the Manufacture of Explosives.* C. W. Curtis, London. Eng. Pat. 15,647, November 27, 1884.

THIS invention has reference to the preparation and use in the manufacture of gunpowder, of charcoal rich in hydrogen and comparatively poor in carbon, derived from cocoa-nut fibre and other fibrous substances. Such charcoal, in which the hydrogen bears to the carbon a proportion of one to ten or one to eleven, is obtained by slowly charring or roasting, for from four to six hours, the fibrous material in the usual apparatus consisting of a cylinder revolving within a retort heated to a dull or dark-red heat. Charcoal so prepared is of a rich dark-red colour. The proportions of the ingredients of powder into which this charcoal enters, are preferably 1 of sulphur, 25 of potassium nitrate, and 5½ of the charcoal.—W. D. B.

## XXII.—GENERAL ANALYTICAL CHEMISTRY.

*Analytical Notes.* C. de la Harpe. Bull. Mulhouse, 1885, 245.

(a) THE normal sulphates of the alkali metals are decomposed on heating them with halogen hydracids. Thus : 2·18 grm.  $K_2SO_4$  were heated in a water-bath with HCl, and the residue dried at 120-140°, till the weight was constant ; it then weighed 2·61 grm., showing that conversion into acid sulphate had taken place, according to the equation  $K_2SO_4 + HCl = KCl + KHSO_4$ . Titration of the residue showed that the quantity of acid sulphate obtained was ninety per cent. of the theoretical. With sulphate of soda seventy-seven per cent. underwent conversion. With potassium sulphate and hydrobromic acid, the corresponding decomposition approaches completeness, ninety-five per cent. and ninety-nine per cent. being realised in two experiments, the residue being dried at 140°. The reversal of the decomposition takes place at temperatures varying with the several hydracids ; thus, in the case of hydrochloric acid, when the residue was dried at 110°, it contained eighty per cent. of the potassium sulphate as hydrosulphate ; dried at 140°, on the other hand, only forty to forty-five per cent. With nitric acid and potassium sulphate the decomposition reached eighty-two per cent., the residue being dried at 140°. Formic and acetic acids were found to be entirely without action. (b) To determine the acidity of solutions which cannot, from whatever cause, be directly titrated with alkali, the author distils from sodium acetate, added to the solution in sufficient quantity. The distillation is effected under diminished pressure, whereby it may be carried nearly to dryness, without allowing the temperature to exceed 120°, and the whole of the acid—*i.e.*, the equivalent of acetic acid—obtained in the one distillate. This process is not applicable to solutions containing salts, which are dissociated on boiling—*c.g.*, salts of iron, aluminium and chromium. (c) In determinations of the alkaline earth metals in solutions containing ammonium sulphhydrate, the author points out that the usual preliminary of acidification with hydrochloric acid and boiling is attended with the danger of the formation of sulphuric acid, and consequent precipitation of the metals. (d) The precipitation of tin and arsenic, as sulphides, from solutions of stannates and arsenates, is much expedited by heating with ammonium sulphhydrate, in presence of ammonia in excess, at 80-90°. Hydrochloric acid is then added in quantity sufficient to decompose the sulphhydrate, and the metals are completely precipitated as sulphides. (e) In preparing dithionic acid by the oxidation of sulphuric acid, the author recommends the employment of

the manganic oxide in the hydrated form. The gas is passed into water at 0°, and the oxide added from time to time in the form of paste, taking care to keep the sulphurous acid in excess. (f) The author describes a triangle for supporting crucibles, the dimensions of which may be varied at pleasure, consisting of three wires, which may be made to include any angles by insertion into holes pierced in series, in a suitable ring, at corresponding segments. Such a triangle will be found especially economical in the case of platinum wire. (g) The ordinary method of carrying out Bunsen's process of indirectly estimating elements and radicles which may be made to liberate iodine from potassium iodide, has the defect of being difficult of control. The author describes a simple apparatus whereby the distillation may be conducted in a stream of carbonic acid gas, and the process thereby brought within the complete control of the operator. The author recommends the process for the estimation of nitrates. He is investigating its adaptation to the indirect determination of sulphurous acid and other reducing agents.—C. F. C.

*Determination of Strength of Permanganate Solutions.* G. Krüss. Ber. 18, 1580.

To avoid the usually tedious process for determining strength of solutions of liquids possessing a characteristic absorption spectrum, the author proposes to utilise this property for such determinations, as being more rapid and equally reliable. Quantitative spectrum analysis gives us a method for determining the coefficient of extinction (E) in certain regions of the spectrum of a solution, of which the relative absorption power for light (A) is known. The concentration (C) of the solution can be determined for  $E \cdot A = C$ . Potassium permanganate was prepared pure, according to Gregory's method, and the extinction coefficient determined for different strengths of solution by the method of Vierordt. The observed results agree well with the ordinary volumetric determination with standard sodium hyposulphate solution. For further details and table of observations, the original paper should be consulted.—J. B. C.

*Dimethylanilindiozobenzene as an Indicator in Alkalimetry.* B. Fischer and C. Philipp. Chem. Zeit. 56, 998.

THE end reaction is marked by a change of colour, from yellow to pink. The indicator is prepared by dissolving 9·3 parts aniline in 30 parts 25 per cent. hydrochloric acid, diluting with water, and then adding an aqueous solution of 7 parts sodium nitrite to the cooled liquid. The solution is then poured into one containing 12 parts dimethylaniline dissolved in 15 parts 25 per cent. hydrochloric acid ; finally about 30 parts sodium acetate are added until the solution smells of acetic acid. Crystals separate out which can be purified by crystallisation from alcohol. It is neutral towards free carbonic acid.—S. R.

*Gravimetric Determination of Manganese.* H. v. Jüptner. Chem. Zeit. 9, 692.

FOR the determination of manganese in iron and steel, also in iron ores and slags, the following method is adopted. The HCl solution of the substance to be tested (in which any ferrous salt must be previously oxidised with  $KClO_3$ ) is neutralised with  $Na_2CO_3$  in a graduated flask,  $NH_4Cl$  solution added, precipitated cold with  $NaCO_3$ , and after adding an excess of ammonia digested for some time by agitation. It is then filtered to the mark, well mixed and filtered through a dry filter. An aliquot part of this filtrate is treated with  $H_2SO_4$  to precipitate the larium present, and neutralised with ammonia with or without previous filtration ; heated to boiling and precipitated with  $(NH_4)_2S$ . It is then filtered through a small filter and washed with  $(NH_4)_2S$  water. If the precipitate is small it may be treated directly with boiling acetic acid, and to limit the amount of liquid the funnel should be furnished with a glass tap ; with larger quantities, the precipitate is washed with acetic acid through the filter

into a beaker. The acetic acid solution is filtered off into a weighed platinum basin evaporated to dryness, heated and weighed as  $Mn_2O_4$ .—J. B. C.

*Apparatus for Fractional Distillation.* F. Anderlini. Chem. Zeit. 9, 941.

This apparatus consists of a worm of five or more convolutions, according to the number of which, four or more upright tubes corresponding with the connecting tubes in Bel and Heninger's apparatus, connect each coil of the worm with that next but one below it. The diameter of these connecting tubes is somewhat contracted at the bend which they take before entering the lower coil. These connecting or draining tubes serve to prevent an accumulation of liquid in the worm, and thus obviate any risk of a quantity of liquid being ejected into the condenser, should a sudden evolution of vapour take place.—W. D. B.

*Examination of the Ash of Vulcanised Caoutchouc.* C. Reinhardt. Stahl und Eisen, 1884, p. 649.

For the estimation of the ash in vulcanised caoutchouc, from 0.5 to 1 grm. of the sample is cautiously heated in a covered crucible until the evolution of gas has ceased, and then in the open crucible until the organic matters are burnt off. The stronger the heating the less accurate are the results, since calcium carbonate loses  $CO_2$ . Gypsum is converted into calcium sulphide, and oxide of zinc transformed into sulphide or reduced and the metal volatilised. For the accurate estimation of the mineral constituents, sulphur excepted, from 0.5 to 1 grm. of the caoutchouc in shavings is warmed in a beaker upon the water-bath with nitric acid of 1.4 sp. gr., until solution is effected. After cooling somewhat the solution is transferred to a porcelain basin, evaporated upon the water-bath to dryness, moistened with hydrochloric acid, and dissolved in water. Silicic acid and barium sulphate remain undissolved. The solution contains oxide of zinc, lime, magnesia, ferric oxide, and alumina, which are separated in the usual manner. The total sulphur is estimated by warming about 1 grm. of the sample with 20 cc. of nitric acid, potassium chlorate being thrown in from time to time. The solution is evaporated, dissolved in hydrochloric acid and water, filtered, and the sulphuric acid estimated in the filtrate and also in the barium sulphate, forming a part of the insoluble residue. The sulphur added to effect the vulcanisation is estimated by burning a portion in a current of oxygen at a low temperature and passing the gases of combustion into hydrochloric acid containing bromine; or the caoutchouc may be heated in a glass tube closed by fusion, and the sulphur estimated in the distillate.

—W. D. B.

*Estimation of Fat in Palm-nut Meal and other Palm-nut Preparations.* V. v. Wilan. Bied. Centr. 14, 140-141.

When treating palm-nut meal in the ordinary way for fat determination in Soxhlet's apparatus for the usual time, 3 to 4 hours, low results are obtained, owing to the dense nature of the cake, and a subsequent extraction for from 5 to 6 hours yield another 1 per cent. of fat. Other feeding materials yield up their fat to within a very minute quantity during the four hours' extraction. This peculiarity of palm-nut preparations is attributed to the mechanical retention of fat which is closely pent up in the cells; and can, therefore, only be attacked by the ether with great difficulty, and only after some time comes into solution. The results of experiments with this material ground to different degrees of fineness confirm this view, for coarse samples retained considerable quantities of fat, whereas finely-pulverised samples yielded up all their fat in the 3 to 4 hours.—D. A. L.

*Improvements in Sampling and Testing Apparatus for Spirituous Liquors or other Liquids.* J. O'Neil Mackle, Liverpool. Eng. Pat. 12,555, September 19, 1884.

This improvement consists essentially of a glass cylinder fitted with a valve at bottom opening inwards, acting

automatically or by hand, so that an average sample or a sample at any required depth may be taken from a cask or vessel containing the liquid. The cylinder carries inside a hydrometer, inside which is a thermometer, the means for ascertaining the specific gravity and the temperature of the sample being thus comprised in the sampling instrument.—G. H. B.

*An Improved Method of and Apparatus for the Quantitative Estimation of Hemoglobin in the Blood.* A. M. Clark, Middlesex. From Dr. E. Fleischl, Vienna. Eng. Pat. 5991, May 15, 1885.

THE method consists in comparing the depth of colour of a solution of the blood in water with a standard made of ruby glass ground into a wedge-shape and fixed in a form of chlorimeter, which admits of the thickness of the wedge at any point being read off on a scale. In order to provide the same tone of colour being transmitted through the ruby glass and the blood, the yellow light of a lamp or candle is used for the illuminant.—G. H. B.

*Test for Chloralhydrate.* M. Hirschfeld. Archiv d. Pharm. 1885, 223, 26.

By adding to a solution of chloralhydrate a small quantity of calcium hydrosulphide, a red colouration ensues after the lapse of about half a minute. A fainter but still clearly perceptible reaction takes place when a solution of sulphuretted hydrogen and lime water are added to a chloralhydrate solution.—F. M.

*A New Reagent for Aromatic Orthodiamines.* O. Hinsberg. Ber. 18, 1228.

For the detection of small quantities of *m-p*-tolylene-diamine and *o*-phenylenediamine the author found phenanthrene-quinone a very suitable reagent. The reaction depends upon the formation of diphenylene quinoxalines, which are only slightly soluble. An alcoholic solution of the diamine to be tested is boiled for a short time with a solution of phenanthrene-quinone in glacial acetic acid. If an orthodiamine be present, a bulky precipitate, consisting of fine yellow needles, is formed while the liquor is still boiling. On separating it by filtration and moistening it with hydrochloric acid it turns deep-red. The paradiamines form a similar compound with phenanthrene quinone, but it is not acted upon by hydrochloric acid. The author thinks that this reaction may probably be generally suited for the detection of aromatic orthodiamines.—S. H.

## New Books.

ALKALI, ETC., WORKS REGULATION ACT, 1881. Twenty-first Annual Report on Alkali, etc., Works. By the CHIEF INSPECTOR. Proceedings during the Year 1884. London: Printed by Eyre & Spottiswoode, East Harding Street, Fleet Street. 1885. Price 6d.

THIS Government Blue Book, just recently issued, contains the Chief Inspector's Annual Report to the Local Government Board for the year 1884. It contains in all 91 pages of matter, preceded by a table of contents arranged as follows:—Introduction; Alteration of Districts; Arrangement of Districts; Location of Inspectors; Wool Carbonising Works; Venetian Red Works; Manure Works; Deposit of Alkali Waste; Bleaching Powder Chambers; Apparatus for Testing the Air of the Chambers; Proposed Rule for Bleaching Powder Makers; Provisional Orders; Prosecution under the Act; Inspectors' Reports—the districts reported being numbered and named as follows:—District No. 1. Scotland and Ireland; No. 2. North; No. 3. Cheshire, North

Wales, and part of Lancashire; No. 4. East Lancashire and Yorkshire; No. 5. Midland; No. 6. South West; No. 7. South East, District of Wilnes. From the Report it would appear that sulphate of ammonia works are being gradually but surely made innocuous through the persevering efforts of the Chief Inspector and his colleagues. In no case is sulphuretted hydrogen now allowed to escape mingled with carbonic acid from the sulphate tanks as of old, and the turning the gases into boiler-flues or the after-parts of fire-places at best only a process of conversion of one form of nuisance into another, is also being rapidly discontinued in favour of the direct condensation of the sulphuretted hydrogen in oxide of iron purifiers, by which the sulphur can be readily recovered and the oxide of iron regenerated for renewed use. (See pages 48, 49, 59, and 72, *loc. cit.*).

**A TREATISE ON THE MANUFACTURE OF SOAP AND CANDLES, LUBRICANTS AND GLYCERIN.** By WM. LANT CARPENTER, B.A., B.Sc., etc. With 87 illustrations. E. & F. N. Spon, 125 Strand, London. New York: 35 Murray Street. 1885.

THIS work, as the preface informs us, has in part appeared, though in a detailed manner, in Spon's "Encyclopedia of Manufactures and Raw Materials." In the present work the whole subject matter is rearranged and very carefully revised. The book contains 332 pages of subject matter, illustrated with 87 woodcuts, a table of contents, and an alphabetical index covering 12 pages. It is of medium size, and is bound in cloth. The work is subdivided into fifteen chapters treating of the various portions of the subject, these chapters being preceded by a "Historical Epitome and References." The writer of the present notice has himself seen and examined the remains of the old Pompeian soap factory referred to, with its lead-lined pans, each containing about 15 to 20 gallons. It forms one of the most interesting relics in the ruined city. He can thus bear full testimony to this interesting fact mentioned in Mr. Carpenter's "Historical Epitome." Chapter I. Theoretical Principles. Chapter II. Raw Materials: Their Sources and Preparation. Chapter III. Raw Materials: Refining, Clarifying and Bleaching. Chapter IV. Raw Materials: Their Proximate Analysis. Chapter V. Caustic Alkali, and other Mineral Salts. Chapter VI. Manufacture of Household Soaps: The Process of Saponification. Chapter VII. Treatment of Soap after its Removal from the Soap Copper: Household, Manufacturers', and Toilet Soaps. Chapter VIII. Theory of the Action of Soap—Its Valuation and Analysis: Distribution and Position of the Trade. Chapter IX. Lubricating Oils, Railway and Wagon Grease, etc. Chapter X. Candles: Raw Materials, their Sources and Preliminary Treatment. Chapter XI. Processes for the Conversion of Neutral Fats into Fatty Acids: The Manufacture of Commercial Stearin. Chapter XII. The Manufacture of Candles and Night-lights: Their values as Illuminants. Chapter XIII. Glycerin. Chapter XIV. Summary of Patents. Chapter XV. Bibliography.

## Monthly Patent List.

### ENGLISH APPLICATIONS.

1885.

#### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

8740 G. Raven, London. Improvements in or relating to smoke-consuming furnaces and fire-places. July 20  
8866 D. Jarvis, London. Improvements in retorts and seals therefor. Complete specification. July 22

8970 A. C. Hill, Middlesbrough. Improvements in regenerative hot-blast stoves for heating air, steam, or other gases. July 25

9204 D. K. Clark and W. J. E. Foakes, London. Improvements in filter-presses. July 31

9275 W. Alden, Barstow—Communicated by A. R. Pechney et Cie., France. Improvements in apparatus for heating solid substances out of contact with the products of the combustion of the fuel employed. August 1

9281 H. W. Todd, Liverpool. Improvements in metallic drums for containing chemical and other substances. Aug. 1

9275 J. Kuscoe, Manchester. Improvements in machines for facing the ends of, and turning or boring gas-retort mouths, lids, pipes, or valves of D, oval, or any other shape or section than round; also for cutting oval-shaped holes in boiler and other plates, castings, and the like. August 1

9298 A. H. W. Brown, London. Improvements in means for economising fuel and consuming smoke in steam boilers. August 4

9306 W. L. Wise, London—Communicated by J. G. Hansel and F. L. Krumbiegel, Saxony. Improvements in furnaces. August 1

9308 W. A. Martin, London. An improved mode of developing and increasing the draught of furnaces. August 5

9387 W. Thompson, London. Improvements in stoves for heating the retorts or blast furnaces, or for other analogous purposes requiring hot blast. August 6

9416 J. G. Betts, London. Improvements in apparatus for heating or cooling air for drying or for other purposes. August 7

9437 W. W. Nightingale, London. Improvements in means or apparatus for forming and maintaining ice surfaces, and treating the atmosphere of glaciers or such like places, and for cooling chambers. August 7

9446 W. H. Hudson and C. H. Bonne, Manchester. An improved apparatus for carburetting atmospheric air and other gases. August 8

#### II.—FUEL, GAS, AND LIGHT.

8663 F. Siemens, London. An improvement in gas-producers. July 17

8745 S. A. Sadler, London. Improvements in means and apparatus for utilising mineral, tar, and other oils as fuel. July 20

8816 P. Jensen, London—Communicated by J. E. Dery, Belgium. Improvements in or in connection with apparatus for the carburation of gas in railway and other carriage lamps and lanterns. Complete specification. July 31

8880 J. Hanson, Bingley. Improvements in the construction or arrangement of hydraulic mains and ascension pipes, connected therewith for the manufacture of coal gas. July 23

8882 J. Bromilow, Liverpool. Improvements in apparatus for the application of gases to metallurgical and other purposes requiring high temperatures. July 23

9089 F. L. Harris, London. Improvements in gas batteries for the production of electric currents. July 28

9203 J. Robbins, London. An improved artificial fuel. July 31

9302 A. R. Upward and C. W. Pridham, London. Improvements in gas batteries. August 4

9365 H. Baker, Derby. Lighting by coal gas, houses, streets, etc., by which a much greater lighting power is obtained from the gas. August 6

9541 R. Dempster, jun., Manchester. Improvements in centre valves employed in connection with gas purifiers. Complete specification. August 11

9543 H. E. A. Wallis and H. T. Rateliff, London. An improved arrangement or means for effecting direct conduction of gas-flame heat to hydrocarbon for enriching the flame and increasing light. August 11

9591 J. McCulloch and W. Black, Glasgow. Improvements in machinery for preparing and compressing materials for use as fuel or for smelting purposes. August 12

9650 H. E. A. Wallis and H. T. Rateliff, London. Improved construction of carburetting apparatus for burning coal gas with hydrocarbons. August 13

9679 H. J. Rogers, Watford. Improvements in gas retorts, and in apparatus connected therewith. August 14

9701 N. J. Holmes, Seacrofts. Improvements in the construction of self-igniting and inextinguishable signal lights for marine and other purposes. August 11

9720 B. Andreae, Halifax. Improvements in the generation of gas for light and heat purposes, and the necessary apparatus thereto. August 15

9725 R. W. Anderson, Liverpool. A new and improved means of economising coal, consuming smoke, and raising the heat to a higher degree in the furnaces of steam boilers. August 15

9761 J. J. Barclay and J. Thompson, London. Improvements in gas producers and apparatus for supplying gas to marine and stationary steam-boiler and other furnaces. August 17

#### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, ETC.

8872 L. Mond, Liverpool. Improvements in or incidental to the separation of ammoniacal products and tar from producer or other furnace gases. July 25

9416 H. de Solchenhoff, London. A continuous arrangement of regenerating apparatus for coke-ovens. July 29

9611 A. A. Vale, London.—Communicated by the Chemische Fabrik, Actien Gesellschaft, Germany. Treatment of the waste acids resulting from the purification of the light oils of coal-tar for the utilisation of the said waste acids, and of the by-products resulting therefrom. August 12

#### IV.—COLOURING MATTERS AND DYES.

9211 M. Hoffmann and A. Weinberg, London. The production of new azo colours. July 31  
9510 H. J. Hadden, London.—Communicated by The Färbefabrik, vorm. Bayer & Co., Germany. A new manufacture of violet and blue azo dyes. August 10  
9694 G. M. Snow Horton, London.—Communicated by Root and Tinker, United States. Recovering the excess of sulphuric anhydride used in the manufacture of certain dyes, etc. August 11

#### V.—TEXTILES: COTTON, WOOL, SILK, ETC.

8753 W. Mather, London. Apparatus for treating textile materials with liquids, gases, or vapours. July 21  
8791 W. Mather, London. A process for bleaching vegetable textile fabrics. July 21  
8795 C. D. Abel, London.—Communicated by La Société Dubus, Cojet, et Cie., France. Process for the removal of vegetable impurities from wool by chemical means in combination with steam. July 21  
8850 J. C. Sigerist, Manchester.—Partly communicated by E. Mattier, France. A new or improved process of treating and weighting silk. July 23  
9129 A. M. Clarke, London.—Communicated by J. Haug, France. An improved machine for decorticating ramie and other similar fibrous plants. July 29  
9377 C. Comt, S. Hersee, H. C. Williams, and S. Hersee, London. Improvements in treating all vegetable substances for the production of fibre for use for spinning purposes and for the manufacture of paper pulp. August 6

#### VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

9197 H. J. Hadden, London.—Communicated by E. Haefelly, France. Improved process for dyeing cotton yarn. July 31  
9300 T. Salt and W. Stead, London.—Communicated by F. Pasquay, Germany. Improvements in apparatus for washing, scouring, bleaching, drying, steaming, drying, and otherwise treating fibrous material in the form of slivers, slubbings, rovings, yarns, or fabrics. August 11

#### VII.—ACIDS, ALKALIS, AND SALTS.

8092 F. Foster, London. Generating carbonic acid gas automatically. July 18  
8723 W. P. Thompson, Liverpool.—Communicated by Solvay et Cie., Belgium. Improvements in filters applicable for caustic soda solution. July 20  
8721 W. P. Thompson, Liverpool.—Communicated by Solvay et Cie., Belgium. Improvements in the manufacture of chlorine from by-products of the ammonia-soda process, or similar chemicals obtained from other source. July 20  
888 W. P. Thompson, Liverpool.—Communicated by J. Weeren & F. Weeren, Germany. A new or improved process for obtaining silicates of the alkalis and alkaline earths from the corresponding sulphates, together with sulphurous acid or sulphur, and apparatus therefor. Complete specification. July 22  
8916 C. F. Claus, jun., London. Improvements in the process of obtaining phosphoric acid and alumina from Redondo and similar phosphates of alumina. July 23  
8903 F. Bruns, London. An improved process for the production of carbonate of potassium from chloride of potassium or sulphate of potassium. July 25  
9225 W. Weldon, Burston.—Communicated by A. R. Pechiney et Cie., France. Improvements in apparatus for heating solid substances in contact with the products of the combustion of the fuel employed. August 1  
9227 W. Weldon, Burston.—Communicated by A. R. Pechiney et Cie., France. Improvements in and relating to the decomposition by means of magnesia of the residual ammonium chloride of the ammonia-soda process. August 1  
9125 F. J. P. Cheesbrough, Liverpool.—Communicated by J. Hawliczek, Austria. An improved method of manufacturing soda crystals and caustic soda direct from the bicarbonate resulting from the ammonia-soda process, and recovery of ammonia and carbonic acid, and apparatus employed therefor. August 7  
9616 G. Kruger, London. Recuperation and utilisation of the alcohol and acetic acid lost by evaporation in the manufacture of vinegar. August 13  
9691 G. M. Snow Horton, London.—Communicated by Root and Tinker, United States. Recovering the excess of sulphuric anhydride used in the manufacture of certain dyes, etc. August 11

#### VIII.—GLASS, POTTERY, AND EARTHENWARE.

9390 J. Bevington, London. An improved method for the drying or hardening-on of printed earthenware in biscuit state. August 6  
9122 W. W. Boulton, London. Improvements in decorating glass with acidised air-chambers. August 7

#### IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

8730 D. Crossley, Halifax. Improvements in the manufacture of bricks, which are thereby rendered porous or cellular. Complete specification. July 29  
8736 H. W. Merritt, Somerville, Massachusetts, U.S. Improvements in plastic compounds. Complete specification. July 29  
8814 R. Stanley, London. An improved method of preparing and burning bricks, tiles and the like. July 22  
8890 O. Hertrampf, London. Improvements in brick-kilns. Complete specification. July 25  
9017 J. H. Wood, London. Improvements in ovens for drying slaty and other similar substances. July 27  
9087 A. W. L. Reddie, London.—Communicated by T. Eggleston, United States. Improvements in the method of and compounds for preserving stone. Complete specification. July 28  
9154 W. Joy, London. Improvements in the manufacture of cement. July 30  
9222 A. T. Fullicks, London. Improvements in the manufacture of blocks and slabs for structural and ornamental purposes. July 31  
9222 C. J. Howe, London. Improvements in the manufacture of Keene's cement. August 1  
9361 A. Wilkinson, London. An improved construction of ventilating brick. August 11  
9320 R. W. Taynton, London. An improved process for seasoning timber. August 13  
9633 F. Boyes, East Hartlepool. The making of bricks, called lubricating brick die. August 13  
9730 W. O. Wood, London. Improved compounds for the manufacture of furnace bricks and linings, and for making converter bottoms in one piece, tycres, and the like. August 15  
9731 W. B. Westlake, London. Improvements in machinery or apparatus for the manufacture of artificial fuel, bricks, and the like, and in preparing materials for the same. August 15

#### X.—METALLURGY, MINING, ETC.

8651 D. Rose, W. N. Rose, and A. T. F. Rose, London. Means for utilizing wrought iron and steel scrap in the formation of piles to be rolled into finished iron and steel. July 17  
8661 W. Wood and M. H. Hurrell, London. Improvements in apparatus for refining copper and other metallic matters by electrolytic and chemical actions. Complete specification. July 17  
8677 J. Riley, Glasgow. Improvements in the manufacture of steel in regenerative open-hearth furnaces. July 18  
8693 J. A. Longridge, London. Improvements in the construction of ordnance. July 18  
8756 H. White, London.—Communicated by W. H. Purdy, United States. Improvements in and relating to the purification of iron and steel. Complete specification. July 21  
8806 H. W. Hollis, London. Improvements in and connected with the rolling and forging of metals. July 23  
8965 W. H. Duncan, Coalbrookdale. Extracting, washing, and delivering gold, silver, diamonds, lead, and other metals. July 25  
881 T. Hampton and J. Faer, Manchester. Improvements in the method of casting steel ingots. July 25  
9116 J. L. Thompson and W. White, London. Improvements in the production of aluminium from its salts, and apparatus for the purpose. July 30  
9169 H. Hall, London. Improvements in the mode of coating metal plates or sheets with tin, lead, or other metals or alloys of the same, and in apparatus to be employed therein. Complete specification. July 31  
9347 R. W. Taynton, London. Improvements in the manufacture of oil baths for toughening steel. August 5  
9351 E. Grooters, London.—Communicated by L. Grooters, Belgium. Improvements in kilns or furnaces for smelting copper and other ores at one operation. August 5  
9176 H. H. Lake, London.—Communicated by P. A. Vergez, France. Improvements relating to the separation or recovery of tin from scraps of tinned plate. August 8  
9196 F. J. P. Cheesbrough, Liverpool.—Communicated by J. Hawliczek, Austria. Improvements in furnaces for melting metals. Complete specification. August 10  
9536 H. J. Hadden, London.—Communicated by E. Phillips and T. Jones, United States. Improvements in the preparation of the charge for zinc furnaces. Complete specification. August 11

#### XI.—FATS, OILS, AND SOAP MANUFACTURE.

9162 A. Domeier and B. Nickels, jun., London. Improvements in the preparation of oils for burning in lamps. July 30  
9352 M. Bauer, London.—Communicated by J. Merz, Austria. Improvements in extracting fat and other substances from dissolvable materials, and in apparatus therefor. August 5  
9391 P. A. Newton, London.—Communicated by S. Horne-mann, Germany. An improved process for preserving crude animal fats. August 6

9903 C. Benson and J. W. Garrett, Kingston-upon-Hull. Improved wringers or chylouses used for extracting oil from seed in the manufacture of cake. August 10.  
9973 C. Rumble and F. Sear, Battersea. Improvements in soap making. August 13.

## XII.—PAINTS, VARNISHES, AND RESINS.

8737 W. R. Lake—Communicated by J. P. Perkins, United States. An improved paint or pigment. July 20.  
9141 W. Macrae, London. Improvements in the manufacture of dry colours. Complete specification. August 7.  
9149 T. Harrison, London. Coating the insides or outsides of iron and steel ships, barges, and all and every description of iron and steel vessels, griddles, tanks, etc., where the preservation of iron, steel, or any other metal is desirable. August 7.

## XIII.—TANNING, LEATHER, GLUE, AND SIZE.

8728 W. J. Goulborne and E. Morse, London. Compressed leather. July 20.  
8963 M. Zingler, London. Improved substitutes for leather applicable for driving belts, boot and shoe soles, covering machine rollers, and other uses. July 21.  
9259 T. Laycock and J. Owen, London. Waterproofing leather. August 1.  
9113 W. Macrae, London. A new or improved varnish or size. Complete specification. August 7.  
9693 L. A. Groth, London—Communicated by F. W. Grune, Germany. A new or improved method of preparing elastic leather and elastic material suitable for moulding from animal textures or leather containing gelatine. August 12.  
9660 T. N. Ashman, London. Improvements in the method of and in composition for treating leather and leather articles. August 13.

## XX.—SUGAR, STARCH, GUM, ETC.

8786 H. J. Allison, London—Communicated by A. G. Day, United States. Improvements in vulcanised kerite compounds and in processes for the manufacture of the same. Complete specification. July 21.  
8787 H. J. Allison, London—Communicated by A. G. Day. Improvements in vulcanised kerite compounds and in processes for the manufacture of the same. Complete specification. July 21.  
8813 G. M. Newhall and J. H. Tucker, London. Improvements in treating sugar and like substances and in apparatus therefor. Complete specification. July 22.  
8857 C. Lyle and J. Lyle, London. Improvements in apparatus for cleansing sugar. August 1.  
8924 A. Rahu, jun., J. Grathwohl, and H. A. Browne, London. Improvements in preparing and treating syrups and molasses, especially those of sorgho and sugar cane, by mixing them with substances adapted for distillation, and in the manufacture of spirit therefrom. July 23.  
9249 A. G. Wass, London. The improved utilisation of sugar. August 1.  
9226 W. R. Lake, London—Communicated by F. O. Mathieson, United States. Improvements in the manufacture of hard sugar. Complete specification. August 1.  
9343 W. H. Schwartz, London. Improvements in the manufacture of sugar. August 5.

## XVI.—BREWING, WINES, SPIRITS, ETC.

8652 G. F. Redfern—Communicated by C. Volckner, Austria. Improvements in malting houses. Complete specification. July 17.  
8810 G. Brown, London. The preparation of extracts and beverages from the leaves of the coca plant. July 21.  
8908 J. W. Peters, London. An improved process of purifying yeast. July 23.  
8925 A. Rahu, jun., J. Grathwohl, and H. A. Browne, London. Improvements in the preparation and treatment of sweet potatoes, yams, and arums, and the manufacture of spirit from those vegetable substances. July 23.  
8957 J. Pacey, London. Improvements in finings-making machines. July 24.  
8994 F. Springmühl, London. Method of preparing "hoefene," the narcotic principle of hops. July 25.  
9008 R. C. Sinclair and J. Hodson, London. Apparatus for effecting the turning of malt or other grain on the drying floors of kilns. July 25.  
9207 J. Challender, London. An improved apparatus for automatically aerating malt and other liquids. July 31.  
9106 T. D. Harries, Aberystwyth. A beverage called lactarine or aerated whey. August 7.  
9334 W. Duckworth, Halifax. An improved compound to be employed for flavouring and preserving syrup cordials and aerated beverages. August 11.  
9349 B. J. B. Mills, London—Communicated by A. J. Reynolds, United States. Improvements in malt-stirring machines. August 11.

## XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, ETC.

8800 C. Jones, London. Improvements in or connected with furnaces for treating town refuse. July 18.  
8912 J. R. Spence, London. Improvements in the treatment of sewage, at or near the outfall. July 23.

8899 F. G. Broxholm, London. The manufacture of an improved antiseptic compound. July 25.  
9053 C. H. Starman, London. A new process or method for preserving all kinds of vegetable products. July 28.  
9170 J. McErlie, Edinburgh. Ripening and purifying milk. July 31.  
9251 M. Condon, Spennymoor. Improvements in apparatus for heating, purifying, and softening water for boilers. August 1.  
9246 E. Whillier, London. Improvements in apparatus for preserving articles of food. August 1.  
9288 W. Priestley, Wigan. Improvements in sewage-liming machines, and for machines to be used for similar purposes. August 1.  
9339 J. Cowan, London. Softening and purifying water. August 5.  
9341 E. B. Watson and H. B. Fulton, London. Preparation and application of improved hygiene and disinfecting substances, for use as candles, night-lights, tapers, and such like, or as external remedies. Complete specification. August 5.  
9353 W. R. Lake, London—Communicated by M. R. Garcia, France. An improved disinfectant. August 5.  
9382 J. Hoek, London. Improvements in the purification of sewage waters and the like, and the recovery of valuable products therefrom. August 6.  
9486 W. D. Borland, Stowmarket. Improvements in the application of disinfectants. August 10.  
9554 W. Gurn, London—Communicated by the Coal-Economising Co., United States. A new or improved compound for the prevention of smoke in furnaces and other fire-places. August 11.  
9632 C. D. Abel, London—Communicated by C. Linde, Germany. An improvement in the manufacture of ice. August 12.

## XVIII.—ELECTRO-CHEMISTRY.

8661 W. Wood and M. H. Hurrell, London. Improvements in apparatus for refining copper and other metallic matters by electrolytic and chemical actions. Complete specification. July 17.  
8808 W. B. Nation, London. Improvements in the application of electricity to the treatment of vegetable fibre for the production of half stuff and other purposes. July 21.  
9380 A. Muirhead and C. M. A. Wright, London. Improvements in the preparation and production of insulating compounds for electrical purposes. August 12.  
9338 H. J. D. Hadden, London—Communicated by A. Z. Champy, N. G. A. Champy, and L. P. G. Champy, Belgium. Method and apparatus for purifying, separating or decomposing liquids by means of electrolysis. August 17.

## XIX.—PAPER, PASTEBOARD, ETC.

8644 R. F. Dorendorff, London—Communicated by M. Krause, Germany. A process of inserting (during the making of paper, cards, etc.) natural grasses, mosses, ferns, leaves, flowers, or any other decoration suitable. July 17.  
8681 J. P. Cornett, South Hyllon. Trimming the edges of paper or pulp by means of a jet of water or other fluids, named in the complete specification a hydraulic pulp edge trimmer. Complete specification. July 18.  
8760 S. S. Sugden, Woodford. Improvements in the manufacture of cigarette papers. July 21.  
8856 G. Newsum, London. A machine for varnishing and printing paper. July 24.  
9112 R. F. Dorendorff, London—Communicated by M. Krause, Germany. Velvet paper for writing and other purposes. July 29.  
9249 H. W. Morrow, London. Improvements in the treatment of paper and other fibrous material. Complete specification. August 1.  
9411 W. Macrae, London. Improvements in waterproofing paper and other fabrics, and in machinery therefor. Complete specification. August 7.  
9412 W. M. Norton, London. Machinery for varnishing or sizing and applying colours to paper and other fabrics. Complete specification. August 7.

## XXI.—EXPLOSIVES, MATCHES, ETC.

8851 D. Johnson, London. Improvements in the manufacture of explosives. July 24.  
9092 J. A. Mitchell and J. Sinclair, London. An improved cartridge, chiefly designed for use in mines. July 25.  
9003 J. Mitchell and J. Sinclair, London. Improved apparatus for limiting the effects or extent of explosions and fires in mines or other places. July 25.  
9022 H. E. Newton, London—Communicated by A. Nobel, France. An improved receptacle for hygroscopic explosives. Complete specification. July 27.  
9023 H. E. Newton—Communicated by A. Nobel. Improvements in the manufacture of explosive compounds. July 27.  
9125 P. A. Newton, London—Communicated by A. Nobel, France. Improvements in the manufacture and use of explosive substances. July 29.  
9126 P. A. Newton, London—Communicated by A. Nobel. Improvements in the manufacture and use of explosive compounds. July 29.

ENGLISH PATENTS PUBLISHED.\*

APPLIED FOR DURING 1881 AND 1885.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

1881.

11880 F. G. Riley. Apparatus for carbonating liquids or semi-fluids. 8d

1885.

6466 H. J. Haddon—Communicated by J. W. Brightman. Improvements in furnaces. 8d

II.—FUEL, GAS, AND LIGHT.

1881.

11987 G. T. Beilby. Separating solid paraffin from oils. 6d  
12909 J. Inary—Communicated by H. de Bay and C. de Rosetti. Apparatus for combustion of liquid fuel. 6d  
13416 G. T. Beilby. Purifying paraffin oils. 4d  
11468 C. Thompson and C. Hammond. Manufacture of "Virgin gas" for lighting, heating, and other purposes. 6d

1885.

805 A. J. Boulton—Communicated by J. Hanlon. Manufacture of gas for illuminating or other purposes, and apparatus therefor. 10d

1084 J. Reid. The revivification of hydrate of lime after it has been used once for the purification of gas. 4d

REPRINTS.

2071 (1853) P. A. Moreau—le Comte de Fontaine. Combustion of carbon in gas and other lights. 6d

1146 (1880) P. Jensen—Communicated by — Brin. Production of oxygen and nitrogen gas. 6d

1143 (1880) J. Alexander and A. K. McCosh. Separating condensable matters from combustible gases. 6d

3785 (1881) J. Alexander and A. K. McCosh. Obtaining products from blast furnace and other combustible gases. 6d

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, ETC.

1881.

11250 J. Dempster. Method and apparatus for extracting tar and ammonia from the gases of blast furnaces. 6d

11967 R. de Solderhoff. Apparatus employed in the treatment of coal in order to obtain coke and by-products therefrom. 6d.

12286 P. Dow. Retorts for distilling shale, coal and other substances. 6d

12310 H. Sionon. An improvement in coke ovens. 2d

12379 C. Kingsford. Apparatus for utilising the waste heat from coke ovens, or other furnaces for evaporating, calcining, etc. 6d

12384 C. E. Bell. Treatment of oils and tars obtained from blast furnaces and gas producers for the production of valuable hydrocarbons therefrom. 4d

IV.—COLOURING MATTERS AND DYES.

1885.

2206 H. J. Haddon—Communicated by E. Frank and the Farbenfabriken vormals Bayer & Co. Process for the production of soluble combinations of certain azo compounds with bisulphites, and for utilising the same in dyeing and printing. 2d

7630 C. E. Avery. Improved manufacture of extracts and liquors of logwood. 4d

V.—TEXTILES, COTTON, WOOL, SILK, ETC.

1881.

15923 N. A. Alexanderson. Method of rendering cloth, wool, paper, etc., waterproof but not air-tight. 4d

1885.

6922 W. W. Hamilton. Treating animal and vegetable fibres for textiles, cordage and other uses. 4d

6923 W. W. Hamilton. Treating animal and vegetable fibres for textiles, cordage and other uses. 4d

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

1884.

12385 W. Clark—Communicated by E. A. D. Guichard. Process and apparatus for bleaching waste paper, whether printed or written on. 6d

\*Any of these specifications may be obtained by post, by remitting the cost price, plus postage, to Mr. H. Reader Jack, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 5s. ....	2d.
Above 5s. and not exceeding 10s. ....	4d.
" 10s. 6d. " " 20s. 4d. ....	2d.
" 20s. 4d. " " 30s. 4d. ....	2d.

12172 C. R. Preibisch. Dyeing fabrics aniline black, and apparatus therefor. 4d  
13211 D. Dawson and G. W. Oldham. Dyeing silk and woollen fibres with insoluble azo-colouring matters. 4d

VII.—ACIDS, ALKALIS, AND SALTS.

1881.

11035 W. Weldon—Communicated by A. R. Peebney & Cie., Salindres, France. Manufacture of chlorine and hydrochloric acid. 4d

11036 W. Weldon—Communicated by A. R. Peebney & Cie., Salindres. Manufacturing chlorine from hydrochloric acid. 4d

11119 W. R. Lake—Communicated by C. Brison, Macon. Method and apparatus for distilling urine and other substances containing nitrogen. 6d

11711 A. Feldmann, London. Improvements in the process of manufacturing ammonia. 4d

11775 H. Gaskell, jun. Purification of bicarbonate of soda, and apparatus therefor. 6d

11805 P. M. Justice—Communicated by S. G. Thomas. Manufacture of phosphates. 4d

12211 W. L. Wise—Communicated by Solvay & Co. Obtaining hydrochloric acid gas from a solution of hydrochloric acid. 4d

1885.

384 E. W. Parnell and J. Simpson. Improvements in the utilisation of alkali waste from the Leblanc process in the manufacture of carbonate of soda, with production of sulphuretted hydrogen. 6d

1037 E. W. Parnell and J. Simpson. The recovery of ammonia in the manufacture of carbonate of soda by the ammonia process, with production of sulphuretted hydrogen. 4d

6127 C. A. Bartsch. Stills for containing sulphuric acid. 6d

6124 J. H. Johnson—Communicated by Dr. F. von Heyden. Process for the manufacture of naphthol carbonic alkaline salts. 2d

6104 E. Hanisch and M. Schroeder. Obtaining sulphur from furnace gases. 6d

6105 E. Hanisch and M. Schroeder. Obtaining liquid anhydrous sulphurous acid from furnace and other gases. 4d

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

1881.

12097 T. McLaren. A composite paving block. 4d

12216 P. Wilkins. Improvements in asphaltic pavement. 2d

12425 H. Kettmann. Process for the manufacture of asphaltic. 4d

12486 T. Freeman, jun., and C. Eardley. Machinery for and method of manufacturing hollow bricks and other hollow clay or plastic building materials. 4d

12765 W. Day. Kilns for burning bricks and other articles. 6d

13355 W. Smith. Manufacture of waterproof cement. 2d

13380 J. J. Barclay, R. Allison, and J. Barclay. Kilns and apparatus for drying and burning bricks. 8d

11328 C. Thompson. An improved form in bricks for the construction of furnaces, stoves, kilns, etc. 6d

1885.

204 J. Foulds and S. Tomlinson. Crushing and reducing to powder stone, or other hard material. 6d

2927 W. Millar and C. F. Nichols. A new or improved fibrous, fireproof, and waterproof composition for constructive, decorative, and other purposes. 2d

6027 J. Tulloch and T. Tulloch. The construction of fireproof buildings. 6d

7118 C. A. Wilkes and W. Millar. Metallic compound for flooring, paving and other purposes. 2d

X.—METALLURGY, MINING, ETC.

1884.

11170 A. E. Scott. Extraction of metals from carbon, or substances known as such, and treatment of products arising therefrom. 4d

11909 C. J. Hall. Means and apparatus for separating diamonds, gold, tin, and other minerals from earthy and other matters. 6d

12317 G. I. J. Wells. Treatment of complex ores or solutions. 4d

12171 J. P. Roe. Apparatus for the distribution of gas and air in regenerative steel-melting, glass-melting, and other furnaces. 6d

12593 T. Barnard. The economical concentration of ores, minerals, and metallic substances. 6d

12687 J. Riley. Process and apparatus for making steel with open-hearth furnaces. 6d

12725 E. Marchese. Process for electrolytic extraction of copper from its ores. 4d

12793 H. Campbell—Communicated by W. W. Ker. Compound applicable for welding iron and steel, purifying and strengthening cast iron, restoring burnt steel, and imparting to Bessemer steel qualities which enable it to be tempered like cast steel. 4d

- 12876 C. Cheswright - Partly communicated by H. Cheswright, Bordeaux. Laminating metals, and apparatus employed therein. 6d  
 12930 G. W. Moon. The amalgamation of gold and silver with quicksilver. 6d  
 12931 P. M. Justice - Communicated by L. E. Thomas, Paris. An improvement in the manufacture of steel. 2d  
 13126 T. Nordenfellt - Communicated by C. G. Wittenstrom, E. Faustman and P. Osberg. Furnaces for melting metals in crucibles. 6d  
 13252 C. M. Pielsticker - Partly communicated by F. C. G. Müller. Production of steel (and other metal) wire, plates, rods, bars, etc.; and apparatus connected therewith. 6d  
 14264 T. Pitt - Communicated by A. Rollet. Manufacture of iron and steel by the employment of a purified metal. 6d  
 16447 W. Rose. The fabrication or compounding of iron and steel for various purposes. 1s

1885.

- 3386 N. C. Cookson. Smelting sulphide of antimony. 4d  
 6124 J. R. Griffin. Method of and apparatus for reducing ores. 6d  
 6129 W. R. Lake - Communicated by C. J. Eames. Manufacture of iron sponge, iron, and steel; and apparatus therefor. 6d  
 6130 W. R. Lake - Communicated by C. J. Eames. Manufacture of iron sponge, iron, and steel. 4d  
 6131 W. R. Lake - Communicated by C. J. Eames. Manufacture of iron sponge, iron, and steel. 4d  
 6389 A. Greiner and T. Erpf. Method of and apparatus for smelting iron. 4d  
 6994 W. P. Thompson - Communicated by E. H. Cowles and A. H. Cowles. Smelting ores by an electric current, and furnaces or apparatus therefor. 6d  
 7014 H. J. Allison - Communicated by the Compressed Steel Co. Manufacture of steel ingots. 6d

## REPRINTS.

- 4117 (1879) J. Alexander and A. K. McCosh. Utilising the gases of blast-furnaces. 8d

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

1881.

- 12811 C. Harrison. Improvements in the manufacture of soap. 2d  
 13043 J. Swallow. Preparation of mineral oils for woollen manufacturing and other purposes. 2d

## XII.—PAINTS, VARNISHES, AND RESINS.

1881.

- 9803 Sir S. J. Blanc, Bart. Treating white peats (or Kieselguhr) and blast-furnace slag, for production of an agent or material for combining with paints, varnishes, and other materials, to render them fireproof and impervious to moisture. 4d  
 12633 P. Maxwell Lyte. Manufacture of antifouling paints for submerged structures. 4d  
 13492 A. French and J. Bullantyne Hannay. Improvements in making white and other lead pigments, and in apparatus therefor. 6d

1885.

- 7198 H. H. Lake - Communicated by S. Roebuck. Composition or paint for coating brickwork, ironwork, and the bottoms of ships, etc. 2d

## XIII.—TANNING, LEATHER, GLUE, AND SIZE.

1881.

- 12135 W. Clark - Communicated by E. Hermann. Improvements in tanning skins, and in the manufacture of compounds therefor. 4d  
 13967 W. Warwick. Manufacture of leather. 6d

1885.

- 7564 W. Paul. Machinery for boarding, softening, and graining leather. 4d

## XV.—SUGAR, STARCH, GUM, Etc.

1881.

- 12169 A. Fesca. Manufacture of sugar and apparatus therefor. 6d

1885.

- 6132 W. R. Lake - Communicated by F. O. Matthiessen. Manufacture of sugar, and apparatus therefor. 6d  
 6604 A. M. Clark - Communicated by the Havenport Glucose Manufacturing Co. Manufacture of starch, glucose, and other starch products. 2d

## XVI.—BREWING, WINES, SPIRITS, Etc.

1885.

- 6801 R. C. Sinclair and J. Hodson. Apparatus for effecting the turning of malt or other grain on the drying floors of kilns. 4d

## XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

1881.

- 12943 W. Donaldson, J. Shone, and E. Ault. The purification of sewage and other foul liquids, and apparatus therefor. 6d  
 12713 W. Gostwyck Gard. Manufacture of an improved disinfectant, deodoriser, and precipitant. 2d  
 12830 J. W. Slater. Preparation of agents to be used in the treatment of sewage and other liquid or semi-liquid putrescent or putrescible matters, etc. 4d.

1885.

- 6159 F. R. Conder. Improvements in the purification of water, which improvements are also applicable to other sanitary purposes. 2  
 7318 G. H. Ellis. Process for the economical production of a porous carbon for filtering, refining, decolorising, and deodorising liquids. 2d.

## XVIII.—ELECTRO-CHEMISTRY.

1881

- 12725 E. Marchese. Process for electrolytic extraction of copper from its ores. 4d

1885.

- 6994 W. P. Thompson - Communicated by E. H. Cowles and A. H. Cowles. Smelting ores by an electric current; and furnaces or apparatus therefor. 6d

## XIX.—PAPER, PASTEBOARD, Etc.

1881.

- 12385 W. Clark - Communicated by E. A. D. Guichard. Process and apparatus for bleaching waste-paper, whether printed or written on. 6d  
 12127 T. Koutledge. Boilers or digestors to be employed in the treatment of paper-making materials or for analogous operations. 4d  
 12566. A. Mitscherlich. Improvements in sizing of paper. 4d  
 13256 H. H. Lake - Communicated by W. J. Foley, U.S.A. Manufacture of paper, and machinery or apparatus therefor. 6d

1885.

- 1767 A. Behr. Apparatus and process for obtaining cellulose and glucose from wood and other vegetable matter. 6d  
 2722 C. D. Abel - Communicated by the Patent Papier Fabrik zu Penig, Germany. Manufacture of safety paper for cheques and similar purposes. 4d  
 2723 C. D. Abel - Communicated by the Patent Papier Fabrik zu Penig. Manufacture of safety paper for cheques and similar purposes. 4d  
 7156 H. H. Lake - Communicated by J. Jordan. Treatment of paper-pulp, and apparatus or machinery therefor. 6d

## XXI.—EXPLOSIVES, MATCHES, Etc.

1881.

- 13109 G. A. Sweetser. An improved combustible composition to be employed in the manufacture of cigar lights or fuses. 2d  
 13176 G. G. André. Improvements in explosive compounds. 2d

## REPRINT.

- 3294 (1877) R. W. S. Griffith. Manufacture of gunpowder. 4d

# THE JOURNAL OF THE Society of Chemical Industry:

A MONTHLY RECORD  
FOR ALL INTERESTED IN CHEMICAL MANUFACTURES

No. 9.—VOL. IV.

SEPTEMBER 29, 1885.

Non-Members 30 - per annum; Members  
21 - per Set; Single Copies 2 6.

## The Society of Chemical Industry.

### Past Presidents:

Sir H. E. Roscoe, LL.D., V.P.R.S.	1881—1882.
Sir Frederick Abel, C.B., D.C.L., F.R.S.	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
W. H. Perkin, Ph.D., F.R.S.	1884—1885.

## COUNCIL FOR THE YEAR ENDING JULY, 1886.

President: E. K. Muspratt.

### Vice-Presidents:

Sir F. A. Abel, C.B., D.C.L., F.R.S.	David Gamble.
Sir I. Lowthian Bell, Bart., F.R.S.	Peter Griess, Ph.D., F.R.S.
Alexander M. Chance.	W. H. Perkin, Ph.D., F.R.S.
Prof. James Dewar, F.R.S.	John Spiller.
James Duncan.	E. C. C. Stanford.
	J. C. Stevenson, M.P.

### Ordinary Members of Council:

R. Forbes Carpenter.	S. A. Sadler, Ph.D.
Henry Doulton.	Sir Bernhard Samuelson,
John Evans, D.C.L., F.R.S.	Barl, M.P.
Ivan Lewinstein.	Sir Chas. Tennant, Bart.,
Rudolph Messel, Ph.D.	M.P.
B. E. K. Newlands.	Prof. W. A. Tilden, F.R.S.
Thomas Royle.	John Williams.

With Sixteen Chairmen and Secretaries of Sections.

### Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, E.

### Honorary Foreign Secretary:

Ludwig Mond, 28, Park Crescent, Portland Place, W.

### General Secretary:

Charles G. Cresswell.

### Offices:

Palace Chambers, 9, Bridge Street, Westminster, S.W.

## THE JOURNAL.

### Publication Committee:

The President.

Sir F. A. Abel, F.R.S.	F. Hunter, Ph.D.
Joseph Bernays, M.I.C.E.	Ivan Lewinstein.
W. Lant Carpenter.	Prof. R. Meldola.
Prof. Frank Clowes, D.Sc.	Ludwig Mond.
George E. Davis.	C. O'Sullivan, F.R.S.
Prof. Dewar, F.R.S.	John Pattinson.
Prof. Chas. Graham, D.Sc.	Dr. W. H. Perkin, F.R.S.
Peter Griess, Ph.D., F.R.S.	Sir H. E. Roscoe, F.R.S.
D. B. Hewitt, M.D.	John Spiller.
David Howard.	A. Norman Tate.
Prof. A. K. Huntington.	Thomas Tyrer.

Editor: Watson Smith, The Owens College, Manchester.

ASSISTED BY THE FOLLOWING STAFF OF

### Abstractors:

G. H. Beckett.	W. E. Kay.
D. Bendix.	A. J. King, B.Sc.
E. J. Bevan.	D. A. Louis.
W. Dalrymple Borland.	F. Machenhauer.
C. Claus.	Wm. Macnab, Jun.
E. G. Clayton.	J. W. G. McMillan.
Julius B. Cohen, Ph.D.	W. H. Munro, D.Sc.
C. F. Cross.	H. R. Procter.
A. R. Davis.	H. A. Rademacher.
A. G. Green.	F. W. Renaut.
S. Hamburger, Ph.D.	Samuel Rideal.
J. J. Hummel.	James Taylor, B.Sc.
C. C. Hutchinson.	F. L. Teed, D.Sc.
D. E. Jones.	Alex. Watt.
Herbert Jones.	Sydney Young, D.Sc.

## CHANGES OF ADDRESS.

J. T. Brown (d/o Chelsea), 27, Roscanan Road, Albert Road, Battersea, S.W.

S. Dunn (d/o Loughton), 11, South Hill Park Gardens, Hampstead, N.W.

F. W. Fletcher (d/o Highbury), North London Chemical Works, Holloway, N.

A. Hampson (d/o Fairfield), c/o F. Hampson & Sons, Grey Mare Lane, Openshaw, Manchester.

J. G. Heywood (d/o Inverness Terrace), 68, Sutherland Avenue, Maida Vale, W.

C. M. King (d/o Demerara), 1, Bloomsbury Square, W.C.

## CHANGES OF ADDRESS REQUIRED.

A. K. Mackinnon, 1/o 1, Gloucester Street, W.  
S. Studer, 1/o Longshaw & Sons, Warrington.

On the Morning of Sunday, the 20th inst., at his residence, Rede Hall, Burstow, Surrey,

**WALTER WELDON, F.R.S.,**

Chevalier of the Legion of Honour,

FORMERLY PRESIDENT OF THE SOCIETY OF  
CHEMICAL INDUSTRY,

Vice-President of the Chemical Society and of  
the Institute of Chemistry,

DEPARTED THIS LIFE IN THE 53RD YEAR  
OF HIS AGE.

A LOSS DEEPLY REGRETTED BY MANY  
FRIENDS AND COLLEAGUES.

# INTERNATIONAL INVENTIONS EXHIBITION, LONDON.

## REPORT ON THE EXHIBITS RELATING TO THE CHEMICAL INDUSTRIES.

BY WATSON SMITH,

Lecturer in Chemical Technology in the Victoria University, Manchester, etc.

(Continued from page 483.)

## COLOURING MATTERS AND DYES.

ROBERT CHADWICK & SON, OF KIDDERMINSTER  
(Group XIV. No. 1462).

(1.) Improvement in extracting colouring matter and other substances by steam-process from dyewoods; also distillation of ammonia.

(2.) Hygienic crystals and powder disinfectant.

## ACIDS, ALKALIS, AND SALTS.

E. C. C. STANFORD'S NEW METHOD OF TREATING SEAWEED (Group XIV. No. 1431).

Mr. Stanford's name is intimately associated with the British iodine and kelp industry, the seat of which has always been in Glasgow. The exhibit illustrates generally the manufacture of iodine, bromine, and potassium salts from seaweed, besides that of the new and interesting substance *Algin*, first isolated and studied by Mr. Stanford; also many of the metallic alginates. It would appear that amongst seaweeds, the algae possess the power of assimilating the iodine from seawater to about ten times the extent of the bromine, and that amongst the algae the *Laminaria* and the *Fuci* are the kelp-producing species of the genus referred to. It is remarkable that the three gelatinous species, *Chondrus*, *Gilidium*, and *Eucheimia* contain little or no iodine; moreover, the *Enteromorpha* or sea-grass, a plant retaining, when dry, a very strong odour of

sort of sluggy mass, and lose thereby about half the iodine, Mr. Stanford proposed the so-called *Char-process*, by which all the iodine is saved. The weed in this process is submitted to destructive distillation in iron-retorts, leaving behind a loose, porous charcoal, retaining the salts and the iodine, and yielding in the distillate, ammonia, acetic acid, and tar. In a still newer process—in fact, the one referred to in the title of the exhibit—Mr. Stanford extracts first the potassium chloride ("muriates"), potassium sulphate and "kelp-salt" (sodium chloride containing some carbonate and including the iodides), by simple maceration in cold water. The amount so removed from air-dried *Laminaria* is about one-third of its weight (thirty three per cent.), of which twenty to twenty-two per cent. are mineral salts, and the balance consists of dextrin, mannite, and extractive matter, leaving two-thirds of the plant (sixty-six per cent.) for further treatment, apparently unaltered. This residue contains the peculiar new substance *Algin*, and the cellulose. The comparison between the three processes is of considerable interest, as showing the advance made upon the old kelp process so tenaciously adhered to and persisted in by the West Coast natives, by Mr. Stanford's "Char" and "Wet" processes:—

### KELP PROCESS.

Per cent. utilised, 18.

Kelp, 18 tons { Salts, 9 tons } Residuals—Kelp-waste,  
{ Iodine, 570lb. } 18 tons, valueless.

### CHAR PROCESS.

Per cent. utilised, 56.

Char, 36 tons { Salts, 15 tons } Residuals—Charcoal, 36 tons,  
{ Iodine, 600lb. } tar and ammonia.

### WET PROCESS.

Per cent. utilised, 70.

Water extract, { Salts, 20 tons } Residuals—Algin, 20 tons,  
33 tons { Iodine, 600lb. } cellulose, 15 tons, dextrin, etc.

In this new process, the seaweed is to be exported and worked at a central factory, and all the common varieties can be used. The weed is first boiled with sodium carbonate, the solution is filtered and precipitated with sulphuric acid, the precipitate being

SODA SOLUTION.			
RESIDUE.	Precipitated by Sulphuric Acid.		Retained in Solution.
CELLULOSE.	ALGIN.	Sulphate of Soda, crystallised out as GLAUBER'S SALTS.	Mother-liquor, carbonised, is KELP-SUBSTITUTE.

the sea, contains no iodine. The giant algae growing outside the influence of the Gulf Stream, generally supposed to be the iodine-carrier, singularly enough contain very little iodine. The drift-kelp is made from two varieties of red weeds, or *Laminaria*, the *L. Digitata* and the *L. Stenophylla*. The former is known as tangle, and both kinds are always submerged. These seaweeds, and especially the latter, are much injured by rain, and are often, after drying, almost valueless. If well preserved, the *Laminaria* contain ten times as much iodine as the *Fuci*. It furnishes the only kelp now used for making iodine. The usual yield of kelp from 100 tons of wet seaweed is five tons, and as only half of this is soluble, two-and-a-half tons form the total valuable product of what may be termed the *native process*, and this must pay for the labour of cutting, carrying, drying, and burning 100 tons of wet seaweed. As the people in burning the weed use such a heat as to produce a

the new substance algin, which resembles albumen, and contains all the nitrogen, and, moreover, all that is nutritive in seaweed. The solution is now neutralised with limestone, the sulphate of lime deposited, the neutral solution evaporated down and the sulphate of soda crystallised out. The mother-liquor, containing all the potash salts and iodine, is carbonised, forming the "kelp-substitute." The residue on the filter is the cellulose. The whole plant is thus utilised (see table above).

Algin has fourteen times the viscosity of starch, and thirty-seven times that of gum arabic. Algin or sodium alginate in solution is precipitated or coagulated by alcohol, acetone, and collodion, but not by ether. It is precipitated by mineral acids, various salts, and by lime- and baryta-water. The solution is not precipitated or coagulated by alkalis and alkaline salts, starch, glycerol, and cane-sugar. It does not precipitate the ordinary alkaloids. It is dis-

tinguished from albumen, which it most resembles, by not coagulating on heating, and from gelose by not gelatinising on cooling, by containing nitrogen, by dissolving in weak alkaline solution, and being insoluble in boiling water. From gelatin it is distinguished by giving no reaction with tannin : from starch, by giving no colour with iodine ; from dextrin, gum-arabic, tragacanth, and pectin, by its insolubility in dilute alcohol and dilute mineral acids.

It is remarkable that it precipitates the salts of the alkaline earths, with the exception of magnesium, and also most of the metals, but it gives no precipitate with mercuric chloride or potassium silicate.

#### COMMERCIAL APPLICATIONS OF ALGIN OR SODIUM ALGINATE :—

*For Sizing Fabrics.*—As a finish, algin has the advantage over starch that it fills the cloth better, is tougher and more elastic, that it is transparent when dry, and that it is not acted on by acids. It imparts to the goods a thick cloth, elastic feeling, without the stiffness imparted by starch. It has the advantage, possessed by no other gum, of becoming insoluble in presence of a dilute acid, which decomposes starch or dextrin. No other gum having anything like the viscosity of algin, in solution, none will go so far in making up the solution or cover such a large surface.

*The alginate of alumina* in caustic soda, is a stiff dressing, and in the crude, unbleached state, will be a cheap dressing for dark materials ; and in the colourless for finer fabrics. *The ammoniated alginate of alumina* can be used to give a glossy surface, which is quite insoluble after drying.

*As a Mordant and Dung-substitute in Dyeing and Printing.*—Mr. John Christie, of the firm of J. Orr Ewing & Co., states that "there is another application of the alginate of soda—viz., in the fixing of mordants, such as those of alumina or iron upon cotton fibre." Very encouraging results are said to have been obtained, and Mr. Christie believes a very large application will be found for alginate of soda as a "*dung-substitute*." This being the case, the substitution of so harmless a compound for one so poisonous as the generally used arseniate of soda, should be welcomed, and a fair trial be accorded the new dung-substitute. In Germany, where the use of poisonous materials in connection with printing and dyeing textile fabrics is greatly restricted, if not altogether interdicted, one would imagine such a substitute would, when known, be readily adopted. Mr. Christie continues, "The mordants, when precipitated, seem to have full dyeing power," which means that as a dung-substitute the alginate has done its work well.

*As an Article of Food.*—Algin contains—carbon, 44·39 per cent. ; hydrogen, 5·47 ; nitrogen, 3·77 ; oxygen, 46·57, or about the same amount of nitrogen as is found in Dutch cheese. For thickening soups and puddings, as a substitute for gum-arabic in the manufacture of jujubes and lozenges, in making jellies, it is said that it would be very serviceable.

*In Pharmacy.*—It is said that it would be useful for emulsion of oils, as an excipient for pills, and for fining of spirits.

*For Boiler Incrustations.*—Mr. Spiller has proved that a solution of sodium alginate forms one of the best fluids for preventing boiler-incrustation, as it quickly precipitates the lime from the boiler water in a state in which it can be easily blown off.

**ALGIC CELLULOSE.**—This substance bleaches easily, and under pressure becomes very hard, when it can be turned and polished with facility. It makes also a good paper, tough and transparent, but with no fibre. Alone or mixed with algin and linseed

oil or shellac, it may be used as a non-conductor of electricity, where a cheap material is required.

**THE SEAWEED CHARCOAL.**—It is proposed to use this in conjunction with algin for covering boilers, and such a composition has been largely applied under the name of "carbon cement." This is nearly all charcoal, three per cent. of the algin being sufficient to make it cohere. It forms a cool, light, and efficient non-conducting covering.

The foregoing details have been given somewhat *in extenso*, but the subject is one of those for which the claim of *national importance* can be set up.

Mr. Stanford says, in his paper read before the Society of Arts (May 22, 1884) : "No Royal Commission will give the crofters and cottars on the shores of the Hebrides and the West of Ireland anything like the satisfaction that the offer of £1 per ton for all the seaweed they could gather, would. In all these places, the sea-question might soon become more important than the land-question."

*The advantages to Proprietors of Shores* are that such manufacture would afford an export value to a large waste product at present almost worthless. The export of this bulky material must result in a large traffic to and from the Western Islands, thus improving their rental and value, and assisting in imports of coal, meal, &c.

*For Alkali Makers* there would also be advantages in such a new manufacture, creating, as it would, a large demand for alkali, bleach, and other chemicals, with some waste products.

Mr. Stanford's process is protected by the following patents :—Eng. Pats. 142, January 12, 1881 ; and 13,433, October 11, 1884. Also by French Pat. 143,736, July 1, 1881.

The process has been working some time on a semi-industrial scale ; all difficulties are successfully overcome, and already there is a considerable demand for the new products.

The following is a list of the more interesting specimens exhibited by Mr. Stanford :—

#### ALGINATES.

Sodium	Alginate, Soluble	
Potassium	" "	
Ammonium	" "	
Lithium	" "	
Magnesium	" "	(This is a remarkable body ; insoluble alginic acid in the presence of water, freely dissolves Magnesia and its carbonate.)
Calcium	Alginate, Insoluble	
Barium	" "	
Strontium	" "	
Lead	" "	
Silver	" "	
Mercury	" "	{ Mercurous salt, no Mercuric alginate.
Copper	" "	
Iron	(Ferrous)	"
"	(Ferric)	"
Cobalt	" "	
Nickel	" "	
Manganese	" "	

#### ALGINATES—Insoluble.

Tin	Alginate, Stannic	
"	Stannous	
Zinc	" "	(Most of the alginates have not yet been described, and the exact composition is unknown.)
Chromium	" "	
Cadmium	" "	
Bismuth	" "	
Aluminium	" "	
Platinum	" "	
Arsenic	" "	
Antimony	" "	
Uranium	" "	

The following salts are double alginates of the metals with ammonia, and are all very soluble, mostly becoming insoluble when dry, thus forming waterproofing materials:—

Ammonium, Strontium Alginate			
"	Chromium	"	
"	Copper	"	
"	Iron	"	Ferrie
"	"	"	Ferrous
"	Tin	"	Stannic
"	"	"	Stannous
"	Cobalt	"	
"	Nickel	"	
"	Manganese	"	
"	Silver	"	
"	Platinum	"	
"	Zinc	"	
"	Calcium	"	
"	Aluminium	"	
"	Uranium	"	
"	Arsenic	"	
"	Antimony	"	

The Aluminium Alginate is also shown in combination with Aluminate of Soda, making a cheap stiff soluble dressing for cotton and other goods, which can be easily rendered insoluble.

*Shellac Algin.*—Shellac combines with Sodium Alginate, and with Ammonium Alginate, forming a

MESSRS. CHAPMAN & MESSEL (*Group XIV. No. 1467*).

#### MANUFACTURE OF ANHYDROUS SULPHURIC ACID.

This firm exhibits fine specimens of sulphuric anhydride, which is manufactured on a large scale now with the greatest ease, in the Silvertown works of the firm—thanks to the improvements which were the outcome of the investigations and engineering skill of Drs. W. S. Squire and R. Messel.

Specimens of sulphuryl-monochlorhydrin,

and of finely-crystallised 100 per cent. sulphuric anhydride, are exhibited; also a drum made of wrought-iron plate, for packing and carrying the anhydride, is to be seen underneath the show-case. The charging hole of the drum is secured by a kind of screw-stopper, fitting by an appliance known as the bayonet-joint—a simple but powerful means of closing.

Dr. Messel has kindly supplied the writer with some details which are of great interest both for chemist and physicist.

Kohlrausch (*Pogg. Ann. Ergänzungsband*, viii. p. 675) shows that the real hydrate,  $\text{SO}_4\text{H}_2$ , does not present the maximum density of sulphuric acid, as all the tables published had formerly stated, but that water cautiously dropped on the surface of really pure hydrate forms slowly-sinking drops. He found the

SPECIMENS.	PERCENTAGES OF $\text{SO}_3$	SPECIFIC GRAVITY.	REMARKS.

	82.0	1.957 " "	—

soluble compound of great flexibility; by dipping the sheets of it in a dilute acid or chloride of calcium, these are rendered insoluble, and form a tough membrane resembling gutta-percha, and a good electric insulator.

*Calcium Alginate.*—A dried block of this substance is exhibited to show its use for ornamental purposes. The sp. gr. is about 1.6, approaching that of ivory.

*Insoluble Algin*, or Alginic Acid, has a sp. gr. of 1.5, and closely resembles horn.

*Algie Cellulose.*—A block of this is shown on account of its value for turning purposes; the sp. gr. is about 1.4; higher than that of ebony or lignum vitae.

*Algie Boiler Fluid.*—(Already referred to.)

*Carbon Closet System.*—(See *Chemical News*, vol. xxix. 261 and 284.) A series of specimens is shown to illustrate the application of charcoal to this purpose. The method has been in use for many years in some of the largest shipyards on the Clyde, and has given great satisfaction.

*Sewage Filtration.*—The specimens shown are historical, having been first exhibited in the Paris Exhibition, 1867.

densities of concentrated acid at 18° C. (water at 4° C.=1) were:—

Percentage by weight of $\text{SO}_3\text{H}_2$ .	Specific gravity.
90 .....	1.8147
91 .....	1.8200
92 .....	1.8249
93 .....	1.8290
94 .....	1.8325
95 .....	1.8352
96 .....	1.8372
97 .....	1.8383
98 .....	1.8386
99 .....	1.8376
100 .....	1.8342

It will thus be seen in the above table that after exceeding the strength of 98 per cent. of  $\text{SO}_3\text{H}_2$ , the acid becomes lower in specific gravity as it further rises in strength to 100 per cent. of  $\text{SO}_3\text{H}_2$ . It has been found by Dr. Messel that an analogous law holds good with regard to solutions of sulphuric anhydride in monohydrated sulphuric acid ( $\text{SO}_3\text{H}_2$ ), and that whereas solutions of  $\text{SO}_3$  in  $\text{SO}_3\text{H}_2$ , as they increase in percentage of  $\text{SO}_3$ , likewise increase in specific gravity up to a certain point, after passing that

point and attaining a still higher percentage strength in the nearer approach to the condition of the pure anhydride itself, they do not now increase, but diminish in density.

Dr. Messel reserves to himself the right to pursue the investigation, and to repeat his experiments with more stringent scientific exactitude, using absolutely pure materials, so as to gain numbers, doubtless nearly, though perhaps not quite, identical with those hereinafter given.

It will be observed in the exhibit that the specimen cylinders are arranged in a special order, and this the table on previous page will explain, and at the same time the interesting development of a law analogous to Kohlrausch's, will manifest itself.

The 100 per cent. anhydride is crystallised in fine feathery needles. It has been stated that this mode of crystallising is caused by the presence of a trace of water ( $\text{SO}_3\text{H}_2$ ), without which it would crystallise like nitre. This, however, needs confirmation. It will be observed in the above table that we have a 30% liquid body, then 40 to 46% crystallised bodies; and at 60 to 69% we have again liquids, a crystalline stage being again and finally reached at 72.8% of  $\text{SO}_3$ .

**Sulphuryl-chlorohydrin,  $\text{SO}_2\text{Cl}(\text{OH})$ .**—Sulphuric anhydride used for sulphoning organic substances requiring strong treatment, would act too powerfully, and the sudden change of state from the anhydride in the liquefied or fused form to solid sulphonate, in addition to the result of the sudden chemical reaction, causes such a sudden and violent evolution of heat that a considerable portion of the substance is charred. It has been found that by using sulphuryl-chlorohydrin, this tendency to char is prevented, and thus larger yields of sulphonates are obtained, and, moreover, that by its use only one compound is formed, and no isomerides, which is usually not the case when anhydrides are used. The action taking place may be thus explained:—Sulphuryl-mono-chlorohydrin acts on an organic substance capable of yielding sulphonates in such a manner, that whilst sulphonate is formed, hydrochloric acid is simultaneously evolved, and the change of state from  $\text{SO}_2 < \begin{smallmatrix} \text{OH} \\ \text{Cl} \end{smallmatrix}$  to  $\text{SO}_3$  |  $\text{HCl}$ , means that the elements of  $\text{HCl}$  in a liquid substance suddenly unite to form a gas ( $\text{HCl}$ ), heat thus becoming latent. Thus, a large portion of the heat suddenly evolved by the reaction of the  $\text{SO}_3$ , on the substance sulphonated on the one hand, is simultaneously absorbed in the formation of gaseous hydrochloric acid on the other. This signifies, of course, a kind of cooling process which prevents charring, and so contributes to a larger yield of the sulphonic acid.

**Mode of Analysing Specimens of Sulphuric Anhydride.**—Two stoppered bottles, containing bulb tubes, with their extremities open and bent in opposite directions, are shown, and these refer to the method adopted by Dr. Messel as the safest and best for easily obtaining in aqueous solution weighed quantities of samples of anhydrides for analysis. A third bottle stoppered up, and containing water along with the sealed bulb of anhydride, illustrates the stage of the operation when a brisk shake is required to break the bulb, the  $\text{SO}_3$  going at once into solution in the water.

Fig. 1 represents the bulb tube with extremities bent in opposite directions. Fig. 2 shows the weighed bulb in position for filling itself to any given mark or point in the upper stem, from a bottle containing the anhydride specimen. The bent limb, projecting above the neck of the bottle, is then conveniently situated for closing with the blow-pipe flame. After closing in this manner, the bulb is withdrawn, whilst the extremity is still warm, and thus no anhydride

can be forced out at the opposite and previously submerged extremity, as the fingers will be cooler than the place touched in the withdrawal from the bottle. Having reversed the position of the extremities of the bulb, the other limb is in like manner closed with the blow-pipe flame, when after cleansing and wiping dry, the bulb is weighed again. It is next cautiously inserted in the bottle (Fig. 3), and gently induced to take the position indicated, some pure water being introduced about the level shown in the cut. The stopper

FIG. 1.

FIG. 2.

FIG. 3.

is then adjusted, and the bottle being taken in the hand is so held that the former is firmly kept in its place. One vigorous shake now suffices to break the bulb in the bottle, and in this there is no danger, only a sudden vibration being felt at the instant the anhydride comes in contact with the water. A white cloud is observed on the sides of the bottle, but by a few gentle shakes a perfect solution is obtained, and after allowing the bottle to cool, it may be opened and the analysis at once commenced. First  $\text{SO}_2$ , always present to some extent, is determined by titration with iodine solution, and then the  $\text{SO}_3$  after precipitation as barium sulphate, though as a rule volumetrically.

A. BOAKE & CO., LONDON (Group XIV. No. 1467).

This firm exhibits a complete collection of products connected with the sulphurous acid industry. Liquefied sulphurous anhydride is a speciality of the firm, and in the glass syphons arranged to deliver either the liquid or gaseous acid as desired, it forms a most convenient preparation for the use of the chemist or photographer. For use in ice-making, brewing, paper-making, disinfecting, bleaching, etc., liquefied sulphurous anhydride is also exhibited in copper drums, containing 1 and 2 cwt. respectively. A very complete set of sulphites is exhibited, many of these being but little known, and some entirely new. Amongst these sulphites the following specimens deserve special notice:—

Sodium sesqui-sulphite,  $\text{Na}_2(\text{SO}_3)_3 \cdot 9\text{H}_2\text{O}$ . Fine white needles.

Chromium sulphite,  $\text{Cr}_2\text{SO}_3$ . Beautiful transparent green crystalline mass.

Cuproso-cupric sulphite,  $\text{Cu}_2\text{SO}_3 \cdot \text{CuSO}_4 \cdot 2\text{H}_2\text{O}$ . Mass of glistening small needles, of a rich brown colour.

Ammonium sulphite,  $(\text{NH}_4)_2\text{SO}_3$ . White prisms.

Lithium sulphite.

Uranium sulphite,  $\text{U}_2\text{SO}_3$ . Beautiful orange yellow crystalline mass.

Nickel sulphite,  $\text{NiSO}_3 \cdot 6\text{Aq}$ . Fine green tetra-hedra.

A new salt, meta-sulphite of potassium, is exhibited in the form of fine large and sharply-defined crystals. It will probably find considerable application in the arts, seeing that it contains nearly 60 per cent. of  $\text{SO}_2$ , and is at the same time perfectly stable, neither oxidising nor evolving sulphur dioxide on exposure in the air. The ammonio-cuproso sulphite is a singular copper salt, being perfectly white, and crystallising in small white pyramids.

The sulphites at present of greatest industrial value are well represented by sodium sulphite, crystallised

and anhydrous; bisulphite of sodium, solid and in solution, sulphite and bisulphite of magnesium, and sulphite and bisulphite of calcium.

JAMES HARGREAVES, WIDNES (*Group XIV. No. 1467*).

HARGREAVES AND ROBINSON'S PATENT PROCESS FOR MANUFACTURING SULPHATES OF SODIUM AND POTASSIUM.

A model of the Hargreaves plant is shown, and it exhibits in a clear and instructive manner the arrangement of a piece of chemical apparatus, perhaps as difficult as any to explain the working of by means of plans or diagrams.

*The Process.*—Common salt mixed with ground rock salt is moulded into oblong cakes and placed in large iron cylinders 18 to 24 ft. in diameter and 12 ft. deep. Sulphur dioxide from burning pyrites, together with air and steam, is caused to pass downwards through the cylinders so charged, in succession, commencing with the strong gas on the most nearly finished sulphate, and is thus absorbed in its passage. At the same time, the common salt during its conversion is evolving hydrochloric acid, which is subsequently condensed and used for manufacturing bleaching powder.

The cylinders are encased in brickwork, and a small fire supplies the heat necessary to maintain the contents of the cylinders at a uniform working temperature. Theoretically, the heat set free during the process should be sufficient to maintain itself and keep the process going. In the best-designed and larger forms of plant, such as that of Messrs. Sullivan & Co., the British Alkali Works, Widnes, this is actually being done, so that once in working order practically no more fuel is required and the small fire-places are simply closed.

JAMES MACTEAR, GLASGOW (*Group XIV. No. 1467*).

Exhibits (1.) Working model of the Mactear carbonating or calcining furnace, with three large diagrams, giving different views of the furnace; (2.) Two large photographs of the mechanical salt-cake furnace; and (3.) Specimens illustrating the Mactear process for recovering sulphur from alkali waste drainage.

A very full description of the mechanical calcining and salt-cake furnaces will be found in this Journal, vol. i. 26 to 32.

#### MACTEAR PROCESS FOR RECOVERING SULPHUR FROM ALKALI WASTE DRAINAGE.

The drainage liquor, or, as it is termed, "yellow liquor," of the vat waste-heaps, else running into brooks and other water-courses, sewers or drains, and making the first unsightly and unwholesome, and the latter noxious, is treated with a solution of sulphurous acid. The sulphur dioxide obtained from pyrites or from the refuse sulphur of the process, is led into condensing towers built of wood, and bound with iron corner-pieces and tie-rods. Each tower is divided into three stages by means of strong cross-joists, and is then filled with cokes. A tray, with a large number of little tubes of lead covered over with lutes to avoid entrance of air, divides the water into fine streams, and the sulphurous acid gas is then led up one tower, down to the bottom, then up another tower, and so on in succession. The solution of sulphurous acid, in practice, has a specific gravity of only about 2° T. This solution is led, by means of a wooden shoot, to the decomposing vessels, and is mixed on its way with a stream of the yellow liquor; the liquid then runs into the decomposing vessel, where it is met by a stream of hydrochloric acid, and the whole is kept carefully at as near 145° F. as possible. With moderate care little sulphuretted hydrogen is

evolved, and the decomposition is regulated by the following method of testing:—A burette being fixed to a wooden upright and filled with the yellow liquor, a sample is drawn from the decomposing vessel, a drop of solution of ferrous sulphate is added, and then the yellow liquor run in from the burette. The number of divisions required to blacken the solution indicates the acid still present.

The sulphur is allowed to settle, and the clear liquor run off through a catch pit, so as to retain any sulphur that might be otherwise lost. After some five or six operations, the sulphur sludge is run off into a drainer. After draining into a stiffish mud, the latter is melted by steam in a suitable vessel, the arsenic being removed by an application of the fact that alkaline sulphides dissolve sulphide of arsenic.

#### DETAILED COST OF ONE TON OF SULPHUR BY THE "MACTEAR" PROCESS.

	CWT.	QR.	LB.	RATE.	COST.
Pyrites Sulphur .....	8	0	25	39/-	16'08s.
Salt .....	35	1	18	16/-	28'33
Vitriol .....	29	3	27	30/-	45'00
Coal .....	111	2	7	41/-	25'20
Repairs .....	..	..	..	..	4'00
Wages .....	..	..	..	..	38'50
					157'06
Off Sulphate of Soda ....	39	0	21	19/-	96'01
Net cost of one ton of Sulphur .....	..	..	..	..	61'05s.

In the above nothing is charged for hydrochloric acid.

When the "yellow liquors" are very weak, say of specific gravities 5° to 8° T., instead of 11° T., the sulphurous acid solution is replaced by a stronger liquor. This is obtained by preparing a solution of sulphite of calcium in sulphurous acid. The sulphite of calcium is obtained, in a crude form, from old alkali waste-heaps. The oxidised waste is ground with water to a milk, and this is treated with sulphurous acid. More hydrochloric acid is, of course, ultimately required in this latter process.

About 16,000 tons of sulphur have, so far, been made by the Mactear process, as Mr. Mactear informs the writer.

In the exhibit are shown specimens of the hydrochloric acid, of soda waste, and of the clear and perfectly innocuous liquor, free from sulphuretted hydrogen, which is finally run off. Also specimens of sulphur precipitate used for vine dressing, and of rock sulphur obtained by fusion. A bottle contains a mixture of sulphurous acid and "bog liquor," as the drainage liquor is termed at St. Rollox, just ready for decomposition, whilst a specimen in another bottle shows the sulphur as precipitated from the mixed liquid by hydrochloric acid.

LUDWIG MOND, LONDON (*Group XIV. No. 1467*)

#### RECOVERY OF SULPHUR FROM ALKALI WASTE.

There is not the least doubt that this process can be worked even at the present time to profit; in fact, the firm in which Mr. Mond's experiments were first carried out in this country, and for which he first erected plant, still continues the process, and not only utilises its own waste, but some of that from adjoining works. At the first, it was proposed in this process to treat the alkali waste left after lixiviating the black-ash, in the same vats, blowing in air under the false bottoms, so that it should ascend

through the superincumbent mass of waste. This did not seem to answer, and separate vats were afterwards constructed for blowing the waste, the latter being carried from the black-ash to the oxidising vats in tram waggons. Even with Mond's process, a final waste is obtained which does still contain sulphur as calcium sulphide to the extent of somewhat under one-fourth of the original total sulphur as sulphide; but, before getting this extracted, the manufacturer is confronted with two questions, the answers to which, in the ordinary course of working, conspire to give a flat negative to the attempt. The one is, What time would be expended in blowing and oxidising this last residual of sulphide so as to render the sulphur available? and, Would it be profitable, with plant and vat space at disposal, to sufficiently protract the oxidising operations, considering the vast bulk of the material dealt with generally, and specially with regard to this final residuum of sulphide? Dr. Schäppi has, however, shown in an able paper (see this Journal, vol. i. 482—486) that by blowing oftener, and by adopting other precautions, considerably more sulphur can be extracted than usually is, and that if the waste after repeated oxidation and lixiviation could be prevented from hardening, more sulphur still could be extracted. This is a difficulty that might possibly yet be overcome as the result of further investigation and experiments. The first patents were taken out in 1862 and 1863, and a small pamphlet now before the writer, and published by Mr. Mond in 1868, gives an interesting account of the theoretical and practical bearings of the process. Another pamphlet published by him in 1870, gives an interesting statistical view of the subject, "Of the Probable Effect of the General Adoption in Great Britain of Mond's Process for the Recovery of Sulphur from Alkali Waste from a Mercantile Point of View, being a Paper communicated to the River Pollution Commissioners at their request." At that time and previously, vat waste was carelessly tipped and packed in the waste-heaps, and gave vent to copious noxious emanations, both gaseous and liquid, and on the other hand, much hydrochloric acid was allowed to run away, especially weak acid from the wash-towers. If it will pay now to work Mond's process (and the writer was informed by the manager of one firm in Lancashire that the best profit of a recent year of his firm was made by sulphur recovery), it is hard to avoid the conviction that Mr. Mond was not far from the truth then, as to realisable actualities, when he stated that "the total cost of manufacturing 40,000 tons of sulphur being £80,000 a-year, a clear profit of £160,000 a-year would then have been obtainable." Mr. Mond's exhibit includes a coloured diagram of plant for lixiviating black-ash, and for the recovery of sulphur from the vat waste. Samples are shown (1) of fresh alkali waste; (2) of spent alkali waste, the residue of the Mond process; (3) of hydrochloric acid, the condensate of the salt-cake process. (4) The "yellow liquor," containing principally hydrosulphide, polysulphides, and thiosulphate of calcium; (5) precipitated sulphur liquor—i.e., after treatment in the agitator with hydrochloric acid. (6) Wet and freshly-precipitated sulphur. (7.) The fused and finished sulphur as put in the market.

MESSERS. GASKELL DEACON & Co., WIDNES (Group XIV. No. 1467).

The exhibits refer to (1) Deacon's chlorine process with Hurter's improvements, and (2) the manufacture of monohydrated carbonate of sodium, "crystal carbonate," and of bicarbonate of soda by Hurter and Carey's processes.

1. *Deacon's Chlorine Process.*—Excellent coloured diagrams are shown, illustrating a Deacon's chlorine cylinder (superheater and decomposer), with specimens of the baked clay balls saturated with cupric chloride, and a Deacon's shelf bleaching powder chamber, with a specimen of the bleaching powder produced from chlorine which has been generated from hydrochloric acid gas, dried by passing it through the heated cupreous clay balls contained in the Deacon cylinders. With this interesting process, the name of Dr. Ferdinand Hurter is intimately connected. To his admirable paper, "On the Prospects of the Manufacture of Chlorine" (this Journal, vol. ii. 103—109), those specially interested in a study of the question are referred.

2. *Manufacture of Monohydrated Carbonate and Bicarbonate of Soda.*—The investigations and experiments of Hurter have led to the possibility of obtaining in one process what would have previously required at least three to effect, and now in place of the so-called "black salts," as the impure monohydrated carbonate salts, obtained by the evaporation of the black-ash lixivates, are termed, Messrs. Hurter and Carey obtain directly, by evaporation, a pure white crystalline salt, of which Messrs. F. Steiner & Co., the great Turkey-red dyers of Lancashire, declare, "It is the purest form of sodium carbonate in the market," and that, "dissolving readily in water, with a slight evolution of heat, it has thereby an advantage over soda-crystals and soda-ash."

It is well known that the small quantities of iron in soda-ash are derived from cyanides formed in the black-ash process, the nitrogen of these being practically the nitrogen of the coal used in the black-ash mixture, and that on lixiviation in contact with the iron of the vats, ferrocyanides are formed. The monohydrate salts, eventually roasted for the production of soda-ash, retain mother-liquor containing these ferrocyanides, besides some sodium ferrosulphides, and these compounds on roasting decompose, leaving behind ferric oxide. By Hurter and Carey's process, the liquors are first well carbonated by black-ash furnace gases or otherwise. The sulphides in them are also, to a certain extent, oxidised to thiosulphates by the addition of oxidising agents. The silica and alumina in solution are precipitated in the carbonating process, and are separated by settling and subsequently running off the supernatant liquor. By forcing this liquor through a coil of pipe against a loaded valve, the coil being heated by a superheater, so that at least a temperature of 177° C. is attained, the ferrocyanides in presence of the thiosulphates are decomposed with formation of ferrous sulphide, which afterwards is easily separated by allowing the liquors to stand in large settlers. The clear liquors drawn off, on evaporation, yield the pure white "crystal carbonate." See Eng. Pats. 2939, July, 1879; and 608, February, 1880. (This Journal, vol. i. 26—27.)

Ordinary soda-ash roasted in brick furnaces, may contract minute quantities of alumina from the brickwork in addition to that derived from the black-ash mother-liquors, besides containing the small quantities of iron arising from the ferrocyanides, as already mentioned. When soda-ash is used by the dyer or calico-printer, the ash is usually dissolved by steaming in a pan, and is afterwards allowed to settle to deposit any insoluble matters containing iron and alumina, the clear supernatant liquor being eventually used. However, in some cases, the desired settling is not quite effectual, and either iron or alumina in but minute particles on the fibre may, in the case of certain light and bright shades, cause slight but objectionable modifications of colour to develop in

spots or patches. It is plain that the crystal carbonate containing absolutely no alumina or iron, is free from the defects named, and furnishes immediately a pure liquor likewise free from the least causticity, a desideratum with woollen bleachers. The following are analyses of "soda-crystals" and of "crystal carbonate":—

	Soda Crystals. %	Crystal Carbonate. %
Carbonate of soda.....	34.22	82.90
Hydrate of soda .....	0.10	0.00
Sulphate of soda .....	2.54	trace
Chloride of sodium .....	0.27	trace
Water .....	62.84	17.00
	99.97	99.90
Total soluble impurities (water excepted) on 100 of carbonate...	8.21	0.12
Water on 100 of Carbonate .....	183.64	20.50

**SOLUBILITY.**—*Soda-crystals* are soluble in cold water with difficulty, because—

1stly. Being in large lumps, they offer but little surface to the action of the water.

2ndly. By solution they lower the temperature of the water, 122 units of heat being absorbed.

*Crystal Carbonate* dissolves in cold water with the greatest ease, because—

1stly. Consisting of minute crystals, it offers immense surface to the action of the water.

2ndly. By solution it raises the temperature of the water, 35 units of heat being evolved.

One ton of crystal carbonate contains as much alkali as 48cwt. of soda-crystals.

**STORAGE.**—48cwt. of soda-crystals packed in 24 2-cwt. barrels, occupy about 150 cubic feet. One ton of crystal carbonate packed in casks, holding from three to four cwt. each, occupies about 65 cubic feet.

The *Bicarbonate of Soda* is prepared from the "crystal carbonate" by exposing the latter in an iron revolver, resembling closely a miniature black-ash revolving furnace, to the action of moist carbonic acid gas. Heat is evolved, and the cylinder becomes so hot that were a small quantity of bicarbonate of soda placed in contact with the metal outside, it would suffer slight decomposition. Nevertheless, the bicarbonate formed in the interior of the revolver is not decomposed in the slightest, because of the presence of the surrounding atmosphere of carbonic acid in which it is generated. It goes without saying that the employment of so pure a material as the "crystal carbonate," ensures the production of an extremely pure bicarbonate, and since no water escapes during the process, there is no loss of material carried off in solution, and so the process is one purely of conversion *in situ*.

JAMES MUSPRATT & SONS, WIDNES (*Group XIV.* No. 1467).

MUSPRATT & ESCHHELLMANN'S PATENTS FOR MAKING CHLORATE OF POTASSIUM AND CHLORATE OF SODIUM.

(Eng. Pats. 3960, Aug. 15, 1883 : 5183 and 5186, Oct. 31, 1883. *This Journal*, vol. iii. 349 and 445.)

In the patented process, magnesia is substituted for lime for the absorption of chlorine, and subsequent treatment of the liquors obtained, so as to increase the production of chlorate.

**Rationale of the Process.**—In the ordinary process a large quantity of chlorate of potassium is held in solution by the chloride of calcium of the mother-liquor.  $KClO_3$  is much less soluble in magnesium chloride solutions than in those of calcium chloride, and consequently much less chlorate is kept in solution by the magnesium chloride.

The usual proportion of chlorate to chlorides in the liquors obtained by the absorption of chlorine is 1 : 5 ; but by crystallising out nearly 50 per cent. of the magnesium chloride, before adding the  $KCl$ , the quantity of mother-liquor becomes considerably reduced. This, together with the less solubility of  $KClO_3$  in the magnesium chloride liquor, increases the production of chlorate in the new process by from 15 to 20 per cent.

The mother-liquor itself (magnesium chloride) is, after proper treatment, for which patents have also been obtained, a valuable by-product.

For the production of chlorate of sodium, the improved liquor containing chlorate and chloride of magnesium is used, in the proportion of about 1 : 3. This liquor is precipitated by carbonate of soda or caustic soda ; the filtrate, containing chlorate of sodium and chloride of sodium, is evaporated and the salt separated by fishing ; the remaining liquor crystallises, yielding a salt which, after a second crystallisation, is pure chlorate of sodium. The precipitated carbonate of magnesia can be sold as such, or calcined, and the magnesia used over again.

In the Exhibition a diagram is shown, displaying the apparatus used in Muspratt and Eschellmann's process for the manufacture of potassium and sodium chlorates, and, besides this, specimens illustrating the various stages of the processes, as follow :—

1. The improved liquor.
2. The octagon liquor.
3. The neutralised liquor.
4. The chlorate of potassium mother-liquor.
5. Ground potassium chloride.
6. Potassium chlorate. First crystals of the process.
7. Potassium chlorate. Finished crystals.
8. Calcined magnesite, ground.
9. Calcined magnesite (magnesia), unground.
10. Native magnesite in lumps.
11. Magnesium chloride in crystals.
12. Magnesium chloride in crystalline lumps.
13. Sodium chlorate. First crystals and greyish.
14. Sodium chlorate. Finished crystals, in size about that of small beans.

Looked beautifully white and pure.  
Look very white and pure.

Chlorate of sodium ( $NaClO_3$ ) is largely used for aniline black in calico printing, being far more easily soluble than potassium chlorate.

JOSEPH GAMBLE AND SONS, ST. HELENS (*Group XII.* No. 1467).

#### MANUFACTURE OF CHLORATE OF SODIUM.

Messrs. Gamble & Sons employ M. Pechiney's patented process. See *this Journal*, vol. i. 41.

Specimens are shown of—

1. Barium chlorate ( $Ba(ClO_3)_2 \cdot H_2O$ ) Small crystals.
2. " " in medium size crystals ; and
3. " " in large crystals.
4. Sodium chlorate, in fine, medium and large crystals.

There are exhibited, besides, remarkably fine crystals of sodium sulphide,  $Na_2S \cdot 9H_2O$ . These are large and transparent, with a faint brownish tinge, and resemble in appearance crystallised sodium acetate. This sodium sulphide is manufactured at Messrs. Gamble's Works, by Schaffner and Helbig's patent process

\*MR. W. WELDON, F.R.S., of BURSTOW (*Group XII*, No. 1467).

1. PROCESS FOR MANUFACTURING CHLORINE BY MANGANITE OF CALCIUM.
2. PROCESS FOR MANUFACTURING CHLORINE FROM CHLORIDE OF MAGNESIUM.

Mr. Walter Weldon, F.R.S., exhibits a model of the apparatus employed in the well-known process for the manufacture of chlorine which bears his name, and specimens illustrating the different steps in that process. In 1862, except in a single work, chlorine was universally manufactured by digesting together aqueous hydrochloric acid and ores of manganese; and the residual mixed solution of manganese chloride, ferric chloride, and free hydrochloric acid was always sent into the nearest water-course. The manganese employed in the manufacture of chlorine was thus used only once, and was then thrown away as one of the constituents of a most offensive solution, alike poisonous to fish, and extremely destructive to any masonry or ironwork with which the stream into which it was thrown might come into contact. The problem of how to avoid this loss of the most costly reagent employed in the chlorine manufacture, and at the same time to prevent the nuisance occasioned by that manufacture, had long engaged attention, and the late Mr. Dunlop, of Glasgow, had worked out a process accomplishing these objects, which process was in operation in one factory, that of St. Rollox. The Dunlop process, however, never extended beyond that one factory, and even there, so far as the regeneration of manganese for use again in the manufacture of chlorine is concerned, it is now replaced by the Weldon process, though it is still employed for the production of an artificial oxide of manganese for use by glass-makers and others. Mr. Weldon took up the problem of the regeneration of  $MnO_2$  from  $MnCl_2$  in 1866. Chlorine began to be manufactured by means of "Weldon mud" about 1870, and it is now years since an ounce of manganese ore was anywhere employed in the manufacture of chlorine, except to make up unavoidable mechanical loss in the Weldon process. There is no other instance of the old-established methods of a great chemical industry having been completely revolutionised within so brief a period. There are four works in this country and two on the Continent in which chlorine is manufactured by the Deacon process. In the four English works, the two-thirds or so of the HCl treated by the Deacon process, which escapes decomposition in that process, is subsequently treated by the Weldon process. In the two Continental works in question, that HCl is condensed into aqueous acid for sale, and those two works are the only chlorine works in the world in which the Weldon process is not employed.

The residual products of the manufacture of chlorine by the Weldon process is a mixed solution of manganese chloride and calcium chloride, containing also a little free hydrochloric acid. The latter having been neutralised by limestone, milk of lime is added to the neutralised liquor in such quantity that the product is a solution of calcium chloride holding in suspension manganese hydrate and calcium hydrate,

in the proportion of one equivalent of the former to six-tenths of an equivalent of the latter. Into this mixture, which is a thin white mud, air is then injected, until about 80 per cent. of the manganese present has become converted into  $MnO_2$ . The absorption of oxygen from the injected air takes place very rapidly; in large "oxidisers," as the vessels in which the operation is performed are called, more than a hundredweight of oxygen being absorbed per hour. The product is a thin black mud, in which four-tenths of the manganese present is in the state of  $MnMnO_3$ , and six-tenths of it in that of  $CaMnO_3$ , or a compound of  $MnO_2$  with  $CaO$ . It is upon the formation of this compound that the Weldon process depends. When manganese hydrate is treated by oxygen in the wet way, the  $MnO_2$  which forms must combine with a base at the moment of its formation. If the only base present be manganous hydrate, the  $MnO_2$  formed by the combination with oxygen of a portion of the hydrated  $MnO$  combines with the other portion of that  $MnO$ , forming either normal manganite of manganese,  $MnMnO_3$ , being a compound of one of  $MnO_2$  with one of  $MnO$ , or  $Mn_2O_4$ , being a compound of one of  $MnO_2$  with two of  $MnO$ , according to the temperature employed. Thus, when  $MnO$  is the only protoxide present, one-half is the maximum proportion of it which can be converted into  $MnO_2$ , the other half of the  $MnO$  being required to furnish the necessary base for that  $MnO_2$  to combine with. If, however, with the manganous hydrate which is treated by oxygen in the wet way any one of a certain number of soluble protoxides be present, the  $MnO_2$  which forms combines with that soluble protoxide instead of combining with  $MnO$ ; and thus, if the quantity of soluble protoxide present be a full equivalent, the whole of the manganese present may be converted into  $MnO_2$ . But to convert the whole of the manganous hydrate treated, into  $MnO_2$  combined with  $CaO$ , would of itself have no advantage to the manufacturer of chlorine, over the conversion of only half of it into  $MnO_3$ , the half of it converted into  $MnO_2$  being combined with the other half of it as  $MnMnO_3$ : since calcium manganate liberates from hydrochloric acid only the same proportion of its chlorine as is liberated therefrom by manganese manganite, as is seen from the two equations—

The advantage of forming calcium manganite instead of manganese manganite lies chiefly in this, that the absorption of oxygen by manganous hydrate, in the presence of dissolved lime, is enormously more rapid than the absorption of oxygen by manganous hydrate in the absence of a soluble base. To such an extent is this the case, that while, per given quantity of  $MnO_2$  in each respectively, Weldon mud is very much cheaper than native manganese, the product of the treatment by oxygen of manganese hydrate only, would be very much more costly than native manganese.

To convert into calcium manganite the whole of the manganous hydrate treated, would require the presence therewith of a full equivalent of calcium hydrate; but so large a proportion of calcium hydrate cannot be employed industrially, because there cannot be present sufficient calcium chloride to hold it in solution. Hence, only enough calcium hydrate is used to convert 0.6 of the manganese present into manganite of calcium. The other 0.4 of the manganese present is converted into manganite of manganese.

When 60 per cent. of the manganese present in a Weldon oxidiser has been converted into  $CaMnO_3$ , and the other 40 per cent. of it into  $MnMnO_3$ , a

\* The following account was forwarded to the writer of this report by Mr. Weldon two or three months ago. It is printed word for word as written in the manuscript, in accordance with a wish expressed in a letter received at the same time from Mr. Weldon. It is somewhat remarkable that this is the last contribution from his pen for this Journal, is the account of the great work of his life—written with characteristic care, and in that inimitable style peculiar to him whether writing or speaking, which rivets the attention alike of reader and hearer. It is very remarkable that it should be timed to appear in that number of this Journal which also contains the brief notice that his life's work is done.

further quantity of neutral solution of  $MnCl_2$  and  $CaCl_2$  is sent into the oxidiser, and the injection of air is continued. At the temperature employed  $MnCl_2$  can react upon half the line of normal calcium manganate, the products being manganous hydrate and a compound of two of  $MnO_2$  with one of  $CaO$ . The manganous hydrate becomes oxidised, partly into  $MnMnO_4$ , partly into  $Mn_2O_3$ , the final product being a thin black mud consisting of solution of calcium chloride holding in suspension a mixture of manganites of manganese with an acid manganite of calcium, which mixture can liberate more than two equivalents of chlorine from six of  $HCl$ . This product is then run into settlers, in which it separates into clear solution of calcium chloride and a denser mud. The former is then decanted, and the latter run into stone stills which have previously been charged with aqueous hydrochloric acid.

While this process has completely superseded the old method of manufacturing chlorine, and, as Dumas put it, has "cheapened every sheet of paper and every yard of calico used in the world," saving to the community hundreds of thousands of pounds per annum, besides enabling the manufacture of chlorine to be carried on without causing nuisance, and ameliorating the lot of the workmen engaged in that manufacture, who have now simply to manipulate a few cocks and valves, its inventor believes that it is about itself to be superseded. He exhibits also some illustrations of a process for the manufacture of chlorine, which is performed in the dry way, in which manganese is not employed, and which, while it is applicable to the manufacture of chlorine from the hydrochloric acid produced in the Leblanc process, may also prove capable of enabling chlorine to be manufactured in connection with the manufacture of soda by the ammonia process. At present the ammonium chloride of the ammonia-soda process is decomposed by lime, and the chlorine of the salt decomposed by that process is thus finally obtained as calcium chloride, and in that state is thrown away. In 1872 M. Solvay and Mr. Weldon simultaneously proposed to decompose that ammonium chloride by magnesia instead of by lime, and to treat the resulting magnesium chloride for the obtaining of its chlorine as hydrochloric acid. \* Neither Mr. Solvay nor Mr. Weldon, however, succeeded in rendering the decomposition of  $NH_4Cl$  by  $MgO$  industrially practicable; and it is only quite recently that it has been rendered so by MM. Techéne & Co., Salindres. Moreover, the manipulation of large quantities of magnesium chloride was found to present great difficulties, which for many years seemed insuperable. Mr. Weldon's continuous experiments on the subject at length led him to the idea of converting the magnesium chloride into solid infusible oxychloride, before attempting to drive off its chlorine as  $HCl$ ; and it was then found that the oxychloride were heated in a current of air, a large part of its chlorine was evolved in the free state. Mr. Weldon failed to devise apparatus in which this operation could be conducted industrially, but suitable apparatus for it has now been invented by M. Techéne, in conjunction with the engineer of Salindres, M. Boudryard. As this apparatus is not exhibited, it need not be here described.

The starting point of the new Weldon chlorine process is magnesium chloride, which may be obtained either by neutralising aqueous hydrochloric acid by

magnesia, or by decomposing by magnesia the ammonium chloride of the ammonia-soda process, or may be magnesium chloride from any other source. To a hot saturated solution of it free magnesia is added, and there is thus obtained a solid hydrated oxychloride, containing six equivalents of water. This is heated to a low temperature, until a large part of its water has been driven off. The residue is then heated to a high temperature in a current of air, when half its chlorine goes off in the free state, and half as vapour of  $HCl$ , magnesia only remaining behind. The proportion of the chlorine of the oxychloride which goes off in the free state is thus 50 per cent, greater than the proportion of free chlorine obtained by the old Weldon process from an equivalent quantity of hydrochloric acid, and that part of it which does not go off in the free state, instead of being lost as  $CaCl_2$ , is yielded as  $HCl$ , available either as raw material from which to manufacture more chlorine, or for use for any other purpose. The development of this process will be watched with great interest, since its success, by enabling the chlorine of the salt used in the manufacture of ammonia soda to be obtained in the free state, would take away from the Leblanc process its only remaining support.

MESSRS. BRUNNER, MOND & CO., LIMITED (Group XIV. No. 1467).

THE AMMONIA-SODA PROCESS (SOLVAY AND MOND).

This firm exhibits a large photo-lithographed picture of the Winnington Works, near Northwich.

Moreover, specimens are shown illustrating the different steps in the ammonia-soda process—viz:—

- (1.) The natural brine.
- (2.) Ammoniacal brine before carbonating under pressure.
- (3.) Carbonated ammoniacal brine.
- (4.) Crude bicarbonate of soda.
- (5.) Sessquicarbonate of soda.
- (6.) Refined bicarbonate of soda (Mond and Jarmay's process. Eng. Pat. 2296, February 9, 1884. This Journal, iv. 282).
- (7.) Monocarbonate of soda.
- (8.) Pure alkali (unground).
- (9.) Pure alkali (ground).

Messrs. Brunner, Mond & Co.'s Works were established in 1873, and are now producing 7000 tons of carbonate of soda per month. The extension of the works now in progress will raise their producing power to 10,000 tons per month.

The patents of Mr. Ernest Solvay, of Brussels, are being worked by this firm, together with various improvements patented by Mr. Ludwig Mond.

Although the chemistry of the ammonia-soda process was fully described in a patent taken out in England in 1838 † by Messrs. Dnyar and Henning, and although several practical manufacturers of the highest standing, amongst others, James Muspratt, James Young, William Gossage, and Henry Deacon, had devoted time, energy, and capital to its realisation, it was considered incapable to compete with its rival the Leblanc process, until Mr. Ernest Solvay made it an industrial success, by the apparatus which he invented, and the indomitable energy and perseverance with which he worked out the details of the process. Mr. E. Solvay is therefore justly considered the founder of the ammonia-soda industry.

Mr. Ludwig Mond took a license from Mr. Solvay in 1872, which was subsequently transferred to Messrs. Brunner, Mond & Co. At that time the works which Mr. Solvay had established at Conillet,

\* In that last letter received by the writer from Mr. Weldon, and accompanying this communication, he states:—"Except that I could not but take the opportunity of making some explanations of some points in respect of the old Weldon process which are frequently misunderstood, the only part of the enclosed which I really care about is that part of it which gives to M. Techéne and M. Boudryard the credit due to them in respect of the new chlorine process."

† "The Manufacture of Carbonate of Soda," Harrison Grey Dnyar and John Henning. Eng. Pat. 7713, June 30, 1838.

in Belgium, produced about ten tons of carbonate of soda per diem in two separate sheds. Under Mr. Solvay's guidance Mr. Mond designed plans for carrying out Mr. Solvay's process on a larger scale, according to which works were erected in Winnington in 1873. These works proved capable of producing 20 tons per diem, per element of plant. They were started early in 1874, and were the first works in which carbonate of soda was manufactured from natural brine.

When in 1881 it was decided considerably to extend the works at Winnington, Mr. Mond designed plant upon a much larger scale. Some of the apparatus used was increased in size, but a great part of the plant was constructed according to Mr. Mond's own patents, and entirely different from that hitherto in use.

Each element of this plant produces 60 tons of carbonate of soda per diem, and thus effects a great saving in labour, repairs, and first cost, as compared with the older plant.

Messrs. Brunner, Mond & Co. also exhibit refined bicarbonate, made by Mond and Jarmay's process.

The bicarbonate made by the ammonia-soda process contains a certain quantity of ammonia which cannot be got rid of by washing, and makes the product unsuitable for the market. Messrs. Mond and Jarmay dissolve this bicarbonate in warm water and pass the clarified solution in a constant stream through a series of cooling tanks. In these a pure bicarbonate of soda is deposited in small crystals. These are from time to time removed, passed through a hydro-extractor, then dried and dressed as usual.

All the ammonia remains in the mother liquor, which is used many times over, and is then treated for the recovery of the ammonia.

MESSRS. BELL BROS., LIMITED, MIDDLESBROUGH  
(Group XIV. No. 1467).

#### THE AMMONIA-SODA PROCESS (SCHLOSING).

The patents worked by Messrs. Bell Bros. were taken out by Sidney Pitt (communications from J. J. T. Schlosing) on May 28, 1878, and May 4, 1882, entitled, "Improvements in the Manufacture of Carbonate of Soda by the Ammonia Process," and numbered respectively 2130 and 2110.

The essential difference between Solvay's and Schlosing's processes is that in the former, ammonia and brine are treated together with carbonic acid under pressure; whilst in the latter ammonia is carbonated as *one separate step* of the entire process, and the small crystals of bicarbonate of ammonia precipitating are used in a *second step* to mix with brine in an agitating vessel, so as to yield bicarbonate of soda.

Messrs. Bell Bros., Limited, exhibit the following specimens:—

(1.) The bicarbonate of ammonia representing the first step of the process.

(2.) The bicarbonate of soda produced by mixing the ammoniacal salt with brine, and

(3.) The finished product.

Messrs. Bell Bros. have only somewhat recently started, and they are now manufacturing about 200 tons of alkali per month.

For a full account of the origin of the ammonia-soda process, see Mr. Mond's interesting paper commencing on this page.

THE EGLINTON CHEMICAL CO., LIMITED, GLASGOW  
(Group XIV. No. 1441).

The manufactures of this firm are represented by the following exhibits:—

(1.) *Chromate Leather*, tanned with bichromate of potash, etc.; produced in one-fifth the time of ordinary tanned leather, and at less than half the

cost. It is said to be much more durable than ordinary leather, and thoroughly waterproof. Suitable for all purposes of the ordinary article, and particularly for use in the army and navy, for shooting, fishing, and football boots, hydraulic and pump leather, and for builing purposes.

(2.) *Patent Bichromate of Soda*, as a substitute for bichromate of potash, containing as much chromic acid as bichromate of potash, and salable at about £10 per ton under the price of bichromate of potash. Samples of chromate and bichromate of lime and of alumina are also exhibited.

(3.) *Silica Bricks*, made from pure flint. Practically free from iron; more refractory and less expensive under intense heat than Welsh Dinas bricks, or any other form of silica brick. Specially suited for lining steel and iron heating furnaces, arches of gas retorts, etc., etc.

(To be continued.)

## Communication.

### ON THE ORIGIN OF THE AMMONIA-SODA PROCESS.

BY LUDWIG MOND.

ALL writers on this subject from Brande in 1841\* to Lunge† in 1880, fix the date of this invention at the 30th of June, 1828, when Messrs. Harrison Grey Dyar and John Hemming, both chemists of London, filed the petition for their English patent. Only of recent years an attempt has been made by several French savants‡ to put the date of the invention sixteen years later, in order to claim it as a French invention and to give the credit of it to two of their countrymen, Messrs. Schlosing and Rolland, who took out a patent relating to the subject in 1858, preceded by a patent taken out by Mr. Schlosing alone in 1854.

It would seem superfluous to contradict an error so palpable and so easily refuted by reference to documents accessible to everyone, had not this statement been made by three scientific men of the highest standing, whose name is sufficient to obtain acceptance for it by numbers who have not themselves inquired into the facts.

In justice to Messrs. Schlosing and Rolland, I must state that these gentlemen in their various publications have fully acknowledged that the process they endeavoured to improve had been invented long ago, and that the various chemical operations constituting the process had been described so exactly in a patent taken out in France by Delaunay as to leave to future inventors very little to do.

On referring to Delaunay's patent, dated 27th of May, 1829, this will be found an exact translation of the English specification of Messrs. Dyar and Hemming, of October, 1828, whence it is clear that Delaunay was simply the agent of Messrs. Dyar and Hemming. Inquiring further into this French specification we come, however, upon a remarkable and important fact which has hitherto been left unnoticed. This patent is followed on the 18th of May, 1840, by an additional patent, a facility enjoyed under the French patent law almost free of expense, which has evidently in this instance led the inventors to protect in France most important improvements found out shortly after taking out their original patent, while the high cost of a second English patent has prevented their doing the same in England.

\* Brande: *Manual of Chemistry*, 5th edition, pp. 661.

† Lunge: *Manufacture of Sulphuric Acid and Alkali*, viii. p. 1.

‡ Fremy: *Presidential Address to the French Association for the Advancement of Science*, 1878. Bouley, *Président de l'Académie des Sciences*, *Comptes Rendus*, T.C. No. 11. Scheurer-Kestner: *Conférence à la Société d'Encouragement sur Nicolas Leblanc*, 28 Mars, 1885.

As is well known, the original process of Messrs. Dyar and Hemming consisted in mixing a solution of common salt with solid carbonate of ammonia, separating the bicarbonate of soda formed from the residual liquor, boiling this liquor to dryness, and heating the dry product with chalk in order to recover the carbonate of ammonia employed. It is evident that this series of operations would involve so serious a loss of ammonia as to make the economical application of the process impossible, and if Messrs. Dyar and Hemming had left their process in this very incomplete form, their claim to be considered the inventors of the process now known as the Ammonia-soda Process might well be called in question. The additional French patent referred to above, however, puts the matter in an entirely different light. I give an exact translation of their specification:—

18th May, 1840. *Additional Patents for Improvements.* The operations can be reduced to the following:

*Preparations of the Carbonate of Soda.*

1st. To a concentrated solution of chloride of sodium is added an equivalent quantity of sesquicarbonate of ammonia in order to decompose it.

2nd. A current of carbonic acid gas is passed through the mixture to saturate the ammonia, and to make the decomposition as perfect as possible.

3rd. After a sufficient time the saline deposit is collected on filters.

4th. The deposit is drained and washed either with water or with a concentrated solution of bicarbonate of soda.

5th. The saline deposit is submitted to pressing, or put immediately in a reverberatory furnace or in a retort to drive off the water, the excess of carbonic acid, and the ammoniacal salts which it may contain.

*Extraction of the Ammonia from the Residues of the Operation.*

1st. The liquid collected in the third operation contains ammoniacal salts; it is run into a distilling vessel.

2nd. To this liquid is added a sufficient quantity of lime to decompose the entire quantity of the ammoniacal salts, heat is applied and thus ammoniacal gas is obtained.

The ammonia gas can be employed in several different ways.

It can be simply dissolved in water.

It can be passed into a concentrated solution of chloride of sodium.

When the gas has been dissolved in water chloride of sodium is added in sufficient quantity relative to the alkalimetric value of the liquor, and then a current of carbonic acid gas is passed through to effect the decomposition of the chloride of sodium.

If the ammonia gas is added to the solution of chloride of sodium, one can at the same time or successively pass a current of carbonic gas through it.

The order of the preceding operations shows that the sesquicarbonate of ammonia is employed only once, and that after it has been decomposed, the ammonia it contains is continually used over.

In all cases, and whatever be the mode of proceeding, the chloride of sodium is decomposed under the influence of ammonia and carbonic acid.

In this operation the ammonia must be considered as an intermediate agent which takes hold of the carbonic acid to give it off again to the chloride of sodium, which it can then decompose, and produce carbonate of soda through the intervention of the elements of water.

The ammonia plays here a part similar to that of the binoxide of nitrogen in the preparation of sulphuric acid, and to that of the acetate of lead in the manufacture of white lead by the process of Thénard.

In order to make this process economical, the principal object should be the preservation of the ammonia, the employment of which ought to be continued till it is, so to say, used up.

As to the carbonic acid likewise employed in this process, it can be produced economically by the combustion of coal, or by the calcination of limestone as practised in other manufactures.

Here we have described in detail all the operations as they are this day carried out in the manufacture of the immense quantities of ammonia-soda now produced, and we may well agree with Messrs. Schloesing and Rolland that, as far as the chemistry of the ammonia-soda process is concerned, Messrs. Dyar and Hemming left very little to do to future inventors. Still there is the fact that from 1840, when the chemistry of the process was fully developed, until 1865, this remarkably simple and beautiful process found no application, although many very eminent engineers, chemists, and manufacturers spent years of their time and large sums of money in endeavouring to realise it on an industrial scale. All these attempts, including the one made by Messrs. Schloesing and Rolland between 1855 and 1858, ended in failure. If it could be shown that these gentlemen, by the apparatus they have patented, or by the experiments they have made to work the process on a large scale, had advanced the ultimate success of the process, they would, although not being the inventors of the process, deserve great credit, and no objection could be raised to the award of the diploma of honour which they have obtained at the Vienna International Exhibition. A close examination of the facts unfortunately does not show that they have in this direction done more than their predecessors and contemporaries.

The fact that bicarbonate of soda is formed by mixing carbonate of ammonia with a strong solution of salt has been known, although it was never published, long before the date of Messrs. Dyar and Hemming's patent. A. Vogel\* tells us that he found this fact mentioned in his father's note-book as far back as 1822. Dr. Angus Smith has told me that his friend Mr. John Thom has shown him this reaction, performing it in the palm of his hand, several years before 1838. I owe to Mr. Watson Smith fuller particulars of Mr. Thom's early work in connection with this subject, contained in several letters from Mr. Thom himself, which are corroborated by a letter from Mr. William Henderson, of Glasgow. These letters leave no doubt that Mr. Thom actually manufactured soda by the action of carbonate of ammonia upon salt in 1836 at the works of Messrs. Turnbull & Ramsay at Camlachie, where he was employed as chemist. Mr. Thom mixed the two salts intimately with a small quantity of water, and put the resulting magma in bags into a press in order to separate the liquid from the bicarbonate formed. The bicarbonate was used for making soda-crystals, of which about two hundred-weights per day were produced. The liquid was evaporated, mixed with chalk, and heated in iron retorts to recover carbonate of ammonia. After working the process for about a year, Mr. Thom left the works at Camlachie, and did not follow up the subject any further. Here we have in all probability the first attempt to turn the reaction between salt and carbonate of ammonia to practical use. But the operations were still so crude, the separation of the bicarbonate of soda from the chloride of ammonium so unsatisfactory, the reaction between salt and sesquicarbonate of ammonia without the aid of carbonic acid so imperfect, and the process used for recovering the carbonate of ammonia so impracticable, that how ever highly we may think of Mr. Thom's merits as the discoverer of the principal reaction, and as the first who attempted to manufacture soda by its aid,

yet he cannot be considered to have invented a chemical process industrially applicable for this purpose. The merit of having invented the series of reactions now forming the ammonia-soda process remains thus undiminished with Messrs. Dyar and Hemming, who, as far as can be inferred from Mr. Thom's letters, have worked quite independently of him and without knowledge of what he had been doing.

According to information, for which I am indebted to Mr. Richard Muspratt, Messrs. Dyar and Hemming built a small works to demonstrate their process in Whitechapel very shortly after taking out their patent. These works were regularly visited by Dr. Sheridan Muspratt and Mr. James Young of paraffin celebrity, then assistant to Professor Graham in London, in order to study the process. Shortly afterwards, probably in 1840, Mr. James Muspratt engaged Mr. Young to erect plant for the process on a considerable scale, at his large chemical works at Newton. This plant was worked under Mr. Young's direction for about two years, when the process was given up because it was found more expensive than the Le Blanc process, principally on account of the heavy loss of ammonia. Mr. Carrol, at the time foreman of the works at Newton, has told me that about £8000 were spent in this experiment.

It is well known that various other attempts to work the process were made about this time on the Continent, amongst others, by Kunheim in Berlin, and Seybel in Vienna. A few years later a small plant was erected near Leeds by Mr. Bowker, and kept at work for several years, the product being regularly sold in the district, but this also was subsequently abandoned. The first attempt to construct a more perfect plant for carrying out the process was made by Mr. William Gossage (patent of 21st February, 1854). In the same year, and following each other in close succession, patents were taken out by Turck (26th May), Schloesing (21st June), Henry Deacon (through his agent, Henry Johnson, 8th July). I am informed by Mr. Holbrook Gaskell, who entered into partnership with Mr. Deacon in 1854, that Mr. Deacon leased land for the purpose of erecting ammonia-soda works in 1853, and that in the following year he was already engaged in the manufacture of ammonia-soda, which he carried on for about two years at the rate of several tons per day. After a sum of from five to six thousand pounds had been expended upon it, the firm decided to abandon the ammonia-soda process, and commenced the erection of the large Le Blanc Soda Works, which have since become so well known, and which have proved such a fruitful field for the display of Mr. Deacon's great powers as a manufacturer and as an inventor.

Judging from Mr. Deacon's patent, and from what he has told me himself many years ago, the plant which he used for making ammonia-soda was very similar to that described by Messrs. Schloesing and Rolland in their patent of 1858, except that Mr. Deacon went a considerable step further than these gentlemen by using carbonic acid under pressure. He used horizontal cylinders with agitators for absorbing the carbonic acid, and a still of the Coffey type for recovering the ammonia.

Messrs. Schloesing and Rolland commenced in 1855 to erect works at Puteaux, near Paris, which were kept going for two years, and during this time produced 316 tons of soda—86 tons during the first 14 months, and 230 tons during the last ten. At the end of the two years the experiment was given up, like all the preceding ones had been, although the soda manufactured was sold at a price varying from 65 to 75 francs per 100 kilogrammes, equal to £26 to

£30 per ton, or about five times its present value. Messrs. Schloesing and Rolland assert, in a very lengthy paper published in 1868 (*Ann. de Chimie und Physique*, T. xiv.), and this assertion has been repeated by various writers, that their want of success has been due, not to the insufficiency of their apparatus, but solely to the high tax levied on salt at the time in France. They state that they had to use 180 kilogrammes of salt per 100 kilogrammes of soda, where the Le Blanc makers used 150 kilogrammes, and that the tax they had to pay on this extra quantity of salt made competition impossible. This duty amounted to 10 francs per 100 kilogrammes of salt. Messrs. Schloesing and Rolland would thus have to pay 3 francs per 100 kilogrammes of soda more than their competitors, an amount very much below the difference in cost of production between the two processes at the present time. The total tax they had to pay on salt would have amounted to 18 francs per 100 kilogrammes of soda manufactured. The selling price of soda at the time being 65 to 70 francs per 100 kilogrammes, Messrs. Schloesing and Rolland ought to have realised enormous profits in spite of the tax if they had at all understood the manufacture. The selling price to-day is below 18 francs per 100 kilogrammes, and this leaves a very handsome profit. Moreover, it would have been easy to reduce the quantity of salt consumed per ton of soda in the ammonia-soda process to a less quantity than is used in the Le Blanc process, by recovering the undecomposed salt from the residual liquor of the distillation. We can, therefore, not accept the assertion that but for the salt duties Messrs. Schloesing and Rolland could have manufactured at a profit; their own figures prove plainly that their experiment was no more successful than their predecessors; that it was not carried out on any larger scale, nor persevered with for a longer period of time.

After 1858 no further serious attempts were made to overcome the engineering difficulties of the ammonia-soda process, until Mr. Ernest Solvay undertook this task in 1863. It is now a matter of history how completely Mr. Solvay succeeded, after five years of incessant work, under trying circumstances, in inventing and working out new apparatus for carrying out on a large scale all the various operations of Messrs. Dyar and Hemming's beautiful but hitherto barren invention; how quickly the ammonia-soda manufacture has developed in his hands, and what enormous proportions it has attained in a comparatively short time. While recognising Messrs. Dyar and Hemming as the inventors of the chemical operations which constitute the ammonia-soda process, we have to give to Mr. Solvay the honour of being the inventor of the apparatus, which alone has made this process of value to the public, and of having thus become the founder of the ammonia-soda industry.

## Journal and Patent Literature.

### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

*Improved Process and Apparatus for Purifying Water used in Steam Boilers.* D. Clerk, Glasgow. Eng. Pat. 10,515, July 31, 1884.

THE water of the boiler is made to circulate, by means of pipes and a steam pump, through a filter, and is redelivered at the upper part free from the solid matters which separate from it during evaporation. The feed water is also caused to pass through the same filter.

—C. C. H.

*Improvements in and Apparatus for the Production of a Vacuum in the Evaporation or Refrigeration of Liquids.* G. Hambrach, Berlin. Eng. Pat. 11,483, August 21, 1884.

To produce a vacuum more quickly and efficiently than by means of ordinary pumps, under such circumstances as the evaporation of liquids under reduced pressure, it is proposed to use an aspirator, or liquid jet pump resembling a "Körting's aspirator," worked by a liquid such as sulphuric acid, caustic soda, etc., which readily absorbs aqueous vapour. The best results are obtained

by aspirators delivering the liquid in flat sheets or annular jets. In the annexed illustration A is the aspirator, a is the pipe from the vessel to be exhausted, B the reservoir for supplying the liquid under pressure, and P the pump for returning the liquid to B. The absorbing liquid becomes diluted and must be changed at intervals.

—C. C. H.

*Improved Apparatus for obtaining Fresh Water from Salt Water.* J. Weir, Glasgow. Eng. Pat. 11,863, September 2, 1884.

THE apparatus consists of three vessels placed in series, and intended to be worked in conjunction with the engines and boilers of a steam-ship. The vessels are upright cylinders, provided with a tight cover, and a worm in the interior. The first vessel communicates with the worm of the second, and the worm of the third is a continuation of that of the second. The first of the series is filled with sea-water, steam is admitted to the worm from the boiler, or the exhaust of the main engines, and the vapour thus generated is condensed in the worm of the second vessel, and, passing over into the worm in the third, is cooled by a current of cold sea-water. The condensed water from the steam admitted into the coil in the first is returned to the hot well of the engines. The second vessel communicates with the condenser of the main engines, so that the vapour given off is condensed and returned to the boilers to make up for the loss due to waste in the whole system.

—C. C. H.

*Improvements in the Manufacture of Asbestos Membranes for Filtering Purposes.* O. Imray, London. From F. Breyer, Vienna. Eng. Pat. 5864, May 12, 1885.

THIS invention relates to the manufacture of thin layers of asbestos felt suitable for filtering purposes. Only those asbestos fibres are suitable which, when ground, give a woolly product, and not a powdery one. After reduction to this state, by a mill or edge-runner, the product is chopped so fine that the fibres do not exceed 0.2 inch in length. It is then mixed with crystalline carbonate of lime, or magnesia, the granules of which do not exceed 0.2 inch in size, and ground with water so as to effect a further reduction. The semi-fluid resulting is then treated with an acid to remove the carbonates. After washing, to remove the excess of acid, the emulsion is ready to be filtered. This is best carried on by depositing successively even layers upon a woven fabric stretched on a frame. When a felt of sufficient thickness has been obtained, the fabric to which it adheres is dried in a kiln, and the whole is then ready for use.—C. C. H.

*Improvement in Filter Presses.* O. Imray, London. From H. B. Scott, Calais. Eng. Pat. 5903, May 13, 1885.

THE improvement described consists in forming the plates of a filter-press of flat sheets of wrought-iron, the plates being covered with cocoa-nut matting, to form a soft bedding and a drainage surface. The filtering cloth is fixed on the plates in the usual manner. The chambers are formed by the interposition of distance frames between the flat plates.—C. C. H.

*Improvements in Concentrating Aqueous Solutions, etc., and Apparatus therefor.* W. P. Thompson, Liverpool. From A. Büttner and C. Meyer, Merdigen. Eng. Pat. 6065, May 18, 1885.

THE concentration of liquids is to be effected by direct contact with the products of combustion, generator gases, etc., without subjecting the concentrated material to burning. The gases are first deprived of ashes and soot by passage through a V-shaped chamber, the solid matter being thrown down into a pocket by a curtain wall. The hearth of the evaporating furnace is divided by cross walls into compartments, into which the concentrated materials successively flow. In each of the compartments there is one or more gratings suspended, with the bars vertical and provided with cams and rods for alternately lifting them out of and lowering them into the liquid. The bars are toothed or serrated so that they pick up more liquid. The current of hot air is passed over the liquid, and hence through the gratings and the liquid raised by them, and the heat is uniformly conveyed through the body of the liquid. The solid matter from the end of the hearth is conveyed by a creeper into U-shaped vessels, through which currents of hot air are passed, rakes and scrapers at the same time keeping the semi-solid matter from baling. The passage of the matter is so arranged that dry matter is discharged from the end trough of the series.—C. C. H.

*Apparatus for making Fresh Water from Salt Water.* A. Chapman, Liverpool. Eng. Pat. 11,461, August 20, 1884.

REFER to Branch XVII. (B) of the present number of this Journal.

## II.—FUEL, GAS, AND LIGHT.

*Improvements in the Manufacture of Illuminating Gas from Hydrocarbon and other Oils, and in Apparatus therefor.* A. J. Bonlt, London. From J. Hanlon, New York. Eng. Pat. 802, January 20, 1885.

THE operation of the apparatus, for the construction of which the patent must be consulted, is as follows:—Heating gas is generated in a producer, partially

burned in a retort chamber, and passed on to one of the fixing chambers, where a further air supply completes its combustion. When all is heated to the proper temperature, the gate valves are reversed, turning the heating gas into the other fixing chamber and opening the connection between the retorts and the now heated fixing chamber. Oil is admitted to the one and superheated steam to the other compartment of each retort. The steam passing downwards through the heated charcoal is decomposed, and, passing through the aperture in the partition, assists in the vaporisation of the oil, the hydrogen acting as a carrier for the rich, heavy hydrocarbon vapours, which would otherwise probably condense in the connections. The mixed gases pass onward to the fixing chamber, whence they emerge as a homogeneous illuminating gas of high candle-power.—A. R. D.

*Improvements in the Construction of Coke-Ovens.* A. F. Link, London. From T. Bauer, Munich. Eng. Pat. 11,040, May 7, 1885.

THIS specification describes a coke-oven system claiming economy of space, building material, and working expenses, with a superior quality of coke. See this Journal, vol. iv. 485 and 486.—A. R. D.

*An Improvement in Coke-Ovens.* Henry Simon, of Weissbad, Apenzell, Switzerland. Eng. Pat. 12,340, June 2, 1885.

THIS invention is a modification of that described in Specification 554, of 1883 (this Journal, vol. iii. 507). Therein it is shown how the products of combustion on their way to the chimney are employed to heat the air or combustible gas required for the working of the ovens. This is done by causing the latter to traverse flues adjacent to those in which the former are passing away, forming what is known as a recuperator. In this way the air was frequently rendered hotter than was necessary, and, therefore, according to the present invention, cross-flues or channels, having openings provided with valves and dampers, are constructed at various points in the length of the longitudinal recuperator flues, so that the cold air can be admitted at these different points and be made to take up more or less heat according to the length they have to traverse on their way to the combustion chamber.

—A. R. D.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

*Coal-Tar Crescote.* Dr. Tidy. Analyst, 10, 115.

THE author suggests the following as an amendment to the late Dr. Voelcker's specification for coal-tar crescote.

1. The crescote to be completely liquid at a temperature of 100° F., no deposit afterwards taking place until the oil registers a temperature of 95° F. 2. Crescote to contain at least twenty-five per cent. of constituents which do not distil over at a temperature of 600° F. 3. That, tested by the process afterwards described, the crescote shall yield a total of eight per cent. of tar-acids. 4. There shall be no admixture of bone-oil, shale-oil, or other substance not obtained by the distillation of coal-tar, and the first twenty-five per cent. of the distillate shall have a specific gravity greater than that of water. *Process for determining the coal-tar acids.*—1. 100cc. of the well-mixed crescote to be distilled at 600° F. until no further distillate comes over. Distillate to be mixed and well shaken in a stoppered flask, with 30cc. of caustic-soda solution (sp. gr. 1.200). Mixture then to be heated, and afterwards again shaken vigorously. The contents of the flask are now to be placed in a separating funnel, and the soda solution is drawn off. The crescote is to be heated a second and a third time in a similar manner with caustic-soda solution, only 20cc. of soda solution being used, instead of 30cc., as in the first extraction. 2. The three soda solutions are now to be

mixed together. When cold, any particles of crescote are to be got rid of by means of a separating funnel. The solution is now to be thoroughly boiled, in order to expel the last traces of crescote present in the solution. The mixture is then to be allowed to cool. When cold, about 35cc. of sulphuric acid (one of acid to three of water) is added, until the solution becomes slightly acid to litmus. The whole is then transferred to a separating funnel, and allowed to stand until quite cold. The tar-acids are now to be dissolved in 20cc. of the caustic-soda solution and 10cc. of water, and the mixture is boiled and filtered through asbestos. The latter is to be washed with not more than 5cc. of boiling water. The solution is allowed to cool perfectly in a 100cc. measure; it is then slightly acidified with sulphuric acid (one to three), and again allowed to stand for two hours, until perfectly cold, when the percentage of the tar-acids (by volume) is to be read off. *Process to be adopted in estimating the quantity of distillate.*—The operation is to be conducted in a retort fitted with a thermometer, and heated with the naked flame of a Bunsen burner. The heat is gradually to be raised to 600° F., and continued at that temperature until no further matters distil over. The distillation of the 100cc. should be completed within an hour.—E. G. C.

*An Improved Method of and Apparatus for Extracting Tar and Ammonia from the Gases of Blast Furnaces.* J. Dempster, Newton Heath. Eng. Pat. 11,250, August 14, 1884.

THE apparatus employed is placed in a position between the blast furnaces and the steam boilers or stoves to which the gases from the furnaces are conveyed. It consists of an ordinary ammonia still, with its usual "sulphate" apparatus, and of "dust boxes" and "condensers." The gases are afterwards taken to "washers" and "scrubbers," where the last traces of ammonia are absorbed, and after leaving the scrubbers they are conveyed to the boiler furnaces.—D. B.

*Improvements in the Treatment of Oils and Tars obtained from Blast Furnaces and Gas Producers for the Production of Valuable Hydrocarbons therefrom.* C. E. Bell, Durham. Eng. Pat. 12,681, September 22, 1884.

IN a former specification (Eng. Pat. 9510, 1884), the treatment of oils and tars obtained from coke-ovens was described, the object being the production of hydrocarbons of the benzene, naphthalene, and anthracene series. The inventor has since discovered that a similar treatment is applicable to oils and tars obtained from blast furnaces and gas producers by passing such oils into a retort heated to or beyond a full red-heat, and by preference charged with coke.—D. B.

### IV.—COLOURING MATTERS AND DYES.

*A New or Improved Process for the Manufacture of Naphthol Carbonic Alkaline Salts, and also their Subsequent Treatment for the Production of  $\alpha$ - or  $\beta$ -Carbonylnaphthol Acid Alkaline Salts.* From Dr. Carl Kolbe and Carl Reusch, of Radeben, Saxony. Eng. Pat. 6134, May 19, 1885.

THE authors act upon dry alkaline salts of  $\alpha$ - or  $\beta$ -naphthol by dry carbonic anhydride to produce the alkaline salts of the acid carbonic  $\alpha$ - or  $\beta$ -naphthoethers—

The alkaline salts of the  $\alpha$ - and  $\beta$ -naphthol are treated with carbonic anhydride, at ordinary temperatures, and after lapse of time and frequent stirring, the conversion of the naphthol salt into naphthol carbonic salt (oxynaphthoic acid salt) is completed; then the vessel is heated to 120–140° C., in order to effect conversion into simple  $\alpha$ - or  $\beta$ -oxynaphthoic acid salt. Dry alkali naphthol salts are placed in an autoclave and sufficient solid carbonic acid is thrown in to bring about the formation of the naphthol carbonic alkaline salt.—T.

## V.—TEXTILES: COTTON, WOOL, SILK, Etc.

*On Rhea Ramie Fibre, or China Grass.* From a Lecture delivered in the Manchester Technical School, July 21, 1885. By Dr. Forbes Watson.

THERE are two principal varieties, the one *Boehmeria nivea*, or *Urtica nivea*, with a white underleaf, and the other, *Urtica utilis*, with a green underleaf.

In China, when the stalks are cut, the bark is stripped off at once by hand, and this can be very easily done when the stems are quite fresh, and in this case the bark contains the whole of the fibre. The China grass of commerce is obtained by scraping this bark by hand by means of a knife, but only a small quantity can be produced per day by these means. In China a very clever worker can produce up to two pounds of fibre per day, while on the average only a half to one pound is generally obtained. In experiments made in India with unskilled labour, the production was very small indeed, in fact, not more than four ounces per day could be produced by each worker. As will be easily understood, this slow method of preparation has prevented the development of the industry.

China grass, as usually imported, varies from three to four feet in length, and therefore it can be inferred that the plant is allowed to reach a height of 3½ to 5 feet.

China grass contains from twenty-two to twenty-eight per cent., and in some cases up to thirty-five per cent. of gum; this has to be removed in order to obtain the pure fibre capable of being spun.

In Beheca, in Bengal, the bark is simply stripped off from the stalks, and dried, and is then brought into commerce in this raw state.

When the stems have been cut for any length of time the stripping by hand could not be performed without leaving a certain amount of the fibre adhering to the stalks, while if the stems are fresh the amount of fibre left behind is very insignificant.

The Favier's process consists in exposing the stems in the green state to the action of steam for fifteen to thirty minutes in a wooden box, after which the bark can be very readily stripped off by hand; by this process also those stems can be treated which have been standing for some time after being cut, without leaving any appreciable amount of the fibre adhering to the stalks.

Some years ago Dr. Watson made numerous experiments on a large scale with the dry stems sent him by the India Office, and he proved that it is not at all difficult to obtain the fibre when the stems are quite dry.

In his report to the Government he called attention to the importance of this treatment of the dry stems, but the reply was to the effect, that it is all very true if the stems can be dried, but the best crops are obtained in India during the rainy season, when it is all but impossible to dry them, except by expensive artificial means. They are, if not quite dry, very liable to ferment, and this results in the spoiling of the fibre.

The Government of India has for many years been endeavouring to find out a machine capable of treating the stems in the green state, and very many trials have been made. In the competition of October last in Calcutta, the Deane and Elwood machine was found successful for the separation of the raw fibre from the wood. The fibre produced Dr. Watson had found to contain fifteen to twenty per cent. of gum, but in some instances the figure is as low as five per cent.

The machine is also useful for the separation of the fibre from the pine-apple leaves and the agaves and other plants. It consists of a cylinder with beaters revolving at a high speed in front of a table where the stocks are introduced, being pushed against the beaters, which separate very quickly the wood from the fibre; a jet of water is supplied which helps considerably in the cleansing of the fibre, either by washing off the gum and other soluble matters or by keeping the fibre up to the action of the beaters, and in this case the water acts also as a kind of cushion. The stems are treated so, that after half of their lengths has passed through, they are taken out and the other half is exposed in its turn to the action of the beaters.

The cost of producing the fibre by this machine is estimated by Dr. Forbes Watson to average £4 to £5 per ton, but in no case did it exceed £7. The yield from the machine was from one to two tons of green stalks per day, and he expected that, properly worked, this would produce about 100 lbs. of cleaned fibre.

In order to utilise the China grass for industrial purposes it was necessary to deprive it of its gum, and make it into pure fibre ready for spinning. Different chemical methods have been recommended for the purpose of ungumming. As to the question, "Which is the best process?" Dr. Watson saw the Frény-Urbain process at Paris some time ago, but thought it was very imperfect. Since, then, however, it has undergone several improvements, as the abstractor (Mr. A. Sansone) can also testify, having lately seen it in Paris. The process is principally applied for the treatment of the dry barks or ribbons obtained by the Favier's steaming method.

Dr. Watson thought that in some cases the fibre might be injured by this process, or, at all events, that the amount of short fibre or noils obtained when spinning the material so prepared would be much larger than it ought to have been, and that consequently the amount of longer fibre, which fetched a much higher price, would be considerably reduced. He evidently objected to the use of pressure boilers or kiers for the treatment of the material with caustic soda, and stated that the operations of ungumming could be carried on without such apparatus; he had also seen samples successfully ungummed by other workers, and he knew of at least twenty processes which had been recommended. The question was not if the operations could be carried out on small samples, but if they can be conducted on a manufacturing scale. What is now principally wanted is raw material to work upon. Dr. Watson did not believe that in all Europe there is as much as forty tons of the fibre at the present moment. He thought that the cultivation of the plant ought to be extended and encouraged. The beautiful patterns of yarns and fabrics exhibited showed what was being done on the Continent. In reply to a question as to what kind of flowers and seeds the plant bore, Dr. Watson said that none of the plants they had in India had produced fertile seeds. The amount of pure fibre obtained from the green stalks was from two to three per cent., in some cases up to 3½ per cent.

Mr. Sansone, who said he had lately been in Paris and Louviers to see the Frény-Urbain process at work, stated that the treatment of the plants in the green state was suitable principally for large plantations, but for small cultivators like those found sometimes in his own country (Italy) it would be less suitable; they would have to deal with the dry stems, or strip the bark by hand, for as the peasants only cultivate small plots of ground they could not afford to put up either boilers or machinery for the treatment of the green stems.

As regards the employment of pressure kiers, the ungumming could be performed without them, but it had been found that a certain amount of pressure facilitates the operations considerably, as it allows the liquor to penetrate through the mass; this is of importance when working on large quantities. On the amount of very long fibre yielded by any process, no great stress need be laid, since the long fibre is generally cut in lengths of eight to ten inches before spinning. In the opinion of practical men engaged for years in the manufacture of China-grass goods, it would be even an advantage to have only to deal with a short fibre.

From what Mr. Sansone had seen in the ungumming processes as carried on at Paris, or rather at Louviers, he considers that there is neither in the chemicals nor in the treatment anything to injure the fibre, if the operations are performed with care. The process resembles in a certain sense the scouring and bleaching processes as generally carried on with cotton-goods in Lancashire.

*Method of rendering Cloth, Wood, or Paper Water-proof, but not Air-tight.* N. A. Alexanderson, Stockholm. Eng. Pat. 15,923, December 3, 1884.

This invention is based upon the well-known property of fibres of decomposing certain salts—e.g., those of

alumina,—alumina or a basic salt being taken up by the fibres and preventing water from moistening them. In this way it is possible to give a cloth a certain amount of impermeability by the double decomposition of lead acetate and aluminium sulphate. An improvement on this method consists in giving the tissue so treated a subsequent rinsing in a soap solution, whereby an aluminium soap is produced. A very essential improvement consists in depriving the salts used of their acid property, which is injurious to impregnation, and so to increase the capacity of fibres for alumina. Inventor has attained this result by using basic salts instead of the acid compound formerly employed. These basic salts are obtained by neutralising alum, sulphate or acetate of alumina, or any suitable salt of aluminium by equivalent quantities of any neutralising matter—*e.g.*, the carbonates or hydrates of the alkalis and of alkaline earths or hydrates of heavy metals. Thus the following equation may be considered a type:—

Inventor may use tartaric or citric acid or glycerol to prevent premature deposition. Basic salts deposited *in statu nascendi* are easily taken up by the fibre. Aluminate of soda and basic chromium and iron salts may also be used.—H. A. R.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

*Improvements in Machinery for Dyeing Textile or Fibrous Materials.* W. R. Lake, Middlesex. From C. Corron, France. Eng. Pat. 11,824, August 30, 1884.

THIS invention relates to apparatus for mechanically dyeing spun materials, which are wound into skeins, and preventing the skeins from becoming entangled with each other. The apparatus may be used for boiling, washing, mordanting, brightening, and staining silks, cotton, wool, linen, China grass; or any textile or fibrous material, by the submersion of a frame charged with skeins, and by the rotation of rollers. For drawings and details the original specification should be consulted.—H. A. R.

## VII.—ACIDS, ALKALIS, AND SALTS.

*A New Variety of Pyrites for Sulphuric Acid Manufacture.* Drinkwater. Analyst, 10, 109.

THE author, after referring to the fact that pyrites nearly always contain arsenic, gives analyses of two samples recently examined by him, and found to be free therefrom. One was a Welsh pyrites, the other Algerian. The former contained:—

Insoluble matter	...	...	...	5.8
Sulphur	...	...	...	48.3
Iron	...	...	...	42.1
Arsenic	...	...	...	nil.
Alumina	...	...	...	1.4
Carbonate of calcium	...	...	...	2.5
				100.1

The Algerian pyrites contained:—

Sulphur	...	...	...	44.8
Insoluble...	...	...	...	5.2
Iron	...	...	...	46.6
Lead	...	...	...	0.02
MnO <sub>2</sub>	...	...	...	0.22
Calcium carbonate	...	...	...	3.1

The acid manufactured from the Welsh pyrites contained:—

Hydrated sulphuric acid	...	...	...	97.14
Water	...	...	...	2.826
Sulphate of lead	...	...	...	0.003
Saline matter	...	...	...	0.031
Arsenic	...	...	...	nil.
Nitrogen compounds	...	...	...	nil.

99.80

This acid is as good, for any commercial purpose, as the best sulphuric acid, and is much cheaper. The Welsh ore is raised from the Cae Coch Mine. The sulphur known as recovered sulphur is not always free from arsenic. The following figures represent the amounts of arsenic discovered by Dr. Drinkwater in various specimens of pyrites, and in one of recovered sulphur:—

	1.	2.	3.
Cornish pyrites	0.93	0.56	0.5
Norwegian „	0.32	0.20	—
Belgian „	0.40	1.03	0.22
Spanish „	1.81	1.65	0.89
Irish „	2.00	—	—
Recovered sulphur	0.68	—	—

—E. G. C.

*Improvements in obtaining Hydrochloric Acid Gas from a Solution of Hydrochloric Acid.* W. Lloyd Wise, London. From Messrs. Solvay & Co., Brussels. Eng. Pat. 12,421, March 18, 1885.

THE solution of hydrochloric acid is introduced into a nearly boiling solution of calcium chloride so concentrated that the boiling point of the mixed liquids does not fall below 100° C. A solution of calcium chloride boiling at 150° C. to 160° C. answers very well. Agitation is produced by suitable means, and the hydrochloric acid is evolved in the gaseous form, while the water in which it was dissolved is retained by the calcium chloride. The operation may be made continuous by passing through an apparatus divided into several compartments a current of hot calcium chloride solution, and at the same time such a quantity of liquid hydrochloric acid as it is capable of decomposing. To the calcium chloride solution remaining at the end of the operation a little lime or carbonate of lime is added to neutralise the traces of acid retained. It is then concentrated and used over again.—A. R. D.

*An Improved Method of Making Sodium Carbonate and certain By-products.* W. Robinson, Gateshead. Eng. Pat. 10,080, April 10, 1885.

THE inventor intimately mixes together common salt, pulverised coal, or other carbonaceous material, and sulphuric acid. The mixture is heated in a furnace, and the evolved gases treated for the recovery of hydrochloric acid, sulphurous acid, and sulphuretted hydrogen. The contents of the furnace are treated by certain well-known methods for the production of sodium carbonate, sodium bicarbonate, soda ash, sulphur, sulphuretted hydrogen, etc.—A. R. D.

*Improvements in Furnaces for Chemical Processes.* J. Mactear, Glasgow. Eng. Pat. 10,812, July 31, 1884.

THIS specification describes improvements upon patents 4870 of 1879, and 4511 of 1880, granted to the author, and their object is to so apply the heat that the fire gases may not come in contact with the materials to be fired or be mixed with the gases evolved therefrom. The improvements will be better understood by reference to the annexed drawings. The revolving bed of the furnace (3), made of fire brick and bound with the iron or steel frame (4), is rotated on the rollers (5) by the pinion (34) and the rack (33). Above the bed is the domed crown of the furnace (8), and immediately over this the flue (9). Under the bed another flue (10) is formed; the gases from the furnace (13) circulate above and below the rotating bed. Entering the flue (9) from the passage (12) communicating with the source of heat, the hot gases pass between walls (11), Fig. 1, across the centre of the crown, and diverging right and left escape down the vertical flues (14), and emerge into space (10) by flues (15) and (16). From thence they pass by openings (18) into exit flue (17). The material fired overflows the edges of the hearth into the ring (20), and with the curb (23) forms a hute between the interior of the furnace

and the air. A similar device (27) and (28), the trough being filled with sand, lutes the flue (10) against the air. The furnace product is removed continuously by hopper (24) and creeper (25). Stirring gear (29), as at present used, is provided, and when applied to salt cake the fixed plough (31) and centre pan (30), to effect a partial preliminary decomposition, are also used. The patentee claims the improvements as described. (See this Journal, vol. i. 27—29.)—C. C. H.

*A New or Improved Process for the Production of Phosphate of Soda, or of Potash from Basic Process Slugs, and other Phosphatic Materials.* W. P. Thompson, Liverpool. From Luigi Imperatori, Düsseldorf, Germany. Eng. Pat. 5216, April 27, 1885.

100 PARTS of slag (containing say 50 per cent. lime, 5 per cent. of magnesia, 19 per cent. iron, 20 per cent. phosphoric acid, and 6 per cent. silicic acid) are mixed with 170 parts of sulphate of soda and 74 parts of coal. The mixture is worked in a black-ash furnace, and the semi-fluid mass so obtained is moulded into blocks. These blocks must first be treated in any suitable way with carbonic acid gas to convert the caustic lime which they contain into carbonate. After this they are lixiviated, by which a solution of mixed carbonate and phosphate of soda is obtained. These salts are separated by crystallisation. If the blocks above mentioned were lixiviated directly with water the caustic lime present would cause the almost entire reversion of the phosphate. In preparing the mixture for the furnace it is well to use an excess of slag.—A. R. D.

*Improvements in Apparatus for Carbonating Liquids or Semi-Liquids.* F. G. Riley, Vauxhall, London. Eng. Pat. 11,880, June 2, 1885.

THE apparatus, with its improvements, is designed for the conducting of carbonic acid through liquids, so that convenience in manipulation, economy of time and safety are secured. The blue-book, with its drawings, must be consulted.—A. R. D.

## VIII.—GLASS, POTTERY, AND EARTHENWARE.

*Improvements in the Production of Toughened Glass, and in Apparatus therefor.* C. D. Abel, London. From La Compagnie General du Verre et du Cristal Trempe, Paris. Eng. Pat. 10,748, July 29, 1884.

HITHERTO it has been usual in the operation of toughening articles of glass to heat them, after formation, in the same furnace in which the glass was originally heated by simply introducing them into the mouth of the furnace. The result of this is unequal heating, due in some measure to the configuration of the article. The present invention proposes to obviate this by the employment of a special reheating furnace either of the muffle form with two compartments, or else of the ordinary form, but with openings in the sides so that the thinner parts can be kept cool by exposure to the air, whilst the thicker parts are reheated prior to quenching in the bath. To ensure uniformity in the temperature of the oil-bath, the vessel is constructed either with double sides, filled with a non-conductor, or else a movable vat is used which can be placed in a screen or casing.—C. C. H.

*An Improved Manufacture of Toughened Opal Glass Articles and Apparatus therefor.* C. D. Abel, London. From La Compagnie General du Verre et du Cristal Trempe, Paris. Eng. Pat. 10,768, July 30, 1884.

THE "toughening" process cannot be applied with advantage to articles made from opal glass. To render such objects amenable to this process the present invention proceeds thus:—Articles or sheets of opal glass are coated with ordinary crystal glass and can then readily be "toughened." Any device or pattern can be interposed between the two surfaces of glass, and thus be rendered permanent. A special furnace and appliances are necessary in operating upon articles made from sheets of opal glass as above described. The furnace in which

the sheets are heated is constructed after the muffle pattern in order to secure uniformity of temperature. The articles after being mounded must be successively heated upon two moulds which are the reverse of each other, so as to bring the surfaces to the same temper. The invention is covered by two claims—(1.) The manufacture of articles of opal glass toughened as described. (2.) The apparatus used therein.—C. C. H.

*Improvements in Gas Kilns for Burning Glass, China, Pottery Ware, and other such like Articles.* G. W. Wilkinson, London. Eng. Pat. 1633, February 5, 1885.

THE improved kiln is constructed in wrought iron, of a  $\Omega$ -shape, and the interior is heated by "atmospheric" gas burners. The exterior of the kiln is covered with fire-bricks, and the ends fitted with doors. The articles to be fired are placed on shelves in a closed chamber similar in shape to the furnace, into which it is run on wheels. When firing has proceeded to a sufficient extent the interior chamber may be removed and run into another chamber, where it is allowed to cool gradually. Three claims cover the invention.—C. C. H.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, CEMENTS.

*Colouring Stone, Marble, and other Materials for Building and other Purposes.* Baron de Liebhafner, Eng. Pat. 15,628, May 23, 1884.

THIS inventor uses a solution of nitrate or chloride of copper, followed by caustic soda and sulphides, for the purpose of dyeing stone blue, black, or bronze. Yellow prussiate of potash produces a pink or light red colour on marbles and calcareous stones in their natural state; but on those previously treated with salts of copper, a purple or dark red colour is produced. A blue colour is imparted to stones of any nature, impregnated with yellow prussiate of potash, by means of fluoric acid. On ferruginous stones, such as Bath stones, yellow Yorkshire sandstone, etc., a red colour is produced by coating the surface with a very fine layer of chlorate of potassium, and then directing upon it the flame of a blast lamp until the whole surface is reddened to a slight depth.—E. G. C.

*Improvements in the Manufacture of Artificial Stone and the Treatment of its Surface.* Herbert John Allison. Eng. Pat. 16,000, December 5, 1884.

THE artificial stone, slate, or marble, consists of various mixtures of sand and crushed stone with Portland cement, as follows:—Composition No. 1. By measure, four parts of ground slate, four parts Portland cement, one part (or less) of hydrate of lime mixed by sieving and made into a paste with water. Composition No. 2 has hydraulic lime (lime of Fiel) wholly or partially substituted for the hydrate of lime. Composition No. 3 same as No. 1, without lime. Composition No. 4. Four parts ground slate, four parts powdered limestone or marble, or sand, or a mixture of both; and one part of slaked or ground quicklime made into a paste with water. Nos. 5 and 6 are slight variations of above. These compositions are compressed or tamped into moulds and hardened by carbonating in a closed chamber, with water containing carbonic acid, or by the gradual action of the carbonic acid and moisture of the air.—H. R. P.

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

*On the Examination of Fats.* R. Benesmaun. Rep. Anal. Chem. 11, 163.

AS a test of the genuineness and purity of fats, the author determines the melting point of the fatty acids insoluble in water in the following manner. A drop of the previously fused mixture of fatty acids is placed in the wide portion of a drawn-out tube, as shown at *a* in

the figure, and is then allowed to completely solidify. The tube is now placed perpendicularly or nearly so in a beaker of cold water, containing a thermometer, and heated as gradually as possible over a very small flame, until some of the fat begins to flow down the side of the tube. The temperature observed at this moment is called by the author the "initial point of fusion." The application of heat to the water in the beaker is continued until the fat-drop has taken the appearance and position shown at *b*; and when the last trace of turbidity has disappeared the temperature is again read. This is the "concluding point of fusion." The author finds that this method gives very satisfactory

and concordant results; the two points are very clearly marked and are about 3–4° C. from one another. With pure fats the concluding point is less clearly marked than with fatty acids; in the examination of the former, therefore, the initial point only need be noticed. The author takes 5grms. of the fat for saponification (with 2grms. of caustic alkali and 25grms. of alcohol). The fatty acids obtained by decomposing the soap with hydrochloric acid are thoroughly washed, first with cold and then with hot water. They are then dried at a temperature of 90–100° C. The drying must be continued until the acids cease to lose weight.

The following table contains some results obtained by the author:—

## XII.—PAINTS, VARNISHES, AND RESINS.

*Treatment of Kieselguhr and Furnace Slag for the Production of a Material applicable for rendering Paints, Varnishes, and other Substances Fire-, Damp-, and Weather-proof.* Sir S. J. Blane, Bart. Eng. Pat. 9803, July 5, 1884.

POWDERED furnace-slag is treated with hydrochloric acid and steamed, and the jelly-like mass is strained through canvas and freed from acid by washing with water. The slag jelly is then well mixed with ignited and finely powdered kieselguhr, and to this a little "lime water and gum, or glue solution, or both," are added.—E. G. C.

*An Improved Black Pigment.* J. Connor, Scotland. Eng. Pat. 11,930, September 3, 1884.

THE material employed is a bituminous or carbonaceous mineral, resembling coal and bituminous shale, and known as "bonnet." This mineral is ground to a fine powder, mixed with about five per cent. of lime, and heated in a retort. After being thus heated, the mixture is reground, and subjected to elutriation and other finishing processes.—E. G. C.

*Improvements in the Manufacture of Sulphide of Zinc, and the obtaining of Sulphuretted Hydrogen and Sulphurous Acid as Products of the said Manufacture.* J. H. Johnson, London. From T. Macfarlane, Montreal. Eng. Pat. 13,045, April 7, 1885.

ZINC, impure zinc oxide, or ores containing oxide or carbonate of zinc, are dissolved in hydrochloric acid till the latter is neutralised, and the solution is evaporated to a sp. gr. of at least 1·6 in lead or cast-iron pans. The chloride of zinc solution is added to a "sulphur liquor," prepared as below:—(1.) Two parts of quicklime are slaked and mixed with one part of ground sulphur, and boiled with water for two hours. (2.) One part of quicklime is slaked, mixed with one part of "spent oxide," and boiled with water for two hours. The solutions each contain hydrosulphate and hyposulphite (thiosulphate) of calcium, together with some pentasulphide. (3.) Ordinary tank waste from the alkali manufacture is exposed to the atmosphere for three or four weeks on an inclined water-tight floor. This is leached with water, and the solution so obtained is concentrated to from 10° Tw. to 20° Tw., by treating fresh quantities of weathered tank waste. It then contains from 2½ to 2½ equivalents of sulphur to one equivalent of calcium. When this liquor No. 3 is used for the production of sulphide of zinc as above, there is an abundant evolution of sulphuretted hydrogen, which may be burned in a suitable furnace, and also utilised for vitriol making. The precipitated sulphide of zinc, after ignition, is used as a white pigment.—A. R. D.

	Initial Point of Fusion of the Fat.	Percentage of Fatty Acids Insoluble in Water.	Initial Point of Fusion of Insoluble Fatty Acids.	Concluding Point of Fusion of Insoluble Fatty Acids.

*Improved Composition for Painting Railway Signals.*  
 Horace Wilmer and Thomas Bolas. Eng. Pat. 10,624,  
 July 26, 1884.

THE patentees use a spirit varnish similar to the "sealing-wax varnish" used for electrical purposes, and produced by dissolving shellac (seed lac, button lac, or stick lac) and Burgundy pitch in alcohol, wood spirit, or the mixture of the two known as "methylated spirit," and incorporating vermilion in the solution. The proportions recommended are—

Lac .....	1000 parts by weight.
Alcohol .....	1530 " "
Burgundy Pitch...	200 " "
Vermilion .....	800 " "

—H. R. P.

### XIII.—TANNING, LEATHER, GLUE, AND SIZE.

*Preliminary Note on the Synthesis of Tannin.* Bertram Hunt. Chem. News. 52, 49.

It having been shown, lately, by Böttger and others, that Schiff's digallic acid differs from gallo-tannin, and is probably only isomeric with it, it occurred to the author that possibly gallo-tannin might be produced by the action of mono-bromo-protocatechuic acid on potassic gallate. The reaction may be represented thus:—

The experiment was made as follows:—Mono-bromo-protocatechuic acid was prepared by the action of excess of bromine on protocatechuic acid in the cold ("Watt's Dictionary," vi. 976). Potassic gallate—

was prepared according to the directions given in "Watt's Dictionary," ii. 761.

The bromo-protocatechuic acid and potassic gallate were coheated together on the water-bath for about five hours, in presence of absolute alcohol, a slight excess of potassic gallate being used. The cold liquid was filtered through fine asbestos, and the alcohol evaporated off at a low temperature. The residue was dissolved in aqueous ether, and the solution filtered through asbestos. The ether was now evaporated off, and the residue dissolved in cold distilled water. The filtered, brown-coloured solution gave the following reactions:—It precipitated gelatin solution. It precipitated cupric acetate solution, and the precipitate was insoluble in ammoniac carbonate. It gave a precipitate with tartar emetic solution in presence of ammoniac chloride. It gave a black colour with ferric chloride, and, on standing some hours, a slight black precipitate. It reduced Fehling's solution readily on boiling. It precipitated cinchonine sulphate solution. The cinchonine precipitate was washed and carefully dried. The amount of cinchonine in it was determined by dissolving a weighed quantity in dilute sulphuric acid, boiling, and then precipitating the cinchonine in the cooled solution by a slight excess of caustic soda. The result was 31.56 per cent. cinchonine in the dry precipitate.  $\text{C}_{20}\text{H}_{24}\text{N}_2\text{O} \cdot \text{2C}_{14}\text{H}_{18}\text{O}_5$  gives 32.33 per cent. cinchonine.

These reactions are identical with the reactions of gallo-tannin, and are not given by either gallic or protocatechuic acid, or by a mixture of these acids. Further experiments are of course required to prove the identity of the substance produced with gallo-tannin.—W. S.

*Improvements in the Manufacture of Substitutes for Leather.* Maximilian Zingler. Eng. Pat. 3171, February 12, 1884.

A COMPOSITION is made consisting of gum-percha 3½ lb., powdered waste rubber 3½ lb., indiarubber 7 lb., sulphuret of antimony 3 lb., peroxide of iron 1 lb., flower of sulphur 1½ lb., lime 2½ lb., asbestos powder 4 lb., sulphuret of zinc 1½ lb., carbonate of magnesia 3½ lb. By gum-percha is meant the gutta-percha substitute described in Patent 1153, March 9, 1882. This mixture is

worked through mixers, or iron rollers, and then vulcanised in a vulcanising press at 280° F., for an hour or more. This is to imitate heavy leather; for light, solid leather, powdered wood fibre, nut shells, or cuscus root is substituted for asbestos. Machine belts are prepared by soaking canvas in a bath of tannin and potash or ammonia alum, or tungstate of soda. It is then drained and steeped for twenty-four hours or more in a bath of sulphate of zinc, drained and allowed to dry. It is then coated with the composition above described, but without the waste rubber, and either dissolved in naphtha or worked up to a soft state between rollers. The canvas is doubled from two to twelve plies, and vulcanised for ½ to 1½ hour; for leatherine, canvas or calico, prepared as above described, is coated with a composition of india-rubber 7 lb., substitute (as mentioned in Patent 242, January 15, 1883, under the heading of oxidised oil), 2½ lb., sulphuret of antimony 3½ lb., peroxide of iron 1 lb., sulphur 1 lb., sulphuret of zinc 2½ lb., carbonate of magnesia 5½ lb., sulphate of baryta 2 lb. This is vulcanised for half-an-hour, cooled, and if necessary again vulcanised. Thin leatherines are treated with a thin coating of india-rubber solution before applying the composition.

—H. R. P.

*A Substitute for Whalebone, Steel, etc., for Stiffening Corsets, etc.* Jas. Royle. Eng. Pat. 4578, March 8, 1884.

THIS consists in strips of buffalo hide, which (presumably first unhaird by liming in the usual way) are softened in cold water. They are then cut to required form, and dried in a current of cold air. After smoothing with pumice, they are rubbed on both sides with palm oil, to give the requisite elasticity, and again allowed to dry. They may be hammered or rolled to increase firmness, dyed black or otherwise, and polished or varnished.—H. R. P.

### XIV.—AGRICULTURE, MANURES, Etc.

*Influence of Malt-dust, and the Non-albumenoid Nitrogenous Compounds contained in it, on the Yield of Milk from Cows.* M. Schrodt and H. Hansen. Bied. Centr. 14, 246–248.

THE experiments were arranged in three periods of twenty-five, thirty, and twenty-five days respectively. In all three the quantity of nutritious matter supplied in the fodder was approximately the same. In the first and third, or normal periods, the rations consisted of clover-hay, oat-straw, roots, wheat-bran, and cotton-seed cake, whilst in the second, or experimental period, the clover-hay and bran were in part replaced by malt-dust, the normal proportions of nutritious matter being sustained by slightly increasing the quantity of roots, straw, and cake, with the addition of starch and olive oil to equalise the carbohydrates and fat. This fodder, rich in nitrogen as amides, produced a slight increase in the total yield of milk, but the quality was rendered slightly inferior, inasmuch as the production of dry matter and fat suffered a very slight depression. It would appear, therefore, that the nitrogen as albumenoids in fodder may be replaced, to a certain extent, by nitrogen as amides, without exerting any noteworthy injurious influence either on the quantity or quality of milk.—D. A. L.

*Composition of Alpine and Valley Hay.* W. Eugling. Bied. Centr. 14, 250–252.

ANALYSES of hay from various localities show that neither the height at which it is grown nor the character of the soil have much influence on the composition of the hay. The author, however, remarks that hay grown at a height of from 1200–1400 meters, has a lower percentage of fibre and ash than that grown in either higher or lower districts, whilst the quantity of albumenoids is greater in the hay from high than from low localities.

—D. A. L.

yields 4 to 5 or even 6 cuttings of 1 to 1½ foot high, whilst in other meadows 3 cuttings of broad-leaved grasses are taken. The rye grass, according to the author, forms excellent fodder for bullocks, milking cows, sheep, horses, and even pigs; it is very succulent, and takes a long time to dry; the haymaking is therefore conducted on a fallow or stubble field, so as not to interfere with the new growth in the meadow. Mangold-wurzel give very good results with not a single bad harvest in 8 years; with sugar-beet, on the other hand, the results are not so satisfactory. White carrots yield well, and chicory gives as much as 753centnr. per hectare. All kinds of vegetables have been cultivated with the sewage as manure, they grow to a very great size, but only red and white cabbage are at present cultivated on a large scale. Large yields are obtained with hemp, which grows so thick as to drive out all weeds, and also with rape and turnips, which are useful crops, as they take up the manurial matter in the subsoil. Rye, wheat, summer rye, and oats have all been cultivated, and barley to a small extent. Irrigation experiments were also made; in September 1175—1565cm. of sewage water were applied per hectare. In one case rye was sown broadcast in October, and yielded the following August 395kilos. of grain, and 878kilos. of straw per morgen (=0.2553hectare). In another field, which had grown in the previous year barley after potatoes, chevalier barley was sown in the April after irrigating, thrived well, and yielded 50kilos. of grain and 1235kilos. of straw per morgen (=0.2553ha.). A bushel weighed 34kilos. In another field, previous cropping had been barley after manured potatoes; oats were sown in April, the plant did well, and yielded 445kilos. of grain and 965kilos. of straw per morgen. The weight per bushel was 23.5kilos. The author recommends the use of sewage-water for agricultural purposes.—D. A. L.

*Manurial Experiments.* J. König. Bied. Centr. 14. 319—320.

In various experiments, land which had been exhausted with the growth of lupinus was much benefited by manuring with kainite, or, better still, with kainite along with nitrogenous and phosphatic manures, the crop being rye after the lupins; on the other hand, with phosphatic and nitrogenous manures without kainite the beneficial result was doubtful. In other experiments similar results were obtained with these manures with potatoes grown on a species of slaty deposit (Grauwackenschiefer). Moreover, kainite exerted a favourable influence on potatoes receiving lime and liquid manure, and on meadow land manured with superphosphate; in this case the first crop was about the same with or without the kainite, but the aftermath was stronger with the kainite, and contained a considerable quantity of red clover and bird vetch. Experiments with potatoes show that potatoes manured with superphosphate and sodium nitrate yield better in most cases than potatoes manured with the same weight of nitrogen and phosphoric acid as bone-meal, although more bad tubers are always harvested in the former than in the latter case. Quick-acting manures should be used instead of bone-meal on lands where the period of vegetation is short.

—D. A. L.

*Artificial Manures for Vines.* A. Stutzer. Bied. Centr. 14. 321—322.

WHILST the cost is about the same, the leaves and wood develop better and the yield of grapes is greater when the vines of black grapes are manured with artificial, than when they are treated with stable manure; the quantity of sugar and acid in the most is not apparently affected by the change of manure. With white grapes the experiments with artificial manures have not been successful, which the author considers is due to the manures not reaching the deep roots of the vines. The manure is composed of 6 per cent. phosphoric acid, 6 per cent. of potash as sulphate, 3 per cent. nitrogen (as ammonia or nitrate). Nitrate is best for vineyards with deep soil.

—D. A. L.

*Peat Litter as Manure.* Wagner. Bied. Centr. 14. 352. COMPARATIVE experiments with peat-litter manure, and straw-litter manure, show that the former is better than the latter for potatoes and oats. For barley they are about equal in value.—D. A. L.

*Phosphates for Sugar-beet.* A. Ladureau. Bied. Centr. 14. 361.

THE present experiments show that precipitated phosphate and superphosphate are about equal in value as manures for sugar-beet, when employed in the quantities used by the author, which, in the case of both manures, were equal to 100, 200, 300, and 400kilos. of phosphoric acid per hectare in the various experiments respectively. The phosphatic manures give rise to a decided increase in the yield, which generally is moderately uniform, but is highest with the 200kilos. of phosphoric acid as superphosphate. The author regards the application of more than 100kilos. of phosphoric acid per hectare as useless.

—D. A. L.

*Manurial Experiments with Hops.* C. Kraus. Bied. Centr. 14. 362—363.

THE author finds that under favourable climatic influences the application of artificial manures, more especially superphosphate and sodium nitrate, exerts a beneficial action on hops. On the other hand, no advantage was derived by such applications in unfavourable weather. Contrary to expectation, a better yield per stock was obtained when three than when two hop bins were trained on the same pole.—D. A. L.

*Maize Silage as Fodder for Milch-kine.* Rose. Bied. Centr. 14. 374—375.

MAIZE (sour) silage from chopped green maize, put in the silo on 16th September, was given as fodder on 11th October. The rations per cow were 30kilos. of maize silage mixed with one-twelfth its weight of chaffed straw, 1.5kilo. oil-cake, 0.5kilo. wheat-bran, 50grm. common salt, and 20grm. of basic calcium phosphate, the last constituent to correct the laxative properties of the silage. With this fodder the yield of milk increased and the butter was yellow and had a good taste. Ewes in lamb fed with this silage received 0.63kilos. per head. Muller deems it advisable to allow the silo to cool considerably before feeding maize (sour) silage. The temperature in a silo filled by Goffard's method after six weeks was 30° C., and after eight weeks 27.5° C. Souring and heating always ensue. Klein found 2 per cent. of acetic and lactic acids in three samples of maize (sour) silage, and did not observe any considerable increase in acidity during its exposure to the air in removal, etc.

—D. A. L.

*Manurial Value (for Barley) of various forms of Phosphates.* Fittbogen. Bied. Centr. 14. 313—318.

EXPERIMENTS were made with barley in pots in ignited levigated sand. Each pot received 4kilos. of sand, 6 barley plants, and a mixture of 3millgrm. molecules of potassium chloride, 0.8millgrm. mol. of magnesium sulphate, 0.8millgrm. mol. of calcium nitrate, and 1 (or more) millgrm. mol. of phosphoric acid in some form or other.\* Preliminary experiments showed that with one millgrm. mol. of monocalcium phosphate the result was slightly superior to that obtained by cultivation in garden soil, and much superior to the yield of field cultivation; whilst the disastrous effects of diminishing the quantity of phosphoric acid added were also distinctly indicated. Hence the above mode of investigation by sand cultivation was proved to be quite sufficient for testing the manurial value of various kinds of phosphates. For application soluble phosphates were dissolved in water, insoluble phosphates were mixed with

\* These quantities of phosphoric acid being regulated according to the recognised value of the phosphates as manures.

soil; in many cases water saturated with carbonic anhydride was employed, and in other experiments humic acids or calcium humate were added to the sand, etc., in the pots. Nine varieties of phosphates were investigated, and a table of results is given. The following table, an extract from the table mentioned, shows the effect of one millgrm. mol. of phosphoric acid (=0.142gm. per pot, corresponding to 72kilos. per hectare) in different forus, and under varied conditions:—

MANURING WITH 1 MIL. MOL. OF PHOSPHORIC ACID AS UNDER.	DRY MATTER IN PRODUCE PER POT.	
	Grams.	Total above ground Growth. Grams.
Mono-calcium phosphate dissolved in water.....	10.13	20.94
"    "    with calcium carbonate .....	10.10	21.19
Di-calcium .....	9.91	20.53
Tri-calcium .....	0.80	3.13
Iron .....	1.65	4.93
"    "    with humic acids .....	3.77	11.01
Aluminium .....	4.17	10.20
Mejillos ground superphosphate .....	9.50	20.88
"    "    "    dissolved in water .....	9.70	21.26
Lahn superphosphates .....	3.41	8.04
"    "    dissolved in water .....	6.81	11.76
"    "    with carbonic anhydride water .....	3.18	8.31
Precipitated calcium phosphate (Wilhelmsburg) .....	10.01	18.37
Cladno phosphate .....	2.00	6.88
"    "    with carbonic anhydride water .....	3.01	7.31
"    "    with humic acids .....	7.01	13.77

Thus normal or good yields were obtained with the one millgrm. mol. of phosphoric acid per pot (=72kilos. per hectare) when applied as mono-calcium phosphate, as Mejillos superphosphate, as di-calcium phosphate, and, as regards the grain, with precipitated phosphate. Increasing the quantity of phosphoric acid applied in these four forms to 2millgrm. mols. or to 3millgrm. mols., in the case of the precipitated phosphate did not produce any considerable increase above the normal yield. The absorptive capacity of sand for phosphoric acid is very small, hence the soluble phosphates when applied to the sand were not altered, and this may account for their activity; but even the addition of 0.5 per cent. of calcium carbonate, which increased the absorptive power of the sand, did not reduce the yield. The 6 plants harvested from three of the above experiments contained the following amounts of phosphoric acid:—From the mono-calcium phosphate pot, 0.0587gm.; from the di-calcium phosphate pot, 0.0554gm.; from the precipitated phosphate pot, 0.0488gm.; thus, by means simply of root activity, even some insoluble phosphates are made to give up the quantity of phosphoric acid required by the plants. Lahn superphosphate and tri-calcium phosphate, when used alone, had to be employed in quantities equivalent to 2millgrm. mols. of phosphoric acid per pot in order to obtain normal yields of barley; whilst the other phosphates enumerated above do not yield normally, even under these favourable circumstances. The addition of humic acids or calcium humates improves the state of things to a very marked extent, for under these conditions (humic acids) 2millgrm. mols. of phosphoric acid as Lahn superphosphate give the greatest yield of all the experiments; and even Cladno, iron, and aluminium phosphates are awakened to a reasonable amount of activity. The author hence concludes that humic matter is the most important and perhaps only medium which aids the assimilation of phosphoric acid from very insoluble compounds. The author divides phosphatic manures into

three groups:—1. Phosphates of greatest activity or most rapid action, such as mono- and di-calcium phosphate, precipitated phosphate, and good superphosphate (from guano, bone-ash, pure apatite, etc.). 2. Phosphates of medium activity, such as tri-calcium phosphate and superphosphates from inferior materials. 3. Phosphates slow in action, such as iron, aluminium and Cladno phosphates. To produce the same effect as a superior fertiliser, an inferior phosphate must be used in propor-

tionately larger quantities, and should therefore cost proportionately less. Field experiments in the same direction have also been conducted, and confirm the results from the pot experiments. Treating with carbonic anhydride water was found to be useless for increasing the activity of insoluble phosphates. The phosphates employed were chemically pure preparations. The phosphoric acid in the superphosphates, etc., was in the following condition:—

	Water soluble.	Citrate soluble.	Total.
Mejillos guano superphosphate ..	19.18	1.73	21.71
Lahn superphosphate .....	4.13	5.83	18.84
Wilhelmsburg precipitate .....	0.33	11.12	28.85
Cladno phosphate .....	—	6.08	11.30

—D. A. L.

#### *Injurious Effect of Hydrochloric and Sulphurous Acid Vapours on Vegetation.* J. König. *Bied. Centr.* 14, 418—419.

IN a forest exposed to hydrochloric acid vapour the leaves had a sickly appearance similar to that induced by sulphurous acid. The injured oak leaves contained 0.084—0.104 per cent. more chlorine than healthy oak leaves from same forest, whilst in the sickly beech leaves this excess of chlorine was 0.128—0.153. Oats exposed to sulphurous acid vapours, from coke-ovens, etc., were seriously injured and yielded badly; 1000 grains of injured oats weighed only 11.79gm., whilst 1000 grains of healthy oats from another part of the same field weighed 25.30gm. The injured straw contained 1.080 per cent. in dry matter, or 17.22 per cent. in ash, of sulphuric acid in excess of that contained in the uninjured oat straw, whilst the proportion in excess in the grain was 0.308 per cent. dry matter or 6.67 per cent. ash, thus showing without doubt that the sulphurous vapours were the cause of the mischief.—D. A. L.

*Pasture Feeding in Oldenburg.* H. C. Tantzen. Bied. Centr. 14, 424-425.

THE following figures show average results of pasture feeding in 1884:—

	Average weight in kilos.	Increase in kilos.	Days in pasture.
	Before feeding.	After feeding.	
3-year old bullocks	505	705	296
2-year old bullocks	411	611	290
2-year old cows	411	611	290
Cows	582	723	215

Forty-seven three-year old bullocks required 23 hectares of pasture for the production of 9402 kilos. of flesh, and the cost of production was 18.30 marks per 50 kilos. live weight. The two-year olds cost about the same; whilst the cows cost 17.35 marks for every 50 kilos. live weight produced. Some of the cows calved in January, hence their average increase is rather low.—D. A. L.

*Temperature Requirements of the Vine.* Roger. Bied. Centr. 14, 426.

THE following figures are the means of nine years' observation. Vine shoots open as soon as the mean day temperature exceeds 11° or 12° C. Leaf development begins at a mean temperature of 13.6° C., and a mean of 27.5° of rain. From the opening of the shoots until the blossoming, 25 to 32 days intervene, when a mean aggregate temperature of 46.6° C. is necessary, and from the blossoming to the maturing the grapes require 1926° of heat daily; thus the mean temperature during these 104 to 115 days should be 14.7° C. If the temperature stands below 12.5° during this period, the ripening is interrupted. The mean temperature for the last 20 days of the growth of the grape is 17° C.—D. A. L.

## XV.—SUGAR, GUMS, STARCHES, Etc.

*Proposed Nomenclature for Sugars.* C. Scheibler. Rep. Anal. Chem. 5, 185.

THE names customary hitherto have not exhibited the division of sugars into the two great groups of which the formula  $C_6H_{12}O_6$  and  $C_{12}H_{22}O_{11}$  are types. The author proposes to retain the affix *ose* only for the group  $C_6H_{12}O_6$ , thus—Dextrose, levulose, arabinose, ceranose, lactose (galactose), sorbin, eukalyun, inosite, dambose, mannitose, etc., and to use the ending *biose* for the invertible sugars of group  $C_{12}H_{22}O_{11}$ . Hence we should have:—

Saccharobiose	for Saccharose.
Trehabiose (mykobiose)	„ Trehalose (mykose).
Melitobiose	„ Melzitose.
Melibiose	„ Melitose.
Maltobiose	„ Maltose.
Laktobiose	„ Galactose (lactose).

Milk sugar being termed by some writers galactose and others lactose, this causes confusion. The sugar  $C_{12}H_{22}O_{11} + H_2O$  would be lactobiose, and its inversion product lactose. To avoid confusion in the case of arabinose, the author proposes "arabiose" as a substitute.—H. A. R.

*Estimation of Moisture in Starch.* L. Boudonneau. Rep. Anal. Chem. 14, 222.

FROM 5 to 10 grm. are placed in a drying chamber, the temperature of which rises within three hours to 60° C., and then during one hour to 100° C., and dried until the weight is constant. If the starch be acid, it is dried at 60° C., mixed with its own weight of distilled water and 1 to 2 drops of ammonia, dried again at 40° C., and finally submitted to the desiccating process already described.—E. G. C.

*Presence of Potassium and Calcium Salts, etc., in Sugar, Beet and Maize.* H. Leplay. Bied. Centr. 14, 258-259.

IN a former communication the author has shown that potassium and calcium are taken up as carbonates by the roots of sugar-beet during their growth, subsequently

these bases are found in all parts of the plant as soluble organic salts; but as the tissue develops the lime becomes insoluble and is deposited. In fact, the amount of sugar formed in the root is in direct proportion to the quantity of lime thus stored up in the plant. The potassium salts, on the other hand, accumulate in the leaves. The author has extended his experiments to maize, and has observed a similar sequence of phenomena. As maize matures in one year, these observations extend farther, and the author shows that the potassium salts accumulate in the leaves until the ears begin to form; they then migrate to the stem, thence by the stocks to the ears, and finally to the seed. Sugar plays an active part in these migrations, and both lime and potash are in maximum quantities in the leaves and stem when the sugar in these parts is at its maximum, and they are present in the seed in greatest quantities when the starch has reached its maximum. An increase of starch in the seed is always accompanied by a corresponding decrease of sugar in the stem.—D. A. L.

*Formation of Gum in Wood, and its Physiological Signification.* B. Frank and F. Temme. Bied. Centr. 14, 285-286.

THE authors state that the formation of gum in leaved trees takes place both in the wood vessels and cells, and also in the sap channels. Inasmuch as whenever and in whatever part of the plant a wound is made, there gum is sure to be found. From numerous observations they conclude that the function of gum in leaved trees is similar to the function of resin in conifera. The gum, in fact, serves to protect the wood beneath a wound from the action of air and water, and is found in all wounds whether caused by the falling of leaves, or ravages of insects, or frost, etc.—D. A. L.

*Preparation of Sugar from Beet without employing Sulphurous Acid, Animal Charcoal and Gravel.* R. Schmidt. Bied. Centr. 14, 286.

LIME and carbon-dioxide are alone used. No difficulties are encountered, and the yield and quality are good. (See *Deutsche Zucker-ind.* 10 Bd. 1885 [1], 9-10.)—D. A. L.

*Improved Method of Decolorising and Clearing Beet Juice by the Lime Process.* G. Fritzsche's Patent. Bied. Centr. 14, 286.

0.4% TO 0.6% of clay is taken for each 2½% to 4% of lime employed. The lime and clay are mixed with water, warmed, and boiled up with the juice. The whole is allowed to subside, and is decomposed with carbonic anhydride, etc. Many impurities are precipitated with the clay.—D. A. L.

*Preparation of Sugar and Purification of Beet Juices by means of Solutions of Magnesium and Aluminium Hydroxides.* Jünemann. Bied. Centr. 14, 358.

ALUMINIUM hydroxide is dissolved in solutions of aluminium chloride or sulphate, and dialysed until free from chlorine or sulphuric acid. The solution of aluminium hydroxide prepared in this manner yields almost perfectly pure sugar juices. Magnesium hydroxide solutions form granular crystalline magnesium saccharate insoluble in water, with hot sugar juices. (Compare this vol. 461.)—D. A. L.

*Drying Beet Cuttings.* Mäcker and H. Schultze. Bied. Centr. 14, 358.

THE cuttings from the presses are mixed with 1.5 per cent. of lime, as milk of lime; they are then reduced by pressure to 25 to 30 per cent. of dry matter, and are finally dried in a kiln.—D. A. L.

*Shaded and Unshaded Beets.* B. Lach. Bied. Centr.  
14, 394—396.

BETTS grown in the shade and in the open field were examined throughout the period of their growth from the middle of August to the end of October, from which observations it is evident that dry hot weather under certain circumstances increases the quantity of sugar in the shaded beets, or in beets cultivated in low and very damp ground. The yield from shaded beet plants is always less than from those not in the shade, although the quality is not inferior.—D. A. L.

*Improvements relating to Apparatus for treating Lignaceous Substances for the Production of Glucose.* H. H. Lake, London. From A. F. Le Mye, and W. de Peyster, Paris. Eng. Pat. 11,407, August 18, 1884.

THE improvements herein described are more especially applicable to the "Dangiville" process, in which gaseous HCl is employed to act upon cellulose or woody fibre for the formation of glucose. An annular column is used in which the cellulose is placed; the gaseous HCl is admitted from a main at several points; the annular space at such parts being enlarged to secure the distribution of the gas. The top is made funnel-shaped so as to be more convenient for the introduction of the material; the whole apparatus is kept cool by a stream of water. The operation is completed by washing out the unconverted woody tissue in the same column by a shower of water. The patentee claims considerable economy of time and material.—C. C. H.

*Improvements in the Manufacture of Sugar and in Apparatus therefor.* W. R. Lake. From F. O. Matthieson, U.S.A. Eng. Pat. 6432, May 26, 1885.

THE object of this invention is the cheap and rapid production of hard white crystalline sugar in the form of cubes or loaves. The process consists essentially of transforming into the above so-called hard sugars, various soft or granulated sugars, especially those known as "A" coffee sugars and "granulated sugars"—which soft and granulated sugars can themselves be prepared from sugars of comparatively low grades by one refining operation. The soft sugars are fitted into moulds of shapes and sizes which vary according to the particular form in which it is desired to obtain the final product. They may be previously dried or they may contain a certain amount of moisture, and they are then treated with a hot concentrated solution of white sugar, which on cooling cements the whole mass together by means of the sugar which crystallises out from the cooled solution. When thoroughly cooled, the mass is drained either by centrifugal or other means, and dried at a comparatively low temperature. The sugar produced has a peculiar glistening appearance, due to the presence of small sugar crystals, not only on its exterior, but also upon its planes of cleavage when broken. The charging of the sugar with "white liquor" may if preferred be performed in an air-tight chamber, from which when charged with sugar the air is exhausted before admitting the liquor. The temperature of the "white liquor," and also of the soft sugar to be operated upon, varies with the nature of the final product required; but the temperature of the "white liquor" may be as high as 220° F., or even higher. As by this method soft or granulated sugars or mixtures of the two are transformed into cakes of hard sugar by a process of cementation by crystallisation, the product of the process is designated "double crystallised sugar." Full descriptions of various kinds of plant and apparatus for carrying out the above process are given, with numerous diagrams.—A. J. K.

*Improvements in the Manufacture of Starch, Glucose and other Starch Products.* A. M. Clark, London. From the Davenport Glucose Manufacturing Co., U.S.A. Eng. Pat. 6661, June 2, 1885.

IN the ordinary process of preparing starch from corn and other grains it is usually the custom to add caustic

soda to the starch milk coming from the separators. Instead of caustic soda the author prefers dilute sulphuric acid. This precipitates the starch milk in the settlers, the liquid containing from 0.1 to 0.2 per cent. H<sub>2</sub>SO<sub>4</sub>. The acid stops fermentation and putrefaction instantly, and the separation of the solid matter is more rapid than when caustic soda is used; the acid water is drawn off from the starch when it has completely settled, and the latter is once more stirred up with a fresh quantity of 0.1 to 0.2 per cent. sulphuric acid. This liquid is then allowed to flow over the starch planes, where the starch settles in a hard mass nearly free from gluten. The trace of sulphuric acid which is present in starch prepared by this process is no detriment if the starch is to be used for the manufacture of glucose or grape-sugar. In cases where the presence of acid would be injurious, it is neutralised with soda and the alkaline sulphate removed by washing. The advantages claimed for the improved process over the old soda process are (1) increased cheapness of production, (2) immediate stoppage by the acid of fermentation and putrefaction, (3) no gluten is left in soluble form, as is the case when soda is used.—A. J. K.

## XVI.—BREWING, WINES, SPIRITS, Etc.

*Use of Grape-Sugar in Brewing.* Rep. Anal. Chem. 5, 188.

ALTHOUGH the Imperial German Brewing Tariff mentions grape-sugar as a malt-substitute, and indeed taxes it most heavily of all the brewing materials—viz., 4 marks per zentner—yet the magistrates of Kempen have fined a brewer for using grape-sugar. This judgment, which was confirmed on 4th March, 1885, by the Imperial Court, rests on the following ground. For longer than five years it has been known that impure grape-sugar (the pure being too expensive for brewing) contains substances incapable of fermentation and injurious to the product. Also that when this sugar is used, fusel-oil is eventually formed, which may under certain circumstances cause the beer to become injurious to health.—H. A. R.

*On the Chemistry of Wine.* R. Keyser. Rep. Anal. Chem. 4, 145; and 4, 167.

THE author remarks that, until a more satisfactory basis for the comparison of analyses of wines has been established, we must be contented with such relative results as can be attained with the wines of commerce; and he has collected together a large number of results obtained by him during the year 1883. The processes used were essentially those recommended by the "Society of Wine Analysts." In the sugar determination, 10cc. of Fehling's solution corresponded to 0.65grm. of sugar. For the glycerine estimation, an evaporation-correction of 0.1grm. was allowed for every 100cc. of fluid evaporated, but allowance was also made for any sugar or mineral matter present in the weighed glycerine. A determination of the specific gravity is of little or no value as enabling one to judge of the character of a wine. The analyses of wine given in the author's paper include determinations of the alcohol, extract, ash, total acidity, tartaric acid, sugar, glycerine, phosphoric acid, sulphuric acid, lime, magnesia, and potash. The tables are too long to be included here, and they include analyses of white and red wines from the Palatinate, from Wurtemberg and from the Moselle districts; also of Franco-German, Italian, Dalmatian, French and Spanish wines. The author has observed that the average percentages of magnesia and phosphoric acid are considerably less in wines that have been treated with grape sugar during fermentation, according to Gall's process ("Gallisierter Weine") than in those which have not been so treated. The wines examined may be classed in three groups:—1. Completely fermented wines, containing only small proportions of sugar, tannin, and colouring matter; to this class most of the German white wines belong. 2. Wines rich in tannin and colouring matter, and either completely fermented or containing less than 0.6 per cent. of sugar; to this class belong most red wines. 3. Wines containing considerable quantities of unfermented sugar (such as Malaga, etc.).—E. G. C.

*On the Nitrogen Compounds in Barley, Malt and Beer Worts.* Bungenier and Fries. Rep. Anal. Chem. **14**, 222.

THE authors' observations relate to the effect of malting, and the various brewing processes, upon the quantity and quality of the nitrogen compounds present in the grain. The increase of the soluble compounds by malting, the production of peptones at 40°, and the diminution of the same, together with albumenous bodies, upon heating the worts, are treated of in the paper.—E. G. C.

*On an Acid present in Hops.* H. Bungenier. Rep. Anal. Chem. **14**, 222.

THIS acid was extracted from fresh lupulin, 6 kilos, of hops yielding over 400grm. of the acid; it was then crystallised, first from solution in warm alcohol, and afterwards from petroleum ether. From the ethereal solution it is obtained in crystals 1cm. long; it is also soluble in water, in all proportions. This body yields a copper compound with acetate of copper; and its character appears to be that of a weak acid, or of an aldehyde.—E. G. C.

*Wine Coloured with Magenta.* Lepage. Bied. Centr. **14**, 286.

MAGENTA was added to wine in proportions equal to 0.20grm. per litre; after six or seven years this colouring matter could not be detected by any known test, either in the wine or in the deposit. It is hence inferred that magenta undergoes some change by prolonged contact with wine.—D. A. L.

*Addition of Yeast.* Thausing. Bied. Centr. **14**, 288. FROM brewing experiments with Vienna draught beer, it is proved that the addition of yeast in quantities ranging from one-third to two-thirds of a litre per hectolitre of wort exerts no noteworthy influence on the duration of fermentation, provided the temperature of fermentation remains the same.—D. A. L.

*Barley and Brewing Experiments from Experimental Brewery at Weihenstephan, Lintae.* Bied. Centr. **14**, 407-408.

THE following are the results of analyses of the 1883 barley from the Munich Scientific Brewery:—

DESCRIPTION OF BARLEY.	In 100 parts of dry matter.				Water.	Germinating Power.
	N.	Albumenoids.	P <sub>2</sub> O <sub>5</sub> .	Starch.		
Erding.....	1.616	10.29	1.003	71.28	8.46	30.80
Unterfranken .....	1.808	11.29	0.931	59.62	17.84	88.60
Bavarian barley.....	1.661	10.38	1.017	66.45	16.58	90.10
Franken.....	1.601	10.00	0.913	66.61	11.82	95.10
Freisinger barley .....	1.623	11.11	0.951	65.84	12.28	80.15
Moosburg .....	1.585	9.90	0.930	65.16	12.17	83.11
Langenback.....	1.680	10.50	0.935	65.82	12.67	90.00
Landshut .....	1.722	10.76	1.031	61.18	13.26	89.20

Brewing experiments were tried with these barleys. The fermentation was normal, but the yield was low, owing to the low germinating power of the barley; and the beer had a characteristic flat taste. Treatment with liquid carbonic anhydride improved the beer considerably in clearness, in taste, and in keeping properties. Carbonic acid has been successfully employed in bottling beer. Finally, the author observes that when barley is cultivated year after year in succession on the same land, without manure, the yield of barley decreases, although its composition does not suffer any important alteration.—D. A. L.

*Production of Spirit from Batatas edulis.* Bied. Centr. **14**, 339.

100KILOS, of these tubers (sweet potatoes) will yield 12.0 or even 13.4 litres of pure alcohol. The spirit is so pure that it is used for wine and in the manufacture of rum and brandy. When stored, the tubers require protection from light, air, and moisture, and a temperature of 8° to 12°. They contain about 67.50 per cent. of water, 10.20 per cent. of sugar, and 16.05 per cent. of starch. In the red variety there is 5.31 per cent. of sugar, and 0.76 of glucose; whilst the white variety contains 4.09 per cent. of sugar, and 0.63 of glucose.—D. A. L.

*An Alcoholic Ferment which does not invert Raw Sugar.* S. F. Teixeira. Bied. Centr. **14**, 416-417.

THE various ordinary ferments—mycoderma, saccharomyces—were removed from an Italian yeast by successive cultivations in cabbage-water, containing three per cent. of sugar, with 0.003 per cent. of acid potassium tartrate, and left a new yeast in a state of purity. This new yeast is remarkable for its stability of form, dimensions, and appearance (globular cells three to five-thousandths of a millimeter in diameter) under various conditions of cultivation, and moreover differs from all other yeasts that ferment saccharoses, inasmuch as it does not invert raw sugar. Hence it is suggested that it may be employed to separate glucose and raw sugar from molasses; the former would be converted into alcohol, whilst the latter would remain intact.—D. A. L.

XVII.—(A) CHEMISTRY OF FOOD. (B) SANITARY CHEMISTRY. (C) DISINFECTANTS, Etc.

(A) CHEMISTRY OF FOOD.

*Preservation of Milk.* F. Hueppe and W. Engling. Bied. Centr. **14**, 415-416.

By heating above 100°, the taste, appearance, and digestibility of milk are impaired. Therefore Hueppe recommends heating the milk in steam for forty-five minutes; all bacillus spores will be destroyed, and the milk will be perfectly fit for keeping. The same object may be attained by heating for one hour at 65° to 70° daily for five consecutive days. Engling remarks that

milk preserved in this manner gradually deposits casein containing a notable amount of calcium phosphate; this may be obviated to a certain extent by evaporating the milk to one-third its volume in a vacuum. The following figures show the composition of milk preserved in this manner, without addition of sugar:—

	1.	2.	3.	4.
Fat .....	10.82	11.25	12.3	13.1
Albumenoids.....	10.33	11.00	11.4	11.8
Milk sugar.....	11.59	12.12	12.6	14.5
Ash .....	2.01	2.21	2.2	2.3

No. 4 received some benzoic acid.—D. A. L.

*On the Examination of Butter.* M. Liebschütz. Jour. Amer. Chem. Soc. 7, 134.

THE author has adopted a modification of David's method of saponification by barium hydrate. Twenty grammes of the clarified butter-fat are saponified with barium hydrate, the alcohol is evaporated off, and the excess of barium removed by sulphuric acid, litmus being used as an indicator. The solution is filtered and concentrated to a syrup, but the glycerol so obtained is not pure. Strong alcohol throws down a large quantity of salts; the alcoholic solution is filtered, evaporated in a tared dish, and the residue dried in the air-bath above 100° C., to a constant weight. The still impure glycerine is then burnt, the weight of the ash being deducted from the total weight; the difference is glycerol. Pure butter gives 13.75 per cent. of glycerol by this method; oleomargarine yields 7.0 per cent. The glycerol derived from pure butter gives five per cent. of ash, while that yielded by oleomargarine is only 0.3 to 0.6 per cent.—E. G. C.

*Substitutes for Tartaric Acid in Baking Powders.* J. Napier. Analyst, 10, 124.

THE author refers to the frequent presence of lead in tartaric and citric acids, and in cream of tartar, substances largely used in the manufacture of baking powders; he condemns the use of bisulphate of potash as a

ozone and hydrogen peroxide aid the natural process of purification of water, but at any rate they only play a subordinate part. The author compares the natural purification of water to the formation of nitric acid in the soil. Müller (*Landw. Versuchsstat.* 16, 263; 20, 391) has already indicated the probability of the self-purification of water being a vital process.—D. A. L.

*The Purification of Water by Means of Iron on the Large Scale.* W. Anderson, M. Inst. C.E.; and G. H. Ogston, F.C.S. Proc. Inst. Civil Engineers, vol. 81.

THIS paper contains a description of the apparatus, devised by one of the authors, for effecting the purification of water by bringing it in contact with spongy iron, as used for purifying the water-supply of Antwerp. The passage of the water through the apparatus is continuous, and the means adopted for ensuring the cleanliness of the surfaces of the particles of iron enables the period of contact of the water and iron to be made much shorter than has hitherto been supposed to be requisite since the method was first proposed by Medlock. Instead of occupying about forty-five minutes, the maximum effect of purification of the Antwerp water is accomplished in 3.5 minutes. The quantity of iron entering into solution is 0.1 grain per gallon; longer contact increases the amount of iron taken up, and does not materially increase the purification. Mr. Ogston

#### THE PURIFICATION OF WATER BY MEANS OF IRON ON A LARGE SCALE

substitute, because of its purgative action; and he writes favourably of the acid phosphates of ammonia, potash, and lime, which can be obtained free from lead, and, together with bicarbonate of soda, are excellent producers of carbonic acid.—E. G. C.

#### (B) SANITARY CHEMISTRY.

*Natural Purification of Water.* F. Emich. Bied. Centr. 14, 292-293.

THE natural purification of water is shown to be a vital process. Experimental evidence demonstrates that the spontaneous purification of water only takes place when the development of organisms in the water is possible, thus water sterilised by boiling when exposed or agitated with sterilised air undergoes no purification; if, however, it is exposed to or agitated with ordinary air purification proceeds. Other experiments show that perhaps

has found that the quantity of albumenoid ammonia in different waters is reduced to from one-half to one-third the amount originally present, and the nitrogenous matter remaining behind totally resists the further action of the iron. He further shows that water so purified is practically sterilised, and generally fails to set up putrefactive fermentation in properly prepared solutions of meat extract. Hence he concludes that the nitrogenous matter left in solution is not such as will afford nourishment for the growth and multiplication of germs of infectious disease. The time of contact to secure the maximum amount of purification depends, of course, upon the relative impurity of the water. The apparatus is shown in the drawings on this and following page.

A is a wrought-iron cylinder capable of rotation on its axis, as will be readily understood from the drawing. B and C are trunnions by which the water respectively enters the cylinder from the main E, and delivers into the straining tank D, from whence it is run on to sand

filters for the oxidation and removal of the iron taken up. Fig. 2 shows the cylinder in section: during rotation the curved blades at the periphery carry the iron turnings up to the highest point and discharge them through the body of the water, thus ensuring proper

contact with the water and affording sufficient abrasion to keep the surfaces clean. Working upon fifteen million gallons per day, the cost per million gallons is 9s. 9d., and about twenty-eight pounds of iron are employed per million gallons of water purified.

—C. C. H.

*On the Presence of Lead in Glazed and Enamelled Cooking Vessels.* H. Fleck. Rep. Anal. Chem. 15, 234.

The author has determined the quantities of lead, yielded by glazed vessels, from different manufacturers, and of varying capacity, to vinegar, of from 4–8 per cent. strength, heated in them for one hour. The results obtained are comprised in the following table:—

Capacity of Cooking Vessel.	Lead dissolved on heating with			Total lead dissolved in the three experiments.
	4 per cent. vinegar.	8 per cent. vinegar.	4 per cent. vinegar.	
I. 725cc.	0'0354grm.	0'0018grm.	0'0032grm.	0'0404grm.
II. 2170	0'0069	0'0066	0'0037	0'0169
III. 1085	0'0172	0'0151	0'0123	0'0446
IV. 1110	0'0062	0'0011	0'0022	0'0095
V. 1045	0'0018	0'0069	0'0013	0'0099
VI. 2550	0'0113	0'0152	0'0108	0'0373
VII. 1520	0'0013	0'0035	0'0009	0'0057
VIII. 1035	—	—	—	—
IX. 1310	0'0046	0'0029	0'0006	0'0072
X. 2150	0'0015	0'0011	0'0007	0'0033

A glance at the above table is sufficient to indicate how differently some glazes behave to others, under precisely similar conditions. The result with the glazed vessel No. VIII., shows that a glaze may contain lead, and yet remain unaffected by vinegar.—E. G. C.

*The Effect of the Drought of 1884 upon the Pollution of the River Thames below London.* R. W. Peregrine Birch, M. Inst. C.E. Proc. Inst. Civil Engineers, vol. 81.

In a former paper in the same journal the author described a method of calculation now known as the "chlorine method" used by him in 1882 to determine the rate at which the Metropolitan sewage is carried away by the river, and the extent of the sewage pollution. The present paper gives an account of observations made during the drought of 1884. The following conclusions are arrived at. All the fresh water and sewage which had entered the river between Teddington and Southend since June 25 was still there on September 8, and that which had entered on June 16 was still there on August

30. The sewage had remained in the river 45 days, and the fresh water occupied 75 days for its passage from Teddington Weir to Southend. There was less fresh water and more salt water in the river than in September, 1882, and the foul mixture travelled seawards at a much slower rate. The calculations also show that though in time of drought there is more sea water in a tidal estuary than a wet season, its circulation is so slow that its effect as a diluent is greatly reduced. The circulation in November, 1882, a time of flood, was nearly three times as great as in August, 1884, a time of prolonged drought.

—C. C. H.

*Action of Water on Lead Pipes.* C. Schneider. Rep. Anal. Chem. 10, 158.

The soft water of the river Bober, supplying the town of Sprottan, and although containing only traces of sulphuric acid and calcium salts, dissolves considerable quantities of lead from new lead piping. A new lead pipe, 20 metres long, was filled with Bober water, and left to stand 48 hours; the amount of lead dissolved was found to be 0'502grm. per hectolitre. Difficultly-soluble deposits, which form a protecting layer on the insides of the pipes, are thrown down in a short time, not, however, under a period of 24–26 hours. Hard spring-water (containing in a hectolitre 106'9grm. of non-volatile constituents, 10'5grm. of sulphuric acid, 14'44grm. of chlorine, 11'20grm. of lime, and no inconsiderable quantity of nitric acid) dissolved a quantity of lead amounting to 0'351grm. per hectolitre. The author considers that even a small quantity of carbonic acid, accompanied by dissolved air, is sufficient cause for the solvent action of a water upon lead pipes.—E. G. C.

*An Improved Method of Softening Water.* P. A. Maignen, London. Eng. Pat. 5745, June 9, 1884.

The softening of the water is effected by the addition of a finely-divided mixture of lime, soda, and alum.

—C. C. H.

*Improvements in the Method of Treating Town Refuse, and Furnace and Apparatus therefor.* B. D. Healey, Liverpool; and B. H. Thwaite, St. Neots. Eng. Pat. 10,035, July 11, 1884.

This invention relates to improvements in the furnaces commonly called "destructors," used for burning town refuse, and to appliances for the treatment of the products therefrom. The furnace is constructed with a receiving pit at the level of the roadway, a drying chamber with a sloping bottom, and an inclined fire-grate. A hydraulic lift is provided for the elevation of the clinkers, which are removed from the fire automatically by a reciprocating motion given to the firebars similar to that in "Vicar's" mechanical stoker. A condensing

apparatus is placed in the flues so as to obtain useful products from the gases, and to ensure the destruction of all noxious vapours.—C. C. H.

*Improvements in Filtering and Treating Sewage.* J. Carter, London. Eng. Pat. 10,973, August 6, 1884 (completed April 28, 1885).

The sewage is collected in a tank or "sewage meter," where it is screened and then precipitated by slaked stone lime, "burned alum," and fine ashes. The mud precipitated is squeezed in long bags horizontally disposed in a suitable press, the bags capable of being opened at both ends. The liquid from precipitation is passed through filtering sacks.—C. C. H.

*An Apparatus for making Fresh Water from Salt Water.* A. Chapman, Liverpool. Eng. Pat. 11,461, August 20, 1884.

THE principle of this apparatus is that of evaporation by multiple effect combined with "evaporation by compression." Three or more closed evaporating vessels are

arranged vertically over each other, or otherwise in series. Each pan contains a surface condensing drum open at the lower part to the atmosphere of the pan below it, as shown in the illustration. Sea water is

pumped into the lower vessel A, through pipe X, and exhaust steam from the engine which works the pumps enters the drum A<sup>1</sup>, through the pipe a; part of the vapour generated in A is withdrawn by a compression pump and forced into A along with the exhaust steam. Further evaporation takes place in A, and the steam in A<sup>1</sup> is condensed and led away by pipe a<sup>1</sup> to a receiver. By excess of pressure, water from A passes through pipe a into pan B, in which evaporation is effected by drum B<sup>1</sup> heated by steam, entering it from pan A through b. The condensed water in B<sup>1</sup> is led away through b<sup>1</sup>. The operation in pan C is similar; water enters from B through pipe c, steam is supplied to drum C<sup>1</sup> through pipe c, and the water condensed led away by pipe c<sup>1</sup>. The vapour from C is condensed in drum D<sup>1</sup>, situated in condenser D. The condensed water from the three pans passes through a cooler imparting its heat to the cold sea-water fed into the apparatus. The operation in the pans is conducted under reduced pressure by means of an air-pump in connection with the condenser D, and the air thus withdrawn utilised for aerating the fresh water obtained from the pans. The sea-water from the top pan is drawn off by a pump and passed through a heater to a steam boiler which supplies the steam to the whole apparatus. The concentrated water from the boiler is frequently blown off, passing first through the heater, giving some of its heat to the partially evaporated water fed into the boiler, and finally through the cooler above mentioned, where it gives up a further quantity of heat to the cold sea-water pumped into the evaporating pans. Little or no heat therefore escapes from the system. The patentee claims the general construction and combination of the apparatus described.—C. C. H.

*Improvements in the Preparation of Agents to be used in the Treatment of Sewage, etc., and Improvements in the Treatment of such Matters.* E. J. Leveson and J. W. Slater, London. Eng. Pat. 11,641, Aug. 26, 1884.

"KIMMERIDGE blackstone shale," or any other shale which contains alumina in a form readily soluble in hydrochloric acid, and in addition 15 per cent. or more of carbon, is treated with hydrochloric acid and allowed to stand. The mixture so prepared is used for the defecation of sewage in conjunction with chloride of copper, carbon and clay. In all cases the sewage, if acid, must be neutralised. Precipitation is effected in the usual way in tanks. The claims are—(1) the preparation of the shale, (2) the treatment by the reagents as described.—C. C. H.

*Improvements in Apparatus for Purifying Water.* W. Anderson, Westminster. Eng. Pat. 12,256, September 10, 1884.

THE present invention is to remedy a defect in apparatus for which a former patent was granted.—C. C. H.

*Improvements in the Purification of Sewage and other Foul Liquids, and in Apparatus therefor.* W. Donaldson, I. Shone and E. Ault, London. Eng. Pat. 12,643, September 20, 1884.

IT is proposed to purify sewage by the oxygenating action of the air, alone, or mixed with other gases, such as sulphuric anhydride, oxygen, chlorine, etc. Three methods are proposed:—(1) submitting the sewage in the form of a spray to the action of the air or gases in closed spray chambers; (2) forcing the sewage into the air in the form of a jet, spray, or fountain, thus securing oxygenation and purification; (3) cascading the sewage through the air in the form of a spray from a higher to a lower level through perforated plates. By using one of these methods it is claimed that the oxygen "burns or oxygenates the impurities of the liquid under treatment."—C. C. H.

*Improvements in the Purification of Water, etc.* F. R. Conder, Guildford. Eng. Pat. 6459, May 27, 1885.

FOR the purpose of (1) purifying sewage or water contaminated with organic matter, or (2) for facilitating the

filtration of impure water, or (3) for the preservation of meat, the patentee proposes to use sulphate of iron either in solution or in the crystallised form. In the case of the meat, the surface is covered with a solution of the sulphate iron. Three claims are made for the applications as above described.—C. C. H.

### (C) DISINFECTANTS, ETC.

*Activity of Antiseptics.* Ratimoff. Bied. Centr. 14, 360.

SEVENTEEN antiseptics were tested on septic and putrefactive bacteria, and on microbes. Determinations were made of the quantity of each antiseptic required to kill or sterilise, and of the quantities which were insufficient to kill or sterilise. From the results of these investigations the antiseptics are arranged in the following order of activity:—(1) Mercuric chloride, (2) silver nitrate, (3) iodine, (4) thymol, (5) copper sulphate, (6) salicylic acid, (7) zinc chloride, (8) phenol, (9) quiniol, (10) kairine, (11) resorcinol, (12) chloral hydrate, (13) boric acid, (14) alcohol, (15) oil of gaultheria, (16) bitter-almond oil, (17) eucalyptus oil. The following table illustrates the mode of observation, and the action on meat broth of some antiseptics, diluted as indicated:—

ANTISEPTIC.	MICROBES.		BACTERIA.			
			Putrefactive.		Septic.	
	Sterilised.	Not Sterilised.	Killed.	Not Killed.	Killed.	Not Killed.
Mercuric Chloride.....	1: 13,300	1: 25,000	1: 800,000	1: 1,000,000	1: 66,700	1: 100,000
Thymol .....	1: 2,000	1: 5,000	1: 25,000	1: 50,000	—	—
Salicylic Acid .....	1: 400	1: 500	1: 1,200	1: 2,000	1: 1,000	1: 2,000
Phenol .....	1: 400	1: 500	1: 570	1: 670	—	—

—D. A. L

*A Combined Disinfecting and Fumigating Compound.* T. Stoner, Bradford; and J. Turton, Shipley. Eng. Pat. 4677, April 16, 1885.

TWELVE parts of finely-crushed common salt are mixed with two parts of tar-oil of 0.700 specific gravity, one part of carbolic acid of 1000 specific gravity, and one quarter part of oil of eucalyptus; chemical action ensues, "the quantity of carbolic acid increases," and the colour changes from yellow to dark grey. Powdered wormwood may be added, equal to one quarter part, when the compound is not required to be wholly soluble in water.—C. C. H.

### XVIII.—ELECTRO-CHEMISTRY.

*Improvements in Electrodes for Secondary Batteries.* R. Tamine, Mons, Belgium. Eng. Pat. 12,824, September 26, 1884.

The author proposes to construct electrodes by heating rosin to its fusing point and adding a mixture of peroxide of lead and lead filings, then letting the mass cement together under a pressure of upwards of one hundred atmospheres.—T.

*Improvements in Secondary Batteries, partly also applicable to Primary Batteries.* G. G. André, Dorking. Eng. Pat. 13,752, October 17, 1884.

A BATTERY is constructed of elements of two different lengths for convenience of connection, which consist of wooden cores soaked in paraffin and lapped round with a layer of sheet lead or wire; these are held in the cell by a removable frame in such a way that they can be bodily removed and sent to the charging station without necessitating the transport of the cell with the electrolyte contained therein.—T.

*Improvements in Secondary Electric Batteries or Electric Accumulators.* C. S. Bradley, Yonkers, U.S.A. Eng. Pat. 2463, February 24, 1885.

AN electrolyte consisting of a nearly saturated solution of a metallic bromide is used, the metal being deposited upon one electrode, and the bromine being set free at the other electrode, and taken up by the solution when the battery is charged.—T.

*Improvements in Smelting Ores by an Electric Current, and in Furnaces or Apparatus therefor.* Eugene H. Cowles and Alfred H. Cowles, both of Cleveland, Cuyhoga County, State of Ohio, U.S.A. Eng. Pat. 6994, June 9, 1885.

THIS process consists in using granular material of high resistance, mixed with the ore to be reduced, which is placed in a retort constructed of non-conducting material embedded in a substance such as mineral wool, which is not a good conductor of heat. An electric current is made to traverse the entire length of the retort, passing at the same time through the mixed substances required to be reduced.—T.

### XIX.—PAPER, PASTEBOARD, Etc.

*The Art of making Paper by the Machine.* J. W. Wyatt. Proc. Inst. Civil Engineers, vol. 79, 1884—1885.

1. MATERIALS: Linen, cotton, esparto.

2. MANUFACTURE: Cutting and dusting, boiling, reducing to pulp; (a) breaking, including bleaching and washing; (b) beating, producing a felted web by means of the paper-making machine; sizing, including animal and vegetable; glazing, finishing.

1. *Materials.*—Vegetable fibre contains 75% to 78% of cellulose, together with glutinous, resinous, siliceous and other intercellular matter which is the object of the paper-maker to remove as far as possible. Rags, having already undergone a process of manufacture, consist of almost pure fibres, and merely require boiling with an alkaline solution at a low pressure. The substitutes, however, contain all intercellular matter in its original form. Cellulose is untouched by boiling with NaHO, unless the action is carried too far. With long and careful manipulation in the pulping-engines, taking precaution to draw the fibre and not to cut it, new cotton will give a much stronger and closer paper than new linen. The author considers that the strongest paper is made from new cotton, and one-fifth or one-sixth of its bulk of new linen. The peculiar value of esparto is the ease with which it is bleached, producing a paper of great whiteness, non-transparent, and when animal-sized, comparing most favourably with that obtained from rags. The fibres of wood are short and brittle as compared with the above-mentioned fibres, and when used alone impart their characteristics to the paper, being too short and thick to yield that suppleness so characteristic of rag-paper. The Russian supply of rags is almost entirely linen, and that of a very strong and fine quality, but coarsely spun, and low in colour.

French and Dutch rags are chiefly cotton, while the German rags are chiefly linen. New linen and cotton cuttings from Great Britain are much superior to those from abroad, being finer and purer. French cottons (used) are flimsy, and when new full of loading and starch. Esparto grass (*Stipa Tenacissima*, or *Machrochloa Tenacissima*), so called in Spain, and Alfa in Africa, is a spontaneous product of the siliceous and ferruginous soils of South and East Spain and North Africa. The

cotton rags lose about 27%. 100lb. of raw esparto produces about 31lb. of paper; 100lb. of raw picked flax yield 56lb. of retted flax and only 9lb. of finished yarn, 63lb. of bleached yarn; and after losing about 25% in being made into paper, this gives only 5lb. of paper from 100lb. flax; 100lb. of raw picked seed cotton gins into 33-4lb. of ginned cotton. From this 29-4lb. of white cotton yarn are got, and a loss of 20% in conversion gives 23-6lb. paper per 100lb. raw cotton.

Spanish grass is shorter and less handsome, but much more easily boiled with less alkali, and bleaches to a good white. The Alfa grass, which is greener and straighter, wastes more, does not come up in colour, and gives a weaker paper. Esparto, during process, has a total loss of about 48%, while all grades of linen and

2. *Manufacture.*—Rags are sorted as follows: Linen and cotton, used and unused, bleached and unbleached, old and new colours and prints, blues, etc. These classes are further subdivided for strength and cleanliness. Rags are first passed through a revolving duster in bulk, and are then cut by hand into pieces of about 14 inches

square. The inherent moisture is from 3% to 6% according to quality, but should not be more. The waste varies with the age and coarseness of the material.

Waste in preliminary dusting and sorting=0.1% to 6%.  
 " cutting and final dusting (for fine new cottons)=1% to 1.3%.  
 " cutting and final dusting (for coarse white cottons)=2% to 4%.  
 " cutting and final dusting (for fine white linens)=1.5% to 2.5%.  
 " cutting and final dusting (for coarse linens)=2.5% to 3%.  
 " cutting and final dusting (for lower grades)=1% higher.

Esparto, after overhauling, is passed through a thrashing-machine, and is then ready for the boiler. The boilers used are either rotary or stationary—the rotary boiler being often 10 to 25 feet long by 7 feet or more. Frequently they are spherical instead of being cylindrical, and about 8 feet in diameter. An ordinary stationary boiler will take 12 to 18 cwt. of rags, and will be worked at 10 lb. for from 14 to 12 hours according to material and quality. The alkaline lye used varies, some using lime, others soda, others a mixture of the two. For esparto the pressure is kept at 35 to 40 lb. for best grass, the time being 3 to 4 hours. After this boil another is given with plain water for about an hour at 12 to 15 lb. in order to remove all caustic solution. Of course steam pressure, amount and strength of lye, etc., varies in every mill. For overhauling after boiling, a machine has been devised similar to, and on the same principle as the paper-machine. The stuff leaves this machine containing about 50% of H<sub>2</sub>O, and ready for the heating-engine. Before the present pulping engines were invented, rags were reduced to their original fibres by pounding under heavy hammers. It was a lengthy and cumbersome process, and soon gave way to the "Holländer." For low papers—i.e., wrappers, etc.—the whole process takes place in one engine; but this will not do for higher classes, as the rolls and bars, while suitable for opening, are not suitable for reducing it to fine pulp. Engines are made to hold almost any quantity, varying from 150 lb. to upwards of 1000 lb. of dry paper. Before bleaching is commenced, all signs of textile nature must have been removed from the material, and afterwards all chlorine must be carefully removed from the pulp to prevent any after action. A heat of 120° to 130° F. is sufficient, and the bleach solution should stand at about 5° Tw. Grass requires 22 to 30 gallons per cwt. of paper made, cotton rags 3 to 11 gallons, and linen rags 11 to 24 gallons. Prouteaux estimates the loss in bleaching at about 1.5% to 3.5% for finer rags, and from 2.8% to 7.5% for coarser grades. The object of adding starch to sizing materials in paper is to render it denser, stiffer, and less spongy. Usually 2% to 4% or more is employed, and added either to the engine direct or else mixed with the size. Writing and printing paper can be made to carry with ease 10% to 20% of clay, and wrappers more than 25%. A considerable amount of attention requires to be given to the drying process in the paper-machine, and Hoffmann calculates about  $\frac{1}{10}$  lb. of coal as being required for drying 1 lb. of paper. The average speed of a paper-machine on fine writings is from 60 to 70 feet per minute, but on thinner weights the machine may be driven up to 120 feet per minute. A ton of good hide-clippings will produce from 2100 to 2600 gallons of size, which, when diluted to working strength, will give about 2500 to 3100 gallons, and will size from 24,000 to 48,000 lb. of paper already one-third engine-sized. Generally 10 lb. of alum are required per 100 gallons of size. The following recipe is given for a non-absorbent engine-size:—Dissolve 55 lb. of soda-ash at 57° in 60 gallons of boiling water, and in this lye dissolve 6 cwt. of ground resin. When cool remove the top layer, which is dark brown, and dilute the lower part with 12 to 13 volumes of water for use. An equivalent quantity of Al<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub> at 7° Tw. will be required for precipitating, and these quantities will size about 20,000 lb. of paper. The cost per lb. of engine-sizing is about 0.068 d., and that of animal-sizing about 0.486 d. All the better papers require smoothing more or less, and this may be done either in the web or in single sheets by hand. Glazing by hand costs for

wages and repairs about 0.32 d. per lb., calculated on 3,250,000 lb. per annum, and with 17 hand-machines. An ordinary web calender will surface at about 300 feet per minute. A very high surface may be given to paper very quickly by "burnishing"—i.e. friction and heat. Generally one surface only of the web is so treated. A chilled roll is used on one of cotton or paper, the ratio being 4:5 =  $\frac{4}{5}$  friction. The highest pressure in either hand or calender glazing amounts to  $\frac{1}{4}$  to 1 ton per running inch across the web. The great bulk of the power required is consumed in driving pulping engines. The total horse-power for all purposes may be roughly put at 300 horse-power per 1000 tons of paper per annum for an engine-sized mill, and 380 horse-power for same amount for a tub-sized mill; 75% of this power is consumed in driving pulping engines. This paper is accompanied by two most valuable plates, with illustrations of paper-making machinery, and contains a mass of interesting and useful information for which the original should be consulted.—H. A. R.

Testing Paper. W. Hertzberg. Rep. Anal. Chem. 5, 189.

THERE is in Prussia a Government laboratory where paper is subjected to various tests. These are *mechanical tests*—i.e., examination as to strength and resistance to tearing,—and *physico-chemical tests*, including the microscopic examination of the fibre, the sizing, determination of certain chemical constituents, of the amount of ash, etc., of different papers. Good paper boiled in water ought not to be changed, whilst a bad paper falls to pieces. The presence of size made from animal matter is determined by treating the aqueous extract of the paper with mercuric chloride, and then with caustic soda. The yellow precipitate, by subsequent heating, is reduced to a black precipitate of metallic mercury, a reaction not ensuing if vegetable sizing materials have been used. The testing as to the permanence and strength of the sizing itself ("Leinfestigkeit") is determined by means of aqueous tannin solution and ferric chloride. The amount of potato starch used for fixing the size is determined by the blue shade produced on dipping the sample in iodine solution. In papers used for certain chemical purposes, it is necessary to be acquainted with the amount of iron present. Mechanical wood pulp is tested for iron with phloroglucol solution, which colours the paper made from it a blood-red tint. Sometimes even free alkali or free acid may have to be sought for. The amount of ash in good papers may, it is stated, reach so high a figure as 1.5 per cent. (*Industrieblätter. Jahrg. xxii. [9].*)—W. S.

Improvements in the Manufacture of Paper Pulp. A. Mitscherlich, Germany. Eng. Pat. 11,816, August 30, 1884.

THE main novel points in this invention are as follows:—(1.) An improved process for mechanically purifying cellulose by guiding the pulp, greatly diluted with water, in a horizontal direction, and at a low velocity, through long and wide channels, and afterwards vertically through a large slit sieve arranged below the level of the liquid, and agitated with a slow vertically alternating motion, substantially for the purpose set forth. (2.) An improved process for drying paper pulp by means of a continuous centrifugal apparatus, in which the water is removed, while the paper pulp remaining on the inside of the screens, forming the surface of the apparatus, is discharged therefrom in consequence of the inclined position of the apparatus.—H. A. R.

Improvements in the Process of, and Apparatus for Boiling Wood with Sulphites. A. Mitscherlich, Germany. Eng. Pat. 11,655, August 26, 1884.

THE most important points in this invention are—(1.) The construction of air-tight kilns by using bricks steeped, when hot, in tar, and by cementing them with mortar containing quartz sand, sieved coal, ashes, etc., with tar. (2.) The conducting of the hot gases through a U-shaped system, cooled by the ordinary current, and, if required, by a special draught. (3.) The employment

of the various descriptions of wood for the production of sulphite cellulose of the dimensions specially laid down, and with removal of the bast, and in the case of larch and Scotch fir also of the core. (4.) The method of boiling sawdust in small heaps between larger pieces of wood. (5.) The method of preventing the spent liquors from sulphite boilings from being obnoxious, by discharging the same through iron pipes into collecting tanks containing cold liquid, and then causing the same to mix with about one thousand times their volume of water. (6.) The method of avoiding discoloration of the cellulose by keeping the temperature of the material at or below about 212° F., both before and after the reaction has taken place.—H. A. R.

*Improvements in Sizing Paper.* A. Mitscherlich, Germany. Eng. Pat. 12,566, September 18, 1884.

THIS invention relates to the use in the sizing of paper of materials, such as the extract obtained when fir (*Picea abies* L. or *Picea excelsa*) is subjected to a process of sulphite boiling. "By this new method of sizing certain paper materials special advantages are obtained. In sizing, for instance, the sulphite cellulose, by use of a sufficient quantity of this glue material (extract and resin soap), under otherwise equal conditions, I get, by the

duction reduced. A scraper, heated by steam, is applied to act on the under surface of the paper immediately on leaving the hot-pressing rolls through which it passes on leaving the bath. The scraper has a bevelled edge, and is heated by conduction by a steam pipe passing through a slot along the whole length of the back of the scraper. The arrangement can be adjusted by screws, and the superfluous matter removed is returned to the bath. Drawings are given, fully illustrating the apparatus.

—H. A. R.

*Improved Process and Apparatus for Bleaching Waste-Papers.* Wm. Clark, London. From E. A. D. Guichard, Paris. Eng. Pat. 12,385, September 13, 1884.

"WASTE printed and manuscript paper has never hitherto been bleached sufficiently to make it suitable for forming a pulp for the manufacture of white paper." This invention relates to the treatment of such paper mechanically in presence of a bleaching liquid. The machine is illustrated in the accompanying drawing, Fig. 1 being a longitudinal section, and Fig. 2 a transverse section of one arrangement. Fig. 3 shows the interior surface of the drum in the flat, and Fig. 4 is a section taken through the walls of the drum to show the studs fixed therein. A wood drum *a* of suitable dimensions is provided with an opening, at which paper and bleaching liquor is intro-

afterwards described proceeding, a transparent and very strong product, which, comparatively, is not too brittle, and similar to the paper parchment." If paper sized by this process be further filled with a body like linseed oil, the inventor claims an increase in strength up to 70 per cent., and nearly perfect transparency. The use of such paper is suggested for tracing purposes, for use instead of dim paues of glass, and generally for the uses to which such transparent papers are put, as are intended to give protection against atmospheric influences at a very low expense; also for the manufacture of board and papier-maché textures.—H. A. R.

*Improvement in Machines for Waxing and Oiling Paper.* H. Mason and W. Rawlinson, Middlesex. Eng. Pat. 547, January 14, 1885.

THE object of this invention is to equalise the deposit, and remove the superfluous wax or oil, whereby the quality of the paper is improved, and the cost of pro-

duced and closed by a wood cover *b*, faced with india-rubber, so as to make a water-tight joint. The interior of the drum is studded with bosses, as shown in Fig. 3. It is also provided with end journals *c*, on which it is mounted in frame *d*, and with a cock *h* for running off the spent liquor. After being cut up, the materials are placed in the cylinder with a quantity of pebbles, and a number of balls of cast-iron or stone, etc. When the drum is revolved the balls and pebbles reduce the paper to pulp, and by means of the bosses the balls and pebbles are projected in all directions. After adding the bleaching liquid required, the drum is revolved until the liquid is almost black, and the operation then repeated if required. Subsequently the pulp is treated in the hydro-extractor to produce cakes of half-stuff with 40–50% of water. The following mixture is recommended for a bleaching liquid:—

Spirits of turpentine .....	2 parts.
Bleaching liquor.....	9 „
Soap-suds.....	9 „

The machine may be modified as shown in the sectional elevation in Fig. 5, in which the same letters of reference indicate the same parts as in the previous figures. The improvement consists in fixing a grating or wire cover *j* over the discharge orifice *k*, which is placed at one end of the drum so as to allow of none but clear liquid to pass and to prevent the outlet being choked. The grating *k* is prevented from being clogged by pulp by pressing against a brush *l*, extending its whole length, and fixed upon the rod *m*, one end of which is supported in the

to effect the said change is applied in the form of a bath, and is made as follows:—

Glycerol ..... 6 parts by weight.  
Calcium chloride ..... 4     "     "  
Add water until sp. gr. = 1.8–2.0° B.

The sheets of parchment, as they come from the maker, are to be immersed in this bath, for a time varying with the thickness of the sheets and the degree of softness required.—H. A. R.

FIG. 5.

FIG. 6.

hollow inlet pipe *h*, at which the bleaching liquid is introduced, the other end being fitted centrally in the grating *j*. In Fig. 6 the rod *m* is dispensed with, and the inlet and outlet for the liquid is at the same end of the drum. For this purpose the inlet pipe *h* is carried through the back *n* of the brush, and is wholly enclosed thereby, so as to be protected from injury by the pebbles and balls. After passing through the grating *j*, the liquid is received in chamber *o*, bolted to the drum, and escapes through openings *p*.—H. A. R.

*Improved Apparatus and Process for obtaining Cellulose and Glucose from Wood.* Adolph Behr, Cöthen, Germany. Eng. Pat. 1767, February 9, 1885.

THIS specification relates to improvements in apparatus described in inventor's patent of July 5, 1884, No. 9797. As novel are claimed the arrangement or combination of several extraction cylinders and their connections with each other, also the construction of the extraction cylinder itself with heating chamber, perforated plates, coolers and stand-pipes.—H. A. R.

*Improvements in Softening Vegetable Parchment.* H. H. Leigh, Middlesex. From C. Eichhorn, of Jülich; and T. Mohr, of Stozheim, Germany. Eng. Pat. 3610, May 6, 1885.

INVENTOR claims to be able to render vegetable parchment supple and soft, and more suitable for covering jars and bottles, as well as for other purposes, for which it would be totally unfit as long as it retained its characteristic crispness and non-elasticity. The substance used

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

*Quantitative Determination of Cinchonidine in Commercial Sulphate of Quinine.* De Vrij. Arch. d. Pharm. 11, 452.

FIVE grm. of the preparation are dissolved in 11cc. of normal sulphuric acid, by warming to about 60° C. The solution is evaporated in a weighed dish till a pellicle forms, and allowed to crystallise. A quantity of distilled water is then added, sufficient to make up the original weight, and the solution which contains the cinchonidine as acid sulphate is shaken with excess of soda and 25grm. of ether. The latter brings the separated cinchonidine in crystals to the surface of the liquid, where they can be collected and weighed. By this method a mixture of 2 per cent. of cinchonidine with quinine sulphate can be detected.—E. G. C.

*Improvements in the Manufacture of Salicylic Acid, and of the Homologues thereof.* J. Y. Johnson, London. From Dr. F. von Heyden, Dresden. Eng. Pat. 10,167, July 15, 1884.

THE object of this invention is to produce one molecule of salicylic acid from one molecule of sodium phenylate without the re-formation of phenol as in the ordinary way. Three methods are described. (1.) Dry CO<sub>2</sub> at the ordinary temperature is passed over dry sodium phenylate; phenyl sodium carbonate is formed. This is heated in a digester to from 120° to 140° C. The salicylic salt is formed by molecular transformation, is then dissolved in water and the acid precipitated by means of a mineral acid, and then recrystallised. (2.) Dry alkaline phenylates are placed in a closed vessel into which dry CO<sub>2</sub> is forced by a

pump or else by the evolution of gas from liquid  $\text{CO}_2$ . If the vessel be kept cool during the process no phenol separates. The phenyl carbonic salt is transformed by heat as before. (3.) The reaction described in (2) is effected by the introduction of solid  $\text{CO}_2$ , and proceeding as before. The patentee claims the production of phenyl carbonic alkaline salts, etc., and the substitution salts and homologues as above described.—C. C. II.

*Improvements in Anæsthetics.* From Robert Jackson Hunter, of Boston, U.S.A.. Eng. Pat. 7343, June 16, 1885.

THIS invention relates to the production of an anæsthetic by mixing nitrous oxide gas with the vapour of alcoholic tinctures of various sedative, anti-spasmodic or diaphoretic substances, such as hops, stramonium, or valerian.—T.

## XXII.—GENERAL ANALYTICAL CHEMISTRY.

*Two New Indicators for use in the Volumetric Determination of Caustic Alkalis in the presence of Carbonates.* R. Engel and J. Ville. Compt. Rend. 100, 1074.

THESE are sulphindigotic acid and Poirrier's soluble blue (c 4 B.), which are not affected by carbonates, but are altered in colour by caustic alkalis, the first-named being changed to yellow and the second to red. The sulphindigotic acid is prepared by neutralising a solution of indigo in fuming sulphuric acid with calcium carbonate, adding ten times the volume of water, and filtering.—E. G. C.

*Separation of Copper and Cadmium.* A. Béhal. Journ. Pharm. Chim. 5 Ser. 11, 553.

A STRONGLY alkaline solution of sodium tartrate produces no precipitate in a solution containing a mixture of copper and cadmium salts. On boiling the solution, all the cadmium is thrown down as oxide, the copper remaining in solution. Ammonium salts must be destroyed by boiling with a slight excess of alkali.—E. G. C.

*New Method for the Determination of Phosphoric Acid by Precipitation with Molybdenum.* Meineke. Rep. Anal. Chem. 5, 153.

THE yellow precipitate, produced by the action of ammonium molybdate on phosphoric acid, loses water and ammonia when heated from 400–500°C., and becomes partially converted into molybdic-molybdenum oxide, a compound which is very stable, only slightly hygroscopic, and admits of accurate weighing. The author finds that it contains 4.018 per cent.  $\text{P}_2\text{O}_5$ , 65.195 per cent. Mo, and 30.787 per cent. O, corresponding to the formula  $\text{P}_2\text{O}_5 \cdot 4(\text{Mo}_6\text{O}_{17})$ . The solution of the phosphate, acidulated with nitric acid, and containing about 20–25 per cent. of ammonium nitrate, is precipitated at 50–60°C. and allowed to stand without further warming for some hours. The precipitate is collected on a filter and washed with a 20 per cent. solution of ammonium nitrate (slightly acidified with nitric acid) until ten drops give no precipitate with sulphuretted hydrogen, and then with water, or with smaller quantities of water, alcohol and ether. The precipitate and filter paper are as far as possible separated, and ignited separately, the filter paper at as low a temperature as possible. The ashes are then added to the precipitate, and the temperature is raised, so as to be sufficient to cause a slow decomposition of the precipitate, which gradually blackens. When the decomposition is complete, the precipitate, which contains 4.018 per cent. of  $\text{P}_2\text{O}_5$ , is allowed to cool, and weighed. The results are accurate.—E. G. C.

*On Sources of Error in the Determination of Phosphoric Acid.* J. König. Rep. Anal. Chem. 4, 161.

IN numerous cases annoying discrepancies between duplicate determinations of phosphoric acid by different chemists can be traced to incorrect sampling, but the author points out that in a great number of cases these differences are due to the unequal purity of the reagents used. For instance, he has met with molybdic acid, which, employed in the usual manner for the preparation of the molybdic solution, yielded, by reason of its greater impurity, results several percentages too low, as compared with a solution made from pure molybdic acid. Great care is necessary in preparing molybdic acid from molybdic residues in the laboratory. Samples of molybdic acid from three different firms were tested qualitatively for chlorine, nitric acid, and ammonia, and the loss on gentle ignition was determined quantitatively, from which it is obvious that differences in composition between different samples of molybdic acid, or of ammonium molybdate may, in consequence of the variations in strength of molybdic solutions prepared from them, have a serious effect upon the quantitative phosphoric acid estimations, and the author advises analysts to habitually use the preparations from one and the same firm.—E. G. C.

*On the Examination of Citric Acid for Tartaric Acid.* Ph. Pusch. (Arch. d. Pharm. 22, 316). Rep. Anal. Chem. 4, 176.

ONE gramme of powdered citric acid is put in a test-tube, together with 10 grm. of concentrated colourless sulphuric acid. The test-tube is held in a clamp, and suspended in a beaker filled with water, which is now kept at the boiling temperature for an hour. The solution changes to a lemon-yellow liquid, and a considerable disengagement of gas takes place. If the yellow colour of the solution does not alter within an hour, the citric acid was pure; but in the event of its having contained only half per cent. of tartaric acid, the tint of the fluid changes altogether, becoming brown after 30 or 40 minutes, and red-brown after an hour's standing. It is obvious that the crystals of citric acid employed must not contain pieces of wood, paper, etc.—E. G. C.

*Improved Burettes.* Ducretet. Rep. Anal. Chem. 5, 185.

A CONVENIENT arrangement for use in laboratories of sugar mills, distilleries, etc., is represented in the cut. The advantage consists in the adjusting of the zero

point without pouring in or out, and without loss; also in the rapidity with which tests can be made, and the complete protection of the contents from the air. R is the reservoir for the standard solution, S a heavy sup-

port, B the burette divided into  $\frac{1}{100}$  c.c., A a holder for the same, P a pinch-cock, P' an indiarubber ball with an opening o, T junction between B and R, F glass-stopper of the reservoir with the opening O', V mixing vessel with the rod  $\alpha$ . R is filled with solution through F, and the air removed from P' by compression and o closed. The liquid is thereby drawn up from R to B, and the zero is each time adjusted by the flow through T. The vessel V is more convenient than a flat one, and the rod  $\alpha$  is for taking samples.—H. A. R.

*Volumetric Estimation of Carbon Disulphide in Sulphocarbonates.* Falières. Rep. Anal. Chem. 4, 219.

TEN grammes of the sulphocarbonate (which can be measured off after the specific gravity has been determined) are mixed, in a granulated cylinder capable of holding 50cc., with 9 to 10cc. of benzene and about 10cc. of water. 20cc. of sodium bisulphide, sp. gr. 1.32, are then added after the mixture has been well shaken. The sodium bisulphide decomposes the sulphocarbonate, and the carbon disulphide formed dissolves in the benzene. The decomposition is complete in about an hour. From 8 to 10cc. of ammonia are now added, and the mixture is shaken and allowed to stand for a little while. The quantity of carbon disulphide present in the sulphocarbonate is calculated from the increase in the volume of the benzene. Tables are given, showing (1) the volumes of sulphocarbonates of different specific gravities, corresponding to the weight 10grm., and (2) the percentages of carbon disulphide corresponding to different increments in volume of the benzene.

—E. G. C.

*Detection of Nitric Acid in the Presence of other Acids which conceal its Reactions.* Antonio Longi. Rep. Anal. Chem. 4, 220.

IF acid, the solution is neutralised with sodium carbonate, and then treated with excess of sulphurous acid. The solution is next gently warmed, and sodium carbonate is gradually added till the solution is slightly alkaline. On boiling, chromium and other heavy metals are separated. The filtered solution is acidified with acetic acid, and again filtered if necessary. Pure peroxide of lead and more acetic acid are now added until the vapours given off cease to colour starch paper. The solution is allowed to cool, filtered, and treated with sodium sulphate, which precipitates the dissolved lead. The filtrate is evaporated to dryness on the water-bath, taken up with water, and tested for nitric acid in the usual manner.—E. G. C.

*On the Employment of Hydrogen Peroxide in Chemical Analysis.* C. Hanowsky. Rep. Anal. Chem. 14, 220.

THE author has studied the action of hydrogen peroxide on compounds of iron, manganese and chromium, and he states that the oxidation of ferrous into ferric oxide can advantageously be effected, in weak solutions of ferrous salts, by boiling with hydrogen peroxide. Manganese is completely separated from neutral solutions of its salts by boiling them with excess of hydrogen peroxide, rendered alkaline by ammonia or potash. The precipitate is washed with hot water (to which a little ammonium nitrate has been added), dried, ignited, and weighed as  $Mn_2O_3$ . Hydrogen peroxide in alkaline solution behaves in an analogous way with solutions of chromium salts, the whole of the chromic oxide present being oxidised into chromic acid, which can be estimated either gravimetrically or volumetrically.

—E. G. C.

*Report of a Commission to inquire into Uniform Methods for the Analysis of Wine.* Rep. Anal. Chem. 4, 227.

AFTER some preliminary instructions relative to the collection, etc., of samples, the following directions are given respecting the processes to be employed in the analysis. *Specific gravity*.—This is to be determined at a temperature of 15° C., by the aid of the pycnometer,

or with a Westphal's balance controlled by means of the pycnometer. *Alcohol*.—For this determination the distillation method is to be employed, and for the calculation, Helmer's or Baumhauer's tables may be used. *Extract*.—50cc. of the wine, measured at 15° C., are to be evaporated on the water-bath, in a platinum dish (of diameter, 85mm.; height, 20mm.; capacity, 75cc.; and weight, about 20grm.), and the residue dried for 2½ hours. In the case of wines containing more than 0.5 per cent. of sugar, a smaller quantity must be taken, so that the extract shall not weigh more than 1.0–1.5grm. *Glycerol*.—To determine this constituent, 100cc. of the wine are evaporated down to about 10cc., in a spacious porcelain dish; some sand and milk of lime are then added till the reaction is strongly alkaline, and the mixture is evaporated almost to dryness. The residue is next treated with 50cc. of fifty-six per cent. alcohol, warmed and stirred on the water-bath, the solution being then passed through a filter. The insoluble matter is washed with successive small quantities of hot alcohol (fifty-six per cent.), of which 50 to 150cc. will, as a rule, suffice, so that the entire filtrate will be from 100cc. to 200cc. The alcoholic extract is now evaporated to a viscous consistency, and the residue taken up with 10cc. of absolute alcohol; this solution is mixed with 15cc. of ether in a stoppered flask, and the mixture allowed to stand until clear. The clear fluid is decanted or filtered into a light tared glass vessel, carefully evaporated, and the residue dried for one hour in the water-bath. It is then cooled and weighed. In the case of sweet wines (containing more than five per cent. of sugar), only 50cc. of the wine are taken for the estimation of glycerol; sand and lime are added, and the mixture is warmed on the water-bath. After cooling, it is treated with 100cc. of ninety-six per cent. alcohol, the precipitate formed allowed to settle, the solution filtered, the insoluble matter washed with spirit, and the alcoholic filtrate treated as above described. *Free acids* (total acid-reacting constituents of the wine).—Estimated in 10–20cc. of the wine by means of one-third- or one-tenth-normal alkali. Any considerable quantity of carbonic acid to be first removed by shaking. The “free acids” to be calculated into and given as tartaric acid ( $C_4H_4O_6$ ). *Volatile acids*.—Determined by steam-distillation, and calculated as acetic acid ( $C_2H_4O_2$ ). The quantity of non-volatile acids calculated as tartaric acid is found by subtracting the equivalent of the acetic acid in tartaric acid from the free acids previously determined. *Potassium bitartrate and free tartaric acid*.—a. *Qualitative test for free tartaric acid*.—Some finely-powdered cream of tartar is added to 20–30cc. of the wine, and after the lapse of an hour, the mixture is shaken repeatedly, and filtered. Two or three drops of a twenty per cent. solution of potassium acetate are now added to the clear solution, which is left to stand for twelve hours. (The shaking and standing at rest must take place at as equal temperatures as possible.) Should any considerable precipitate be produced during this time, free tartaric acid is present, and its quantitative estimation is necessary. b. *Quantitative estimation of the potassium bitartrate and of the free tartaric acid*.—Two measured quantities of the wine (20cc. each) are put into two stoppered flasks, and mixed with 200cc. of ether-alcohol (in equal volumes). To one flask are added two drops of a twenty per cent. solution of potassium acetate (corresponding to about 0.2grm. of tartaric acid). The mixtures are both well shaken, and allowed to stand 16–18 hours at a temperature between 0° and 10° C. The precipitates are filtered off, washed with ether-alcohol, and titrated. The solution of potassium acetate must be neutral or acid, and it must not be added in too great an excess. In some cases, this method may be controlled by that of Nessler and Barth. *Malic, succinic, and citric acids*.—“Methods for the separation and quantitative estimation of these acids cannot at present be recommended.” *Salicylic acid*.—To detect this acid, 100cc. of the wine are shaken repeatedly with chloroform, the latter is evaporated, and the aqueous solution of the residue tested with very dilute ferric chloride solution. For the purpose of an approximate quantitative estimation it is sufficient, on the evaporation of the chloroform, to once recrystallise

the residue from chloroform, and weigh it. *Tannin*.—Should a quantitative determination of the tannin appear necessary, Neubauer's method is to be employed. As a rule, however, the following mode of procedure will suffice: the free acids in 100cc. of the wine are neutralised with standard alkali, after which 1cc. of a forty per cent. solution of sodium acetate is added, and finally a ten per cent. solution of ferric chloride, drop by drop, and avoiding excess. One drop of this solution suffices for the precipitation of every 0.05 per cent. of tannin. *Colouring matter*.—Red wines must always be tested for aniline colours; for their detection 100cc. of wine are to be shaken with ether before and after super-saturation with ammonia. The ethereal solutions are separately tested. *Sugar*.—This is determined, after the addition of sodium carbonate, by Fehling's method, and, in wines rich in sugar, with due regard to the modifications introduced by Soxhlet and Allihn; it is calculated as grape-sugar. Highly-coloured wines are to be decolourised by the aid of animal-charcoal or acetate of lead—the latter to be used if the wine be rich in sugar, and then treated with sodium carbonate. Should the polarisation indicate the presence of cane-sugar, the sugar must be determined after inversion of the solution by heating with hydrochloric acid. The cane-sugar is calculated from the difference. *Polarisation*.—For this purpose only large and accurate instruments are to be employed. *Gum (Arabic)*.—To ascertain the presence of any added gum, 4cc. of wine are treated with 100cc. of ninety-six per cent. alcohol. In the presence of gum the mixture becomes milky, and only becomes clear again after many hours. The precipitate formed clings to the sides of the vessel in firm masses. In pure wines, a loose flocculent precipitate is formed after a short time, and very soon settles down. To determine the gum accurately, the wine is evaporated to a syrup, treated with ninety-six per cent. alcohol, the insoluble matter separated, redissolved in water, and heated for two hours under pressure with hydrochloric acid (sp. gr. 1.10). The reducing power of this solution is now determined with Fehling's solution, and calculated into dextrose. With pure wine there is no material reduction. Dextrose would also be detected by this method. *Mannite*.—If present, this substance is seen in the form of elongated crystals in the extract and glycerine. *Nitrogen*.—To be determined by the soda-lime process. *Ash*.—For this determination 50cc. of the wine should be taken. *Chlorine*.—The wine is supersaturated with sodium carbonate, evaporated, the residue gently ignited and extracted with water. The chlorine is determined in the solution either volumetrically (according to Vohlard), or gravimetrically. *Sulphuric acid*.—Estimated directly in the wine by barium chloride, but only when the qualitative test has shown the presence of an abnormal amount. *Phosphoric acid*.—Determined in the nitric acid solution of the ash, by the molybdc method. *Sulphurous acid*.—100cc. of wine are distilled in a stream of carbonic anhydride, after the addition of phosphoric acid; 5cc. of normal iodine solution are used to receive the distillate. When the first third has distilled over, the distillate, which must still contain excess of free iodine, is acidified with HCl, warmed, and precipitated with barium chloride. *Sophistication of Grape Wine with wine prepared from other fruits*.—The detection of this form of adulteration can, with our present experience, only occasionally be effected with certainty. Specific tests are particularly unreliable; and the conclusion, based upon the absence of potassium bitartrate, or its presence in very small quantities, that a given sample of wine is not the produce of the grape, may not necessarily be a correct one. Among the substances used by manufacturers of adulterated and spurious wines are: Spirit of wine, cane or beet sugar, honey, glycerine, cream of tartar, tartaric acid, other vegetable acids and substances containing them, salicylic acid, mineral matters, gum arabic, tannic acid and materials containing it (kino, catechu, etc.), and foreign colouring matters, together with various ethers and aromatic substances. Tamarinds, dates, and figs are also employed, with the object of increasing the proportions of free acidity, sugar, and extractive matter. In an analysis of wine, the following determinations are,

as a rule, necessary:—Extract, alcohol, glycerine, sugar, free acids (total), free tartaric acid (qualitative), sulphuric acid, total mineral substances, gum, polarisation, and (in red wines) foreign colouring matters. In particular cases determinations must also be made of specific gravity, volatile acids, potassium bitartrate, and free tartaric acid, succinic, malic, and citric acids, salicylic acid, sulphurous acid, tannic acid, mannite, total nitrogen, and separate constituents of the ash. Wines derived solely from pure grape-juice rarely contain less than 1.5grm. of extractive matter in 100cc.; after subtracting fixed acids, the proportion of extract remaining should be at least 1.1grm. in 100cc.; and after subtraction of free acids the residue should not be less than 1.0grm. in 100cc. The ratio of mineral matter to extract is about 1:10. Free tartaric acid should not amount to more than one-sixth of the total fixed acids. The proportion of alcohol to glycerine, in natural wines, ranges between 100:7 and 100:14.—E. G. C.

*Remarks on the Use of Beckurt's Method for the Detection of Arsenic in Cases of Poisoning.* G. Baumert. Chem. Zeit. 9, 904.

BECKURT lately published some investigations on the detection of arsenic and the preparation of hydrochloric acid free from arsenic. The author examined Beckurt's method, and finds it very convenient. To free hydrochloric acid from arsenic, 1 kilo. of pure concentrated commercial acid was treated with 100cc. of a saturated ferrous chloride solution (made by dissolving iron wire in hydrochloric acid), and a small piece of iron wire, and distilled in such a manner that the first 30% of the distillate, and the residue amounting to 10% of the whole, were rejected, whereas the 60% lying between these limits were collected. The latter proved to be absolutely free from arsenic. The same method can be employed to separate arsenic, in cases of poisoning, from various objects, such as internal organs, vomited residues, food, etc. After cutting them up to very small bits, they are stirred up to a thin paste with measured quantities of hydrochloric acid freed from arsenic, treated with 25cc. of a 4% solution of ferrous chloride and distilled. The distillation proceeds very quietly on a gas-stove, and if one-third of the acid used be distilled over, it will contain all arsenic present. The heat must be so regulated that 100cc. of the distillate are produced in 35 to 40 minutes. The apparatus consists of a tubulated retort, of ample size, whose neck is raised and connected in an obtuse angle with a Liebig's condenser. If the object of examination be very liquid, it must at first be evaporated with hydrochloric acid, if necessary, after neutralising with sodium carbonate, and afterwards distilled, as mentioned above. It makes no difference in the method of proceeding, whether arsenic is present as element, trioxide, pentoxide, or sulphide. The hydrochloric acid distillate can at once be subjected to the treatment in the Marsh's apparatus, but the liquid must be previously diluted, and a very strong evolution of hydrogen should be avoided. The gas is dried by passing through tubes filled with calcium chloride and potassium hydrate respectively. In every case, a blank experiment with the reagents to be used, must be previously made.—S. H.

*New Method for the Separation of Strychnine and several other Alkaloids in cases of Poisoning.* Th. Chandon-Zeit. f. Physiol. Chem. 9, 46-48.

THE finely-divided viscera mixed with an equal weight of anhydrous gypsum are dried at 70°, and then warmed with tartaric acid and 90 per cent. alcohol. The residue of the alcoholic extract is taken up with a little warm water, neutralised with soda, mixed with gypsum, dried in a desiccator, and extracted with chloroform. The chloroform extract is treated with an equal volume of a saturated solution of oxalic acid in ether, the oxalates of strychnine, brucine, narcotine, codeine, nicotine, conine, acetonine, hyoscyamine, veratrine, papaverine, and thebaine are precipitated after some time; completely in 24 hours. The oxalate of strychnine is washed with ether and chloroform, dissolved in water and precipitated

by ammonia. In quantitative estimations, one adds to the weight of the precipitated strychnine the weight of that dissolved in the solution (according to the author, 1 part in 6667). With the other alkaloids the oxalate is dissolved in alcohol, the oxalic acid removed with alcoholic potash, the potash by passing carbonic acid through the mixture, and the pure alkaloid is then obtained by evaporation of the alcoholic solution.—S. I.

## New Books.

**PHYSICO-CHEMICAL CONSTANTS, MELTING AND BOILING POINT TABLES.** By THOMAS CARNELLEY, D.Sc., B.Sc., F.C.S., Professor of Chemistry in University College, Dundee. Vol. I. London: Published by Harrison & Sons, 59, Pall Mall, 1885.

QUARTO Volume, bound in black cloth, containing preface, table of contents, explanatory notes, list of abbreviations alphabetically arranged, catalogue of reference literature (with abbreviations) also alphabetically arranged, and subject matter in the shape of the tabulated constants, etc., extending over 352 pages; price £2 2s. This important work the author has very appropriately dedicated to his old teacher, Sir Henry Enfield Roscoe, LL.D., F.R.S. The tables are arranged in vertically divided columns, headed as follows:—Name (of Substance); Remarks; Formula; Boiling Point; Melting Point; Authority; Reference; *Watts' Dict. and Journ. Chem. Soc.* The table of contents includes the following, and thus the compass of the first volume of this work will appear:—Part I.—Elements and Inorganic Compounds. I. Elements. II. Compounds containing two Elements. III. Compounds containing three Elements. IV. Compounds containing four Elements. V. Compounds containing five Elements. VI. Metallic Alloys:—*a.* Alloys of two metals; *b.* Alloys of three metals; *c.* Alloys of four metals. VII. Alloys of Inorganic Compounds: *a.* Alloys of two compounds; *b.* Alloys of three compounds. Part II.—Organic Compounds. I. Compounds containing two Elements. II. Compounds containing three Elements. The "Apology for writing this book" by the author, it is only fair to state. Those who imagine the work to be one of essential value for reference for chemical formulae, melting- and boiling-points are entirely correct, but it serves another equally valuable purpose, for the research-chemist perhaps a still more valuable one—viz., to take the place of a class of works possibly better known in Germany than in this country, as *a.* "General-Register," for ready and rapid reference to the original sources in the whole of the literature of chemical experience or research. In the preface Dr. Carnelley writes:—"My object in preparing the tables has been—*First*: To present as complete a list as possible of *all* known melting- and boiling-point data, and at the same time to indicate which of them is probably the most exact when there are several determinations referring to the same substance. *Second*: To state as fully as possible the constitution of each substance to which the data refer. *Third*: To adopt such a system of arrangement as would facilitate, as far as possible, the ready finding of the data relating to any given substance. *Fourth*: To give the authority and reference to the original memoir in each case. *The tables thus form a catalogue also of the literature referring to most chemical substances.* *Fifth*: As but comparatively few chemists have sufficiently large libraries of their own, or can conveniently refer to the original papers in all cases, I have thought it desirable to give in addition the reference (if any) to either *Watts' Dictionary of Chemistry*, or to the *Journal of the Chemical Society of London*, or both. This is

a feature of the work which I believe will be found particularly useful, more especially to British and American investigators."

## Monthly Patent List.

### ENGLISH APPLICATIONS.

1885.

#### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

- 9818 J. Hill, Glasgow. Improvements in and connected with gas-producers, and regenerators or furnaces, and their construction and arrangement and fittings as applied to steam boilers for the generation of steam. August 19  
9869 W. Hutchinson, London. Improvements in refrigerating apparatus. August 21  
10085 J. Storer, Glasgow. Improvements in constructing furnaces, converters, flues, and other apparatus in which great heat is employed. August 26  
10112 A. Reis, London. An apparatus for producing a draught in boilers and other furnaces, and for purifying the products of combustion. August 26  
10143 J. A. Drake and R. Muirhead, London. Improvements in and connected with filter presses. August 27  
10166 J. Johnston, Manchester. Improvements in apparatus for heating, drying, and other purposes. August 27  
10169 B. H. Remmers and J. Williamson, Glasgow. Improvements for facilitating the removal of cakes or sludge from filter presses. August 27  
10258 A. Dempster, Elland. An improved fastening for retort lids, furnace doors, covers, and the like. August 29  
10355 E. Edwards, London—Communicated by G. Lunge, Switzerland, and L. Rohmann, Germany. Improvements in apparatus for effecting the absorption of gases by liquids or solids. September 1  
10370 B. H. Remmers and J. Williamson, Glasgow. Improvements in filter presses. September 7  
10618 J. Binks Cooper, Whitehaven. Improvements in stationary boiler flues for economising fuel and consumption of smoke. September 9  
10657 F. Bernard Dering, London. Improvements in apparatus for evaporating sea-water, nitrate, or other solutions or liquids. September 9  
10663 E. Edwards, London—Communicated by E. Fournell and E. Jacques, Belgium. Improvements in regenerative hot-air furnaces. September 9

#### II.—FUEL, GAS, AND LIGHT.

- 9773 H. J. Allison, London—Communicated by C. Carroll Yeaton, United States. Improvement in process of generating hydrogen gas. Complete specification. August 18  
9797 H. French Bromhead, London. Improved device or apparatus for purifying gas. August 18  
9876 J. Murrie, Glasgow. An improved method of generating vapour. August 20  
10139 J. Kingsford Field, London. Improvements in treating hydrocarbon bodies or substances. August 27  
10234 L. Chander. A tischolin candle. Complete specification. August 29  
10301 J. H. Selwyn, London. Improvements in liquid fuel furnaces and their appliances. August 31  
10355 H. J. Haddon, London—Communicated by W. St. Martin, Belgium. Means or apparatus for obtaining an inflammable gas mixture from mineral oil and water or steam, and for utilising the said mixture for the production of heat and light. September 5  
10666 C. W. Bradshaw, Tottenham; and J. Carpenter, Hammersmith. Apparatus for generating gas for illuminating and other purposes from mineral and other oils. September 9

#### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

- 10138 H. J. Haddon, London—Communicated by J. Quaglio, Germany. Apparatus for compressing coal and introducing the same into coke-ovens. September 3

#### IV.—COLOURING MATTERS AND DYES.

- 9588 J. H. Johnson, London—Communicated by The Badische Anilin- und Soda-Fabrik, Germany. Improvements in the manufacture of yellow and orange colouring matters suitable for dyeing and printing from dioxytartaric (carboxytartaric) acid. August 19  
10377 W. Clark, London—Communicated by the Fabrik vorm. Brönnner, through Wirth & Co., Germany. Improvements in the production of colouring matters. September 1

## V.—TEXTILES: COTTON, WOOL, SILK, Etc.

- 9811 M. Raabe, A. C. G. Skinner, and S. Henning, London. A new manufacture of yarns and woven and felted goods from animal and vegetable fibres, the said vegetable fibres being treated so as to give them qualities and characteristics of animal fibres, and being applicable also for use alone in the manufacture of yarns and woven and felted goods. August 18.
- 9831 J. V. Eves, London. Improvements in machinery for the preparation of flax, tow, and other fibrous substances. August 21.
- 10046 H. J. Hadden, London—Communicated by Pelzer et. Fils, Belgium. Improvements in the treatment of textile materials with liquids and gases, and in apparatus therefor. August 25.
- 10255 J. C. Mewburn, London—Communicated by F. Lortholais, France. Improvements in and apparatus for desiccating wool to facilitate the removal of vegetable substances therefrom. August 29.
- 10508 R. Wild and H. Ledger, Leek. Improvements in the means and apparatus for breaking, opening, separating, combing, and cleaning and carding of fibrous materials. September 5.
- 10509 R. Wild and H. Ledger, Leek. Improvements in the mode and apparatus for the breaking and opening up and cleaning, washing, bleaching, and drying of fibrous materials. September 5.
- 10554 W. H. Slade, London. An improved waterproof cloth. Complete specification. September 7.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

- 10723 C. J. Cox, London—Communicated by Aug. Jeannelle, France. An improved method of dyeing black upon cotton, silk, or wool, or a combination in raw, hank, or manufactured fabric, producing thereby a solid, clear, and permanent black. September 10.

## VII.—ACIDS, ALKALIS, AND SALTS.

- 9831 W. Weldon, Burston—Communicated by A. R. Pechiney et Cie., France. Improvements in mode of procedure for decomposing by magnesia the mother-liquor of the ammonia-soda process. August 19.
- 9837 F. H. Goble, Dunstable. Improvements in the manufacture of carbon acid, and application of the same to useful purposes. August 19.
- 10080 E. W. Parnell and J. Simpson, Liverpool. Improvements in obtaining sulphur from sulphuretted hydrogen. August 26.
- 10598 A. E. Robinson, Edgbaston. Improvements in the preservation from oxidation of certain salts of iron. September 8.
- 10661 A. Pillars Laurie, Glasgow. Improvements in the preparation of crystal soda and caustic soda from tank liquor. September 9.
- 10700 J. J. Hood, London. Improvements in the manufacture of ammoniac bichromate. September 9.

## VIII.—GLASS, POTTERY, AND EARTHENWARE.

- 10378 G. Jones Atkins, London. A new or improved furnace for burning or firing stained or painted glass and enamels, and for other purposes. September 1.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

- 9780 W. P. Thompson, Liverpool—Communicated by G. Lillenthal, Melbourne. Improvements in the manufacture of artificial stone. August 18.
- 10362 G. Butchard, London. Improvements in the manufacture of cement, and apparatus therefor. September 1.
- 10415 G. Bird, London. Improvements in paving bricks. September 3.
- 10454 W. R. Lake, London—Communicated by F. J. Grenier, France. Improvements relating to cement and similar materials, and to the utilisation of the same for paving and other purposes. September 3.
- 10480 W. G. Margetts, London. Improvements in the method of loading or clamping cement kilns. September 1.
- 10492 W. Clark, London—Communicated by E. E. Farnet, France. The manufacture of a composition suitable for making wall coverings and other fabrics, moulded articles and other uses. September 1.
- 10591 M. Beaumont Parrington, London. Improvements in kilns and other structures employed in the manufacture of lime and cement. September 5.
- 10555 G. Butchard, London. Improvements in kilns. September 7.
- 10740 G. Butchard, London. Improvements in kilns for burning cement. September 10.

## X.—METALLURGY, MINING, Etc.

- 9781 W. P. Thompson, Liverpool—Communicated by E. H. Cowles and A. H. Cowles, United States. A new or improved process for obtaining aluminium and other metals from their ores, alone, or as alloys with copper or other metals. Complete specification. August 18.
- 9809 W. R. Walton, London. Improvements in the process of preparing copper for casting. August 18.
- 9811 D. H. Haggie and G. A. Haggie, London. Improvements in the manufacture of ropes of metal. August 19.
- 9833 G. Leyshon, London. A new or improved method of and apparatus for manufacturing tin and ternary plates or sheets, and for galvanising sheets of iron. August 20.
- 9887 S. H. Emmens, London. Improvements in the chemical treatment of certain aluminous minerals, and in the utilisation of the industrial products thereby obtained. August 20.
- 9894 J. Gilling Williams, London. An improved process for making purple ores or other fine ores into bricks or blocks of required "shape." August 20.
- 9933 H. Grimshaw, Manchester. A new or improved process for treating cast-iron in oil. August 24.
- 10018 H. L. Lake, London—Communicated by the Verein Chemischer Fabriken, Germany. Improvements relating to the separation of tin from tin-plate, and to the production of protochloride of tin. August 24.
- 10021 R. Oxlund and C. Oxlund, London. Improvements in the treatment of ores and materials containing sulphur for the extraction of metals and other constituents. August 24.
- 10035 R. Bonehill and L. Hague-Halton, Liverpool. A blast-furnace for the treatment of all kind of ores. August 25.
- 10083 C. Berry Phillips and G. Borgeat, Chester. Smelting of complex ores, such as the Anglesea and Wicklow blinestone or similar ores. August 26.
- 10119 S. H. Stephens and S. Rodda, London. Improvements in machinery for the reduction of tin stuff and other partially pulverised ores, to extract the metal therefrom, as well as for grinding paint, cement, and other hard substances. August 26.
- 10154 W. H. Duncan, Coalbrookdale. Improvements in extracting, washing, and delivering gold, silver, diamonds, lead, and other metals. August 27.
- 10185 F. M. Lyte, London. Improvements in the manufacture of cupels in the cupellation of metals, and in the production of other refractory apparatus and materials. August 27.
- 10257 O. Morton Thowless, Birmingham. Soldering aluminium and the preparing of aluminium for such soldering. August 29.
- 10256 W. P. Thompson, Liverpool—Communicated by R. Tamine and E. de Cyper, Belgium. Improvements in the manufacture of oxides of tin and tin salts. August 31.
- 10391 L. L. Groth, London—Communicated by D. Mindelef, United States. A method and apparatus for extracting nickel and cobalt from ores containing them. Complete specification. September 4.
- 10428 J. H. Williamson, London. Amalgamating, joining, soldering, and (or) autogenously uniting aluminium. September 5.
- 10621 J. Dixon, F. J. Blades, W. Selby Douglas, D. Gardick and W. Malcolm, London. Improvements in the process of smelting pyrites, and in the tuyeres of blast-furnaces to be used for the purpose, comprising also a novel method and apparatus for feeding such furnaces. Complete specification. September 8.
- 10658 C. M. Pielsticker, London. Improvements in metal-lurgical apparatus. September 9.
- 10688 C. Cochran, London. An improvement in the working of blast-furnaces. September 9.
- 10742 W. Pritchard-Morgan, London—Communicated by F. Ellershausen, France. A process for separating silver from lead. September 10.

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

- 9895 A. Lovell, London. An improved lubricating compound. August 20.
- 10225 W. R. Lake, London—Communicated by T. Howard Jacobs and J. Yeatman Lockwood, United States. Improvements in the manufacture of oil, oleake, and meal from Indian-corn or maize. August 28.

## XII.—PAINTS, VARNISHES, AND RESINS.

- 9882 C. D. Abel, London—Communicated by W. J. Wisse, Holland. An improved protective material for iron and steel. August 22.
- 10311 W. Wells, London. An improved process for the production of carbon from refuse bark, to be utilised for the manufacture of paint, and for other purposes. August 24.
- 10409 H. Gardner, London—Communicated by D. Lubinski, Germany. Improved compound for application to wood, metal, or other substance as a paint or varnish to prevent decay, rust, or other injury by atmospheric action (to be called Keralin). September 2.

## XIII.—TANNING, LEATHER, GLUE, AND SIZE.

- 10147 J. C. Mewburn, London—Communicated by J. Marchal et L. Bories, France. A process of treating tannic extracts or juices. August 27.

10362 W. Moore Riddell, Forest Hill. Improvements in the manufacture of tannin and the treatment of vegetable fibres to render the same suitable for various useful purposes. September 7

# XV.—SUGAR, STARCH, GUMS, Etc.

10053 F. Wheaton Seabury, London. Improvements in method and apparatus for vulcanising rubber. Complete specification. August 25

10110 C. A. Henderson, London.—Communicated by G. Du-rozard, France. An improved process for manufacturing sugar from anylaxa and cellulse matters. August 26

10172 P. Jensen, London.—Communicated by M. C. P. Barbe, Holland. Improvements in the manufacture of refined sugar, and in apparatus therefor. Complete specification. August 27

# XVI.—BREWING, WINES, SPIRITS, Etc.

9798 A. J. Boulton, London.—Communicated by A. S. Bigelow, United States. Improvements in pressure regulators for fermenting liquids. Complete specification. August 18

9816 P. H. Justice, London.—Communicated by A. W. Billings, United States. Improvements in the manufacture of beer. Complete specification. August 19

9869 W. Whitson Crawford, Glasgow. Maturing of spirits in bottle or other non-absorbing vessels. August 20

9930 H. H. Lake, London.—Communicated by A. E. Fewe, United States. Improvements in the manufacture of syrup and beer from maize or Indian corn and malt. Complete specification. August 21

9936 C. R. Bonine, Manchester. An apparatus for testing brewing materials. August 22

10358 M. Hedicke, London. Improvements in the drying of malt and in the construction of malt-kilns therefor. September 1

10327 H. T. Warne, London. Improvements in refrigerators for cooling malt liquors, wines, aerated waters, and other liquids. September 5

# XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

9906 H. Fisher, Chelsea. The filtration of smoke. August 18

9992 J. Clough Thresh, Buxton, and M. Hilton, Prestwich. The purification of sewage, sewage water, bleachers' dyers', and printers' effluent water, impure sewage and effluent water, for the removal of organic matter from potable water, and for the application, utilisation, and recovery of all matters relating thereto. August 24

10123 W. J. Bishop, London. Mixing liquid disinfectants with water in any required proportion by means of an automatic apparatus. August 26

10121 A. J. Boulton, London.—Communicated by L. M. Rousseau, France. Improvements in the preservation and treatment of dried or cooked meats, and the manufacture therefrom of various articles of diet. August 26

10390 H. H. Lake, London.—Communicated by C. Collin & Co., Belgium. The manufacture of an improved antiseptic. August 26

10137 W. Spence, London.—Communicated by F. Sanders, Russia. Improvements in apparatus for removing sewage or other impurities from cesspools, sinks, and the like. August 27

10212 P. Ockenden, London.—Communicated by H. Locke and H. T. Tompsett, Australia. A new or improved antiseptic deodorant, and disinfectant compound. August 28

10332 W. Lucas, Birmingham. Improvements in the preparation and medication of cocoa, chocolate, coffee, and similar substances for beverages. Complete specification. September 1

10331 H. J. Haddon, London.—Communicated by H. T. Beechlin, France. A new frigorific or compound for producing cold. September 1

10379 J. Peachey, Worcester. Manufacturing sanitary urinals and disinfectants. September 2

10381 J. Stewart Edwards and J. Edwards, London. Improvements in apparatus for drying animal matter, fish, and other materials, applicable also for evaporating liquids. September 7

10604 F. Bosshardt, London.—Communicated by U. Egger, Switzerland. An improved apparatus for testing the quality of milk. September 8

10322 H. Compton, Palampur, East Indies. The desideratum desiccator for the rapid desiccating, drying, cooking, roasting, or evaporating of tea, fruit, hops, or any articles for which rapid or thorough desiccation is necessary, and especially for those articles which are injured by a damp heat. September 10

# XIX.—PAPER, PASTEBOARD, Etc.

10092 J. Kenyon, London. Improvements in the manufacture of cotton and woolen drying felts used by paper makers. August 26

10113 G. T. Talbot, London.—Communicated by J. Drew Gay, United States. An improved method of treating vegetable fibres for the manufacture of paper. August 31

10331 J. Plummer, jun., Edinburgh. Improvements in treating fibrous substances to prepare pulp for making paper, and for other purposes. September 1

10368 J. B. Alliot, London.—Communicated by H. Lahousse, France. New or improved apparatus for treating or drying paper-pulp, textile fabrics, and other like substances. September 1

10543 C. J. Richardson, London. Improvements in apparatus for the manufacture of paper. September 5

# XXI.—EXPLOSIVES, MATCHES, Etc.

9884 S. H. Emmens, London. Improvements in the construction of blasting cartridges, and in apparatus for using the same. August 29

10140 W. F. Ruston, London. Improvements in detonating fog signals for railways. September 3

# ENGLISH PATENTS PUBLISHED.\*

APPLIED FOR DURING 1884 AND 1885.

# I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

1881.

13350 J. W. Chalk Webb. Kilns and stores. 6d

13733 S. Smillie. Apparatus for heating and cooling fluids. 1d

13312 E. C. C. Stanford. Compositions or coatings to act as non-conductors of heat. 4d

# II.—FUEL, GAS, AND LIGHT.

1881.

13443 R. W. Thom. Apparatus for washing, scrubbing, and purifying, and also for charging and impregnating coal and gases with hydrocarbon vapours. 6d

13494 H. J. Rogers. Apparatus for the manufacture of gas. 6d

11114 F. Noel Mackay and W. Baxter. Apparatus for solidifying paraffin in oils. 6d

1883.

7581 E. Capitaine and O. Brunler. Production of compressed gaseous compound for use in gas motors, etc., and apparatus therefor. 6d

7615 J. D. Bodwell. Apparatus for the combustion of liquid fuel. 6d

# III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

1881.

13629 H. W. Fenner. Distillation of coal-tar and other hydrocarbon substances, and apparatus employed therein. 6d

13630 H. W. Fenner. Heating of stills or boilers employed in the distillation of coal-tar and other hydrocarbon substances. 1d

13650 B. P. Walker. Method of heating substances for the purpose of distillation. 4d

1885.

8184 L. T. Wright. Improvements in hydraulic mains used in the distillation of coal. 6d

# V.—TEXTILES: COTTON, WOOL, SILK, Etc.

1881.

13815 W. H. Beck.—Communicated by C. Violette, A. Buisine, and A. Vinchow. Process for obtaining useful products from the yolk or grease of wool. 6d

# VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

1881.

13258 W. H. Beck.—Communicated by La Societe Ch. Tons-sant et Cie. Process for cold scouring and dyeing cotton. 1d

13878 C. F. Cross and J. P. Rickman. Improvements in bleaching. 4d

11225 J. Clare. Process of dyeing black on cotton, cotton yarns, or cotton fabric, or other vegetable fibre. 2d

14276 W. P. Thompson.—Communicated by A. Desrois. Dyeing with aniline-black. 2d

11361 J. Douteleau. Process for discolouring and purifying vegetable extracts containing tannin. 2d

\*Any of these specifications may be obtained by post, by remitting the cost price, plus postage, to Mr. H. Reader Luck, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 8d.	.....	5d.
Above 8d., and not exceeding 1s. 6d.	.....	1d.
" 1s. 6d., " " " 2s. 4d.	.....	1d.

1885.

918 (Amended specification) E. J. Homan. Embossing, printing, etc., designs upon tissues and similar materials. 6d

## REPRINT.

12172 of 1881 C. R. Preibisch. Dyeing fabrics aniline-black. 6d

## VII.—ACIDS, ALKALIS, AND SALTS.

1881.

12718 H. Brunner. Treatment of certain phosphatic materials. 1d

12831 W. A. Rowell. Manufacture of chromic acid. 1d

13025 J. Taylor. The preparation of chlorine gas on the large scale. 2d

13433 E. C. Cortis Stanford. Manufacture of algin and other useful products from seaweeds. 4d

15719 H. Knight. Manufacture of sulphide of zinc or of pigments having sulphide of zinc as a constituent or ingredient. 1d

16220 H. Knight. Manufacture of sulphide of zinc and of hydrate or other salts of baryta or strontia. 1d

1885.

7135 P. Römer. Manufacture of bichromate of potash. 2d

7355 H. H. Lake—Communicated by A. Kayser, A. B. Young, and H. Williams. Method or process for the manufacture of carbonate of soda or soda-ash. 2d

## AMENDED SPECIFICATIONS.

3229 of 1883 E. P. Potter and W. H. Higgin. Manufacture of chromates of soda. 1d

4028 of 1881 W. J. Chrystal. Manufacture of bichromate of soda. (Price not given in official journal.)

## VIII.—GLASS, POTTERY, AND EARTHENWARE.

1881.

12901 J. Budd. Process of imparting to glass the appearance of marble or other stone. 2d

12902 J. Budd. Method of ornamenting or decorating glass in imitation of mosaic or similar work. 4d

14285 E. Brooke. Improved construction of tank for melting glass. 1d

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

1884.

13761 M. Dennstedt. Manufacture and preservation of articles of gypsum, stucco, &c. 1d

11010 H. J. Cooper. Manufacture of Portland cement. 4d

## SECOND EDITION.

6983 of 1836 F. Moll. Preserving timber. 1d

## X.—METALLURGY, MINING, ETC.

1881.

13019 G. Nurse. An improved method of finishing terne and tin plates. 6d

13912 E. Morewood. Tinning sheets or plates of metal. 6d

14071 J. Makin. Coating iron, steel, or other metal with lead. 1d

11083 T. Hampton. Manufacture of steel and ingot iron. 4d

11672 H. J. Haddan—Communicated by A. Lambotte. Recovery of tin from tin-plate scrap, and other materials containing tin, such as oxidised metal and residues. 1d

1885.

7858 H. von Groussli. Producing aluminium from chloride of aluminium by employing pressure. 4d

8269 T. Nordenfent—Communicated by C. G. Wittenström. Manufacture of castings from wrought-iron and steel. 2d

8478 J. T. King—Communicated by S. T. Owens. Metallurgical furnaces. 4d

8693 J. A. Longridge. Construction of ordnance. 6d

## SECOND EDITION.

9131 of 1812 J. S. Woolrich. Coating metals. 6d

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

1884.

11109 W. Büttner. Apparatus for extracting fat, grease, or oil from bones, wool, or other greasy substances. 6d

## XII.—PAINTS, VARNISHES, AND RESINS.

1881

12807 J. Imray—Communicated by E. Schaall. Production of the acid ethers of resinous gums, such as copal and the like. 1d

13867 A. J. Boulton—Communicated by S. Bond. Manufacture of paint. 1d

15719 H. Knight. Manufacture of sulphide of zinc or of pigments having sulphide of zinc as a constituent or ingredient. 1d

## XIII.—TANNING, LEATHER, GLUE, AND SIZE.

1884.

14587 A. M. Clark—Communicated by H. Schwalbacher. Manufacture of artificial leather. 1d

1885.

7915 T. R. Clark. Process for the manufacture of glazed leather. 2d

## XIV.—AGRICULTURE, MANURES, ETC.

1884.

13080 W. H. Sampson. Deodorising refuse substances for manures. 2d

## XV.—BREWING, WINES, SPIRITS, ETC.

1885.

127 S. Briggs. Refrigerators for brewers and distillers. 6d

1456 W. R. Lake—Communicated by W. T. Jebb. Manufacture of malt liquors. 6d

6821 C. H. Bonne. Apparatus for producing carbonic acid gas, and for utilising the same in raising malt liquors. 6d

## XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, ETC.

1881.

13588 E. Capitaine—Communicated by M. Nohsen. Purification of waters. 1d

13667 A. J. Bickmore—Communicated by H. Lebrunkrauss. Process of manufacturing from cereals and pulse, an extract containing the nutritious value of the seeds, for use in bakers' and confectioners' articles. 1d

13823 W. W. Nightingale. Manufacture of transparent ice. 8d

15085 O. Matthews Row. Apparatus for condensing steam or obtaining fresh water from salt water or impure water by evaporation and condensation. 6d

1885.

908 G. H. Ellia. Process for the manufacture of a filtering, deodorising, and decolorising substance or medium from carbonaceous or lignite clay. 4d

8282 O. F. Oberg. New mode of manufacturing filtering material for purifying water from micro-organisms. 2d

## XIX.—PAPER, PASTEBOARD, ETC.

1881.

13361 H. P. Howard, S. Jones, and F. Jones. Improved printed waterproof paper. 2d

1885.

8012 A. J. Boulton—Communicated by W. C. Zeidler. Treatment of celluloid, xylonite, and of similar substances. 4d

8120 T. R. Shillito—Communicated by C. Arnold. Manufacture of paper parchment or vegetable parchment. 4d

8685 J. P. Cornett. Trimming the edges of paper or pulp by means of a jet of water or other fluids. 1d

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

1881.

12807 J. Imray—Communicated by E. Schaall. Production of the acid ethers of resinous gums, such as copal and the like. 1d

## XXI.—EXPLOSIVES, MATCHES, ETC.

1881.

14379 F. Maxwell-Lyte and C. L. J. A. Lewall. Manufacture of explosive compounds. 1d

1885.

7109 A. J. Boulton—Communicated by W. F. Wolff and M. de Fürster. Method of charging hollow projectiles with compressed granular explosive substances. 4d

# THE JOURNAL. OF THE Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES

No. 10. — VOL. IV.

OCTOBER 29, 1885.

Non-Members 30s. per annum; Members  
21s. per Set; Single Copies 2 6.

## The Society of Chemical Industry.

### Past Presidents:

Sir H. E. Roscoe, LL.D., V.P.R.S.	1881—1882.
Sir Frederick Abel, C.B., D.C.L., F.R.S.	1882—1883.
Valter Weldon, F.R.S.	1883—1884.
W. H. Perkin, Ph.D., F.R.S.	1884—1885.

## COUNCIL FOR YEAR ENDING JULY, 1886.

President: E. K. Manspratt.

### Vice-Presidents:

Sir F. A. Abel, C.B., D.C.L., F.R.S.	Peter Griess, Ph.D., F.R.S.
Sir I. Lowthian Bell, Bart., F.R.S.	W. H. Perkin, Ph.D., F.R.S.
Alexander M. Chance.	Sir H. E. Roscoe, LL.D., V.P.R.S.
Prof. James Dewar, F.R.S.	John Spiller.
James Dmcan.	E. C. Stanford.
David Gamble.	J. C. Stevenson, M.P.

### Ordinary Members of Council:

R. Forbes Carpenter.	S. A. Sadler, Ph.D.
Henry Donlon.	Sir Bernhard Samuelson,
John Evans, D.C.L., F.R.S.	Bart., M.P.
Ivan Levinstein.	Sir Chas. Tennant, Bart., M.P.
Rudolph Messel, Ph.D.	Prof. W. A. Tilden, F.R.S.
B. E. R. Newlands.	John Williams.
Thomas Koyte.	

With Sixteen Chairmen and Secretaries of Sections.

*Honorary Treasurer:*  
E. Rider Cook, East London Soap-works, Bow, E.

### Honorary Foreign Secretary:

Ludwig Mond, 20, Avenue Road, Regent's Park, N.W.

*General Secretary:* Charles G. Cresswell.

### Offices:

Palace Chambers, 9, Bridge Street, Westminster, S.W.

## CHANGES OF ADDRESS.

W. H. Allen, 10 Toronto; c/o F. Stearns & Co., Detroit, Mich., U.S.A.  
W. Dalrymple Borland, 10 Explosives Co., Stowmarket; 35, Petherton Road, Highbury New Park, London, W.  
G. H. Bostock, 10 Great John Street; 45, Exchange Arcade, St. Mary's Gate, Manchester.  
L. Clausen, 10 Manchester; 26, Gerconstrasse, Köln-a-Rhein, Germany.  
J. H. Clemes, 10 Falmouth; Penrhyn Lodge, Woodberry Down, London, N.  
S. Crowder, 10 Anerley Park; Whitehorns, Palace Park Road, Sydenham, S.E.  
Prof. Jas. Dewar, 10 Brookside; 1, Scroope Terrace, Cambridge.  
U. K. Dutt, 10 Maida Vale; 1, Charles Street, Leicester.  
W. N. Evans, 10 London; 66, Stackpole Road, Bristol.  
Wm. Fox, 10 Trinity Square; 1, Great Lower Street, London, E.C.  
Andrew French, 10 North Shields; Glanleam Villa, Bearsden, near Glasgow.  
C. C. Graham, 10 Margaret Street; c/o Blundell, Spence & Co., Beverley Road, Hull.  
A. G. Green, 10 Ealing; Atlas Works, Hackney Wick, E.  
John Heron, 10 Shepton Mallet; c/o Garton Hill & Co., Southampton Wharf, Battersea, S.W.  
Thos. Hilditch, 10 Bradford; Cedar Grove, Heaton Chapel, near Manchester.  
H. A. Kay, 10 Newcastle; 13, Maida Vale, London, W.  
A. Liebmann, 10 Bonn; 10, Marsden Street, Manchester.  
Oscar Lowman, 10 Nuremberg; 53 3 Karl Strasse, Munich.  
J. A. Macfarlane, 10 Kirkintilloch; Marquesa 2, Barcelona, Spain.  
L. Mond, 10 Park Crescent; 20, Avenue Road, Regent's Park, N.W.  
T. H. Muras, 10 Tooting; The Patent Office, Chancery Lane, W.C.  
W. P. R. Newlands, 10 Anerley; 10, Alkham Road, Stoke Newington, N.  
F. W. Simpson, 10 Derby; Walton House, Belmont Road, Montpelier, Bristol.  
Fred. Smith, 10 Sutton-on-Hull; 16, Oakley Crescent, Chelsea, S.W.  
J. Fleming Stark, 10 Hebburn; 33, Sisters Avenue, Clapham Common, S.W.  
W. J. Stevens, 10 Totterdown; Marsh Soap Works, Bristol.  
A. Sinder, 10 Otten; 10, Marsden Street, Manchester.  
G. Valentine, 10 Tatham Road; 129, Scotland Road, Liverpool.  
W. H. Wood, Northgate Chambers, and 111, Victoria Street, Westminster, S.W.

## CHANGE OF ADDRESS REQUIRED.

F. Giesbers, 10 S. King's Road, St. Pancras, London, N.

## Death.

Arthur Baggallay, 10 Calcutta, at Dnnedin, New Zealand, August 20, 1885.

## LIST OF MEMBERS ELECTED, OCTOBER 23rd, 1885.

Samuel Banner, 1, Ivanhoe Road, Liverpool, petroleum merchant.  
R. B. Batty, Drayton Villa, Erdington, near Birmingham, metal works manager.  
R. Bird, Ellerslie, Roath, Cardiff, tar and rosin distiller.  
S. B. Bowen, Brickfield Chemical Works, Llanelly, South Wales, chemical manufacturer.  
S. B. Brown, Strines, near Stockport, calico printers' chemist.

H. Dawber, jun., Kenmore, Waterloo Park, near Liverpool, chemical student.  
 S. M. Burroughs, Bell Lane, Wandsworth, S.W., manufacturing chemist.  
 A.H. J. Edwards, The Gas Works, Taunton, secretary and manager.  
 H. S. Elworthy, Rosa, N.W.P., India, sugar refinery chemist.  
 Adolf, Ernst, 238, Upper Brook Street, Manchester, chemist.  
 A. E. Fasnacht, 51, Arcade Chambers, St. Mary's Gate, Manchester, chemist.  
 J. A. Fernoy, 12, Railway Approach, London Bridge, S.E., oil expert.  
 H. J. Hardy, 163, Edmund Road, Sheffield, analyst.  
 T. E. Holgate, A.R.S.M., 146, Blackburn Road, Darwen, Metallurgist.  
 F. K. Hurman, Ryton-on-Tyne, chemical apparatus dealer.  
 S. Wright Lee, 7, Church Street, Liverpool, wholesale drug-gist.  
 J. Meadows, 1, Charles Street, Leicester, public analyst.  
 M. Ivor E. Morris, Ammanford, R.S.O., South Wales, colour manufacturer.  
 G. B. Nicoll, Southdown Metal and Chemical Works, Millbrook, Cornwall.  
 A. G. Perkin, 56, Elizabeth Street, Cheetham, Manchester, technical chemist.  
 H. H. Remfry, 5, Fancy Lane, Calcutta, India, Solicitor.  
 M. I. Pat. Ag.  
 K. Reoch, River Point, R.I., U.S.A., printworks superintendent.  
 R. Wightwick Roberts, c/o C. M. Aikman, 12, South Parade, South Kensington, analyst.  
 R. Robinson, Apsley Buildings, Old Hall Street, Liverpool, general produce broker.  
 W. J. Rowley, 110, King Street, Manchester, chemist.  
 W. Lascelles-Scott, Chem. and Phys. Lab., Forest Gate, Essex, analyst.  
 Wilfred T. Skaife, 630, Sherbrooke Street, Montreal, Canada, sugar refinery chemist.  
 W. Thompson, jun., Larkfield, Earlestown, Lancashire, sugar refiner.  
 H. H. Townsend, Avenue House, Cotham Park, Bristol, pharmacist.  
 E. S. Waring, Lillie Terrace, Castle Street, Sneyton, Nottingham, pharmacist.  
 J. W. Westmoreland, 25, Park Square, Leeds, analyst and assayer.

## INTERNATIONAL INVENTIONS EXHIBITION, LONDON.

### REPORT ON THE EXHIBITS RELATING TO THE CHEMICAL INDUSTRIES.

BY WATSON SMITH,

Lecturer in Chemical Technology in the Victoria University, Manchester, etc.

(Continued from page 527.)

## GLASS, POTTERY AND EARTHENWARE.

HENRY KNOWLES, BURTON-ON-TRENT (*Group XXIII. No. 1759*).

Improvements in kilns:—(1.) Models of patent continuous or semi-continuous direct-action kilns. (2.) Models of patent detached down-draught ovens and kilns, with continuous direct action. (3.) Model of patent fireplace for kilns, ovens, glass and other furnaces. (4.) Model of patent binding for kilns, ovens, etc. (5.) Model of patent perforated bottom for kilns, ovens, etc. (6.) Samples of sanitary pipes, firebricks, tiles, terra-cotta, etc., burnt in H. Knowles' patent kilns.

CANDY & CO., LIMITED, LONDON (*Group XXIII. No. 1763*).

(1.) Patent vitreous buff, red and glazed terra-cotta. (2.) Patent terra-cotta and stoneware-facing and paving bricks. (3.) Patent kiln for burning these bricks and glazed stoneware, sanitary pipes and appliances.

THOMAS WELB & SONS, STOURBRIDGE (*Group XXIII. No. 1768*).

Various new methods and improvements in the manufacture and decoration of crystal and coloured glass, etc.

W. DOUGLAS HERMAN, ST. HELENS (*Group XXIII. No. 1773*).

Improvements in the combination of refuse materials of glass-works with other substances for the purpose of making flags, bricks, tiles and other like fictile or vitreous articles; also filter stones, grindstones, etc., these improvements being also applicable to the case of similar materials from other sources than glass-works.

THE GLENBOIG UNION FIRE CLAY CO., LIMITED, GLASGOW (*Group XXIII. No. 1776*).

(1.) Dunnachie's patent continuous regenerative gas kiln for burning fire-bricks, sanitary ware, pottery, etc., without smoke. (2.) Dunnachie's patent drying stove. (3.) Dunnachie's Star heating stove. (4.) Improved fire-clay and silica bricks.

HENRY BRAUN, LONDON AND PARIS (*Group XXIII. No. 2719*).

Specimens of fire-proof china, adapted for cooking utensils.

THE TOUGHENED GLASS CO., LIMITED, LONDON (*Group XXIII. No. 1784*).

Toughened crystal table glass, plain and decorated. Toughened lamp glasses. Toughened glass for chemical and laboratory use, etc.

F. SIEMENS, DRESDEN (J. BATT & CO., LONDON) (*Group of Foreign Exhibitors, No. 2720*).

The manufacture of hard glass.

## BUILDING MATERIALS, MORTARS, CLAYS, CEMENTS.

A. C. PONTON, DORSET (*Group XIV. No. 1467*).

Improvements in the processes of manufacturing artificial stones and concretes, so as to greatly reduce the quantity of silicate of lime, binding the sand and other aggregates.

Lime water, or the finest milk of lime, is boiled with either the finest sand, or dust from stoneware or natural stones, and a little soluble silica is introduced. Boiling under pressure would no doubt lead to the lime combining with the silica, but as this is inconvenient in practice, the fabricated articles after being dried in steam are boiled in a weak bath of silicate of soda. The silica, in separating from its solution of soda, combines with the lime forming crystallised silicate of lime, and the soda recombines with the free soluble silica. Sometimes the proportions of lime may render it difficult for the silica to penetrate through the mass; in this case dry powdered silicate of soda is rapidly introduced just before casting the stone or concrete. The dry silicate of soda fortunately takes a sufficient time to dissolve, so that chemical combination does not commence until the particles or aggregates are settled in position. This is important, since it was found that if the silicate of soda be introduced in solution amongst the "aggregates," disintegration ensues.

Still another method is open for adoption.

Even for artificial stone, as well as for concretes, a porous aggregate is often adopted, such as chips of stone, for the sake of conferring greater density. Advantage may be taken of this to introduce the silicate of soda into the fabric in a dry state, because it is easy for the porous aggregate to absorb weak silicate of soda, and subsequently lose the water by evaporation, and hence when such aggregates are incorporated with the stones or concretes the water introduced for producing plasticity forms a medium in which the chemical change of the lime into the

crystallised silicate can take place, as well as the recombination of the soda with the free soluble silica. The result of these methods is, as seen in the exhibits, that one part of lime binds together as much as 1000 parts of other aggregates, and it has been found by experiment that a certain amount of cohesion is even attained when one part of lime is mixed with 10,000 parts of other aggregates, but the cohesion is so feeble that the chemical recombinations cause disruption when the articles are boiled in the silica bath, although by taking precautions no doubt this difficulty could be overcome; thus, processes could be adopted in which the boiling would be unnecessary. It may be added that present manufacturers of artificial stone or concrete, as a rule, consider one part of cement to ten parts of other aggregates is the limit for successful manufacture.

#### METALLURGY AND MINING, ETC.

S. G. THOMAS AND P. C. GILCHRIST, LONDON (*Group II. No. 156, and XIV. No. 1467*).

*The Basic- or Thomas-Gilchrist process for making steel and ingot-iron from phosphoric pig in the Bessemer and Siemens furnaces.*

The exhibit comprises specimens of:—

(1.) The dolomite used for making the shrunk-lime lining material.

(2.) The shrunk-lime lining material before it is mixed with tar.

(3.) The lining material as used in the converter, prepared by grinding the shrunk material and mixing it with tar and heating to redness in a closed vessel.

(4.) The lime used for additions.

(5.) The steel and ingot-iron made.

(6.) The slag.

Of the steel and ingot-iron made there is a large number of test samples. These consist of specimens that have been tested very severely, both cold and hot, in the form of rails, girders, angles, beams, plates, tubes, wire, and black plates for tin plates. To illustrate how completely phosphorus can be eliminated, there are some samples of basic ingot-iron containing of phosphorus as little as 0.014 per cent., of C and Si traces, Mn=0.05 per cent., S=0.03 per cent., and Fe=99.90 per cent., made by the North-Eastern Steel Company from phosphoric pig.

The basic Bessemer process is represented by the North-Eastern Steel Company, in England; Hoerder Hütten Verein, in Germany; Les Acieries d'Angleur, in Belgium; and Messrs. Schneider & Cie., in France. The basic Siemens is represented by The Brymbo Steel Company, in England, and Messrs. Schneider & Cie., in France. There is also a casket presented to Mr. Sidney Gilchrist-Thomas at Vienna, the figures of which are cast from the same pig as is used in the basic Bessemer converter, and the repoussé work is of basic Bessemer ingot-iron made by the Prager Eisen Industrie Gesellschaft, Kladno, Austria. Before the introduction of this invention little more than one-eighth part of the available supply of iron ore in the world could be used for the manufacture of steel, owing to the presence, in the remaining seven-eighths, of too much phosphorus. The presence of phosphorus in steel is a fatal objection to its employment for many purposes, owing to the brittleness conferred upon it. The problem therefore which urgently awaited solution up to the year 1879, was how to eliminate phosphorus in the Bessemer converter and Siemens furnace, from the pig-iron made from the abundant but phosphoric ores, so that phosphoric pig might be converted into first-class steel and ingot-iron.

The exhibit illustrates the manner in which this result is accomplished by means of the Thomas-Gilchrist process—namely, by certain modifications of the Bessemer and Siemens processes, the chief of which are the manufacture and application of a durable basic-lining, and the making of large additions of ordinary lime to the molten bath, the effect of which practically is, *the complete removal of the phosphorus from the bath into the slag.*

Prior to this invention the furnace linings used were composed of sand, and with such a lining large additions of lime could not be effectively made, because of the chemical action of the lime upon the sand, resulting in "corrosion" or destruction of the sand lining. The Thomas-Gilchrist process is now in use in all the great iron-making countries of Europe; the make of basic ingot-iron and steel being from 70,000 to 80,000 tons per month.

ROBERT OXLAND, PLYMOUTH (*Group II. No. 115*).

Improvements in calcining ores or minerals; especially applicable for the smelting and reduction of ores of gold, silver, copper, tin and zinc, and for the manufacture of arsenious and sulphuric acids.

F. JONES & CO., LONDON (*Group II. No. 125*).

Utilisation of blast furnace slag for the following purposes:—

The manufacture of mantelpieces, paving-blocks, bricks, sand, etc.; also the manufacture of a glassy fibrous material (slag-wool), used for fire-proofing and sound-proofing buildings, and for purposes for which it is necessary to prevent the transmission of heat, cold or sound.

METALLIC SULPHIDES REDUCTION CO. (HOLLWAY'S PATENTS), LIMITED (*Group II. No. 130*).

Improvements in the production of sulphur from pyrites and the separation of metalliferous and other substances therefrom by rapid oxidation without the aid of fuel.

ROYAL MINT, LONDON (*Group II. No. 135*).

Refining gold by the aid of chlorine gas. A process devised by F. Bowyer Miller, of the Melbourne Mint.

G. J. SNELUS, WORKINGTON (*Group II. No. 136*).

Illustrations of improvements in the processes for the manufacture of steel and in the apparatus used for that purpose:—

(1.) Illustrations of the basic process of dephosphorisation. Mr. Snelus was the first to discover and to demonstrate by experiment that in order to eliminate phosphorus from pig-iron by the Bessemer process the converter must be provided with a lime or "basic" lining, and not be lined with the ordinary siliceous material.

(2.) Apparatus for carrying hot steel ingots.

(3.) Improved steel linings for Gier's soaking pits.

(4.) Improvements in moulds for steel ingots, etc.

HENRY R. CASSEL, LONDON (*Group II. No. 153*).

Extraction of gold from refractory ores by electrolysis.

ELECTRO-AMALGAMATOR CO., LIMITED, LONDON (*Group II. No. 154*).

Improved method of extracting gold and silver from their ores by the combined action of electricity and mercury.

**PHOSPHOR BRONZE CO., LIMITED, LONDON (Group II. No. 162).**

(1.) Phosphor bronze alloys for bearings and parts of machinery.

(2.) Silicon bronze wire for telegraph and telephone lines, electric lighting, and other purposes.

**MANGANESE BRONZE & BRASS CO., LIMITED, LONDON (Group II. No. 163).**

(1.) Manganese bronze for heavy castings, such as propellers cast under pressure for ordnance purposes, forgings, shafts, sheathing, plates, bearings, wire, etc.

(2.) White brass for axle brasses, and for filling bearings.

**PYRITES SMELTING CO., LIMITED, LONDON (Group II. No. 172).**

Huntington and Koch's amalgamating apparatus, to be used in the process for extracting precious metals (gold and silver) from their ores. It is also termed the gold amalgamator, and is an apparatus by which the pulp from the stamps may be readily passed through a column of mercury a foot or more in height. Good results are said to have been obtained in Australia. Huntington and Koch also propose to extract silver from ores by passing these after roasting through red-hot molten lead by means of an apparatus similar to the gold amalgamator.

**ERNEST SCOTT & CO., NEWCASTLE-ON-TYNE (Group II. No. 173).**

This firm exhibits Scott and Hilder's machine for extracting iron from other substances by means of electro-magnetism. By the use of this process engineers' refuse and mould-borings are at once rendered valuable, whilst ore can be very economically worked. Special attention is invited to the automatic manner in which the iron is released from the magnets.

**THE COMPRESSED LIME CARTRIDGE CO., LIMITED, LONDON (Group II. No. 177).**

Improved method of and apparatus for breaking down and getting coal and other minerals in mining, quarrying or tunnelling operations, by which all danger of igniting fire-damp in coal mines is avoided.

**GEORGE BOWER, ST. NEOTS (Group II. No. 198).**

Exhibits drawings of a Bower-Barff Furnace, and specimens of iron and steel rendered incapable of rusting by a process which consists in subjecting articles when at a red-heat to the action of superheated steam or air, by which the iron combines with the oxygen, and produces a coating of magnetic oxide not affected by ordinary atmospheric conditions.

**BOILER BROS. & CO., SHEFFIELD (Group II. No. 209).**

This exhibit is illustrative of a process for utilising the spathic and brown ores of the Styrian Alps in the production of steel by the direct process, only charcoal being used for fuel. Samples are shown of Bessemer and Bessemer-Martin steel from the same ores.

**FATS, OILS, AND SOAPS.**

**J. VEITCH WILSON & CO., GLASGOW (Group XIV. No. 1433).**

Improvements in the manufacture of lubricating oils and oil for batching jute.

**MESSRS. ENGELBERT & CO., LONDON (Group XIV. No. 1435).**

This firm exhibits a lubricant termed an "anti-corrosive lubricant;" it appears to be a high-boiling

mineral oil, and is guaranteed free from acid, spirit, odour, and to be unflammable under ordinary circumstances.

**MESSRS. MACKEY, MACKEY & CO., LONDON (Group XIV. No. 1446).**

Exhibit a series of vegetable, animal and mineral oils. The firm states the special advantages possessed by its lubricants to be—Freedom from acid and from gum, freedom from drying properties, a high flashing point, low solidifying point, and that the lubricants have no action on the working parts of machinery beyond keeping them bright and clean.

**PRICE'S PATENT CANDLE CO. (Group XIV. No. 1469).**

Specimens of fatty acids prepared from tallow, etc., by a new process. This method consists in decomposing tallow, palm-oil, etc., in an autoclave, by means of the magnesium salt of a fatty acid or acids. The magnesium is recovered for use again by means of an alkaline salt of a fatty acid or acids.

Specimen of soap made from tallow de-glycerised by the above method and for comparison therewith. Specimen of "Primrose Soap" made from the same neutral tallow.

Specimens of crude glycerine prepared by the foregoing process from tallow, palm-oil, and coconut oil. These illustrate the improvement which has been effected of late in the quality of crude glycerine by the introduction of improved methods of "autoclaving"—i.e., saponifying in an autoclave at a high pressure with the aid of water and a small percentage of lime, zinc, magnesia, etc.

*Solidified Glycerine Soap.*—Soap made transparent by the addition of 50 per cent. of glycerine, and without the use of spirit. Recommended for the use of those whose hands are liable to become chapped after washing.

Specimens illustrating a new method of rendering cloth-oil perfectly safe—i.e., of checking oxidation, and so preventing spontaneous combustion when cotton or wool is saturated with the oil. This method consists in the addition of a small percentage of soap to the oleine. This addition not only makes the oil safe, but otherwise improves its quality, increasing its "body" or lubricating value, and rendering it more readily removable in the scouring process.

*Candles and Candle-making, etc.*—1. Specimens of paraffin, semi-refined and refined paraffin wax, refined without the use of naphtha or other solvent. 2. Specimens of Price's Gold Medal Palmittin Candles, which combine the virtues of high-melting point paraffin and palmitic acid. The paraffin supplies high illuminating value and transparency, while the palmitic acid adds that strength which is necessary to prevent the guttering and bending that occur when paraffin candles are burned in a warm atmosphere. Wax and spermaceti are now practically obsolete candle materials, and it is claimed for the palmittin candles that they exhibit in a high degree the valuable characteristics of the modern and comparatively inexpensive materials—paraffin and stearin.

Price's Co. exhibit the following patented novelties and improvements:—

(1.) *The Making of Palmittin Candles with ends that may be called "self- and tight-fitting."*—Each conical end is formed by means of a cap fitted into the expanded end of the moulding pipe, and consists of a series of sharp or V-shaped flutes, which are readily abraded when the candle is being fitted

"Primrose Soap" here means a best tallow soap like "XXX" or "Honey Pale Soap" of the North of England and Scotland, where, however, "Primrose Soap" signifies a common and "highly run" article, containing from 36 to 39 per cent. of water, a freshly made curd soap of the best quality, containing not more than 31 per cent. of water.

into a candlestick. The caps are removed from the candles in a novel and ingenious way. They are laid on a popping-table attached to the machine, and the row of candles is simultaneously and instantly cleared from the caps by a series of wooden pistons moved by a lever.

(2.) *The Moulding of Spiral Candles.*—Hitherto such candles have been prepared one at a time by cutting, but now Price's Co. mould them 96 at a time. The winding of these screw-shaped or spiral candles out of the rilled moulds is as pretty as it is novel, and has attracted much attention.

(3.) *The old style of Making Candles is illustrated, but with a modern improvement.*—Dips are still consumed, but they are now made self-snuffing. Messrs. Price have introduced a new way of making them. Instead of dipping the wicks they dip a series of steel skewers into the candle material, and after the candles have been formed and cooled, the steels are removed, and the wicks, cut to the required length and specially prepared, are inserted. This method entirely prevents the waste of wick which characterised the old style of dipping, and the saving effected covers the whole cost of the candle-maker's labour.

An improved wick-making machine is shown at work. In this machine an improved switching arrangement has been introduced, which renders possible the employment of large bobbins running at high speed.

All the novelties and improvements exhibited have been invented by officers of the company, and all the candle machines shown are of the company's manufacture.

J. & J. C. FIELD, LONDON (*Groups XIV. and XI.*  
Nos. 1469 and 1192).

This well-known firm exhibits specimens (1) of soaps, (2) detergents, (3) disinfectants, (4) night lights, (5) candles, and (6) candle machines.

F. C. CALVERT & Co., MANCHESTER (*Group XIV.*  
No. 1466).

Exhibit samples of their well-known carbolic acid soaps. (See p. 475.)

J. ALEXANDER & Co., LAMBETH, S.E. (*Group XIV.*  
No. 1447).

Exhibit as a specialité a delicately-scented toilet soap, composed of the purest ingredients, and into which is introduced the extract of the fresh bark of the *hamamelis virginica* or common witch-hazel, which is known as "hazeline." This essence, chiefly composed in all probability of a phenolic substance, possibly analogous to *eucalyptol*, is distilled from the fresh green bark of the hamamelis, and has long been known as a valuable astringent remedy. According to the *Lancet*, "it has a fragrant odour and a cooling taste, and has a high reputation in the United States, where it is used in the treatment of eczema, ulcers, burns, etc. It has undoubtedly the power of arresting many forms of hæmorrhage." It is also stated by the *Medical Press and Circular* to be an admirable substitute for arnica, in all cases where the latter is usually prescribed, at the same time possessing advantages not offered by arnica. "Hazeline" is a colourless oil, possessing a peculiar, pleasant and pungent odour, and sweet astringent taste. It does not stain or soil, and produces a soothing and cooling effect when applied to irritated surfaces.

## PAINTS, VARNISHES AND RESINS.

THE SANKEY WHITE LEAD CO., WARRINGTON  
(*Group XIV. No. 1467*).

The "white lead" originally produced was, it is stated, deficient in density, and although possessing great opacity and a covering power superior to nearly all Dutch-made "white lead," was not liked by grinders, because its larger bulk when dry caused it to take longer to mix. This objection is now removed in an improved method of working, and a lead weighing 200lb. to the cubic foot is produced, without the other good qualities of the article being in the slightest interfered with. Still more important, however, is the announcement that by means of the improvements introduced in Mr. Ed. Milner's patent (Eng. Pat. 4053, November 22, 1875), this firm will very shortly be manufacturing that poisonous substance without the necessity of its being handled by the workmen in any way. On August 10, 1869, a patent (No. 2443) was taken out by J. Galloway Dale and E. Milner, afterwards one by E. Milner (June 22, 1872, No. 1881). The improvements in the last patent are more especially in reference to the 1872 patent.

Finely-ground litharge is taken and mixed with a solution of common salt, in the proportion of 4lb. of dry litharge to 1lb. dry salt, the salt being dissolved in 16 parts, by weight, of water. The mixture is thoroughly agitated for about 4½ hours. The result is an insoluble basic chloride of lead. This basic chloride is now suspended in a solution of caustic soda and common salt. The mixture is then introduced into a lead-lined vessel, fitted with wooden beaters, and there subjected to the action of carbonic acid, beyond the point at which it ceases to show an alkaline reaction. The proper point of saturation is ascertained by a simple test, easily applied by the workmen. When the solution has ceased to show an alkaline reaction, the mixture is a viscid homogeneous mass, and if a portion be shaken in a half-empty glass, it will coat the sides and remain in a layer all over them; but when sufficient gas has been supplied, a small quantity shaken in a clear glass vessel coats the sides with a very thin layer, like frost on a window pane, and after standing for a few seconds the clear liquid separates from the carbonate of lead and leaves an arborescent pattern on the interior of the glass. Should this action of the gas have been continued too long, the product loses its value, becoming like sand, and not coating the glass at all, but settling rapidly out of the solution of salt.

The workpeople can tell to the greatest nicety, by this test, when to stop the supply of gas.

The carbonate of lead thus produced, after being washed to free it from salt, and being dried, is ready for use, and is stated to be of greatly-improved quality, compared with that formerly produced by the former patented method.

THOS. GRIFFITHS, OXTON, LIVERPOOL (*Group XIV.*  
No. 1443).

"GRIFFITHS' PATENT ZINC WHITE" (SULPHIDE OF ZINC).

This pigment is manufactured by Messrs. Griffiths, Berdoo & Co. (the Sanitary Paint Co., Limited), of Liverpool and London. It is claimed for this article that besides being non-poisonous, "it covers one-third more than white lead, and 100 per cent. more than zinc oxide." It is said to have no chemical action upon metals, if not discoloured by foul gases or bilgewater, is fire-proof and unaffected by a red heat. It is also said that most delicate tints or "tones" can be produced with it, not possible with lead. This zinc white is produced as follows:—Either zinc

chloride or sulphate is precipitated by a soluble sulphide—sodium, calcium, and barium sulphides all having been used for the purpose—and precautions are taken lest any iron that may be contained in small quantities as an impurity in the zinc solution, should be precipitated with the sulphide of zinc. The precipitate being collected and dried, is transferred to a furnace, where it is calcined, and after careful stirring it is raked out, whilst quite hot, into vats of cold water, where it is levigated, and afterwards collected and dried. The result is stated by Dr. T. L. Phipson to be a white pigment of exquisite beauty, and possessing a covering power, when mixed with oil, greater than that of any known substance. Phipson's analysis shows that the substance consists of an oxy-sulphide of zinc, the composition of which varies somewhat, according to the duration of the calcination and the exact degree of heat attained. The best product appears to correspond very closely with the composition indicated by the formula  $5\text{ZnS} + \text{ZnO}$ . (See *Journ. Chem. Soc.* for December, 1878.)

H. BOLLMAN CONDY, LONDON (*Group XIV. No. 1445*).

The specimens exhibited illustrate what is termed a *new rapid innocuous* process for the manufacture of white lead  $[\text{2(PbO,CO}_2\text{)} + \text{Pb(OH)}_2]$  of the finest colour and body, of the exact composition of white lead made by the old Dutch process, and of equal density. In this process the workmen are not under the necessity of handling the white lead until the completion of the manufacture, which is effected in seven days, whereas by the old process four or five months are required. The body of this pigment is such that it requires to be ground with from 12 to 13lb. of refined linseed oil to the cwt. At first it appears somewhat thin, but in the course of twenty-four hours it will be found to be firm, and to have, it is said, the quality which has hitherto only been found in white lead which has been ground some months.

DONALD MACPHERSON & CO., MANCHESTER (*Group XIV. No. 1469*).

Exhibit specimens of the so-called Foo-Chow signal paints, a kind of enamel paints, possessing all the long-sought-for characteristics of the Chinese enamels, so much admired for their hardness and brilliancy on tea-trays and papier-mâché articles imported from China. The paints have, on drying, an extremely hard, tough, glossy surface, are not affected by sulphuretted hydrogen and will not crack, blister, or scale off. They dry in five minutes, when a second coat can be applied.

The Foo-Chow lacquers are also valuable for printing pillar letter-boxes, and to machinists, japanners, or for any manufacturers who have to turn out their goods as soon as they are finished, and yet desire a highly-enamelled surface.

J. B. FREEMAN & CO., BATTERSEA, S.W. (*Group XIV. No. 1448*).

This firm shows specimens of its patent "non-poisonous white lead," which mainly consists of lead sulphate of a specially prepared kind. This form of white lead is, according to the testimony of Prof. A. H. Church, superior to the best white lead made by the Dutch method, and is besides said to be really non-poisonous, both as regards workmen making it or using it. As an oil paint, it is free from the disagreeable odour of the ordinary article when ground in oil. In density, body and covering power, as well as in smoothness and the purity and beauty of its whiteness, Freeman's paint is at least equal to the best white lead of the old processes, and in some of the qualities named it is superior. Dr. H. C. Bartlett

has proved by photometric observation of the quantity of light reflected by various samples of the purest zinc white, and by Freeman's white lead, that the whiteness of the latter exceeds that of the former. According to Prof. Church, when submitted for varying periods to the action of air containing sulphuretted hydrogen, surfaces of this paint remain unaffected, or were only very slightly tinged. It does not turn yellow or buff when a surface painted with it is excluded from light for some time—a well-known drawback in the use of white lead.

Now, though the basis of Freeman's "non-poisonous white lead," as already stated, is sulphate of lead, yet the pigment does not consist merely of sulphate of lead; also, the sulphate employed is no mere by-product, but is specially prepared from metallic lead. Many attempts have been made to utilise lead sulphate as a pigment, but without success, the product being quite useless, possessing neither the necessary density, body nor opacity. Moreover, a large quantity of oil is required in grinding it, and as a paint it is what painters term "slimy," and works very badly under the brush.

It was found, however, that by adding about 25 per cent. of zinc oxide (in itself a substance possessing neither good body nor density), and subjecting the mixture to great friction and pressure under heavy edge runners, a complete change is effected in the characters of the substances employed, which it would appear impossible that any mere mixture could effect; and a pigment possessing great density and opacity, and of exceeding whiteness, is the result. The whiteness is said to be greater than that of the finest white lead made by the Dutch process. As regards density, 3 cubic feet of lead sulphate, weighing 170lb. per cubic foot, and 1 cubic foot of zinc oxide, weighing 88lb., when mixed together and treated by the above process, yield the pigment in question, weighing over 200lb. per cubic foot.

The following experiment was made by Prof. Church, with this white pigment, and the description of it is given in his own words:—

"On a sheet of glass three large patches of three different paints were spread with a spatula. The three paints were all ground in linseed oil, they being respectively, (A) Freeman's white lead; (B) Dutch process white lead; (C) zinc white. The sample C had been ground in oil so long ago as 1879. Before the patches of paint had dried at all, a few drops of dilute sulphuric acid (Brit. Pharm. strength) were poured upon them and well mixed with an ivory knife. No saponification with C has occurred, and, therefore, no mixture of acid and paint could be effected. With B the saponification of the oil was complete. With A, saponification had occurred to a very marked degree, quite sufficient for the purpose of causing the paint when dry to produce a tough homogeneous film, not liable to break up into powder by exposure to weather or wear."

Messrs. Freeman also exhibit a case of non-poisonous colours (pigments) of almost every variety of shade.

T. B. ORR & CO., LONDON (*Group XIV. No. 1467*).

This firm exhibits specimens of the so-called Hygienic Paints, the principal ones being the "Charlton White" and "Duresco." The processes by which these paints are produced by Messrs. Orr & Co., are somewhat as follows:—"Barytes" (heavy spar), and "Celestine" native strontium sulphate, are finely ground and mixed with ground coal, and the mixture, of a "leadene hue," is repeatedly roasted at high temperatures in four furnaces. The charge drawn from the fourth furnace, and consisting of the sulphides of the alkaline earth metals, is carried to an upper floor in waggons, and then thrown into a

large pan and mixed with water. After settling, the greenish solution of the sulphides is pumped up to a large receiver on the top floor of the factory. Meanwhile, on the roof is a cistern in which pure zinc is treated with a mixture of sulphuric and hydrochloric acids, until solution is effected. The metallic zinc is especially made from poor calamine; this calamine sometimes contains copper, which is carefully removed from the zinc, or damage would result. The zinc solution is drawn off by pipes, and conveyed to a tank on the lower or first floor, and into this same tank is drawn the green coloured solution of barium and strontium sulphides from the tank on the upper floor, and the solutions are thoroughly mixed. In the barium tank is usually a large residue of undissolved sulphides and probably undecomposed sulphates. This is taken outside, thrown in heaps, and exposed for some time to the air, when it frequently loses its black sludgy appearance and turns yellowish-green. At this stage it is again furnace-d, and then once more lixiviated. The milky liquid obtained in the cistern where the zinc sulphate and chloride are mixed with the barium and strontium sulphides, is run into pans and allowed to settle, when after a time it assumes a semi-solid form, when it is removed and pressed till the mass appears like moist pipe-clay, when it is taken and dried at a gentle heat on stone beds over flues. From these beds the dry pigment, thus chiefly a mixture of barium and strontium sulphates with zinc sulphide, is taken and thrown into a furnace, where it is subjected to an intense heat for several hours, when it is drawn out and plunged into cold water. This treatment is said to confer "solidity" and "density" upon the paint. The paint is now well-ground in water by a grinding stone; as it becomes more and more attenuated, it rises with the water, becoming mixed with it, and overflows through a pipe, which carries the finely-ground white into a second vat fitted with another set of grinders of a different kind. Attached to this second vat is a pump which draws off the white liquid, and conveys it through pipes to another department where it is emptied into a series of capacious cisterns; in these it is allowed to stand until the solid matter is settled out, when the water is syphoned off. The white is then taken out and pressed. The press residue is afterwards taken and placed on small wooden trays made of narrow ribs of wood, and these trays are carried into a drying stove. When completely dried, the pigment is ready for mixing with linseed oil, and is the substance known as "Charlton White." "Duresco" is a so-called temper, made from "Charlton White," and will, it is said, when applied to walls, ceilings, etc., stand washing extremely well, is non-poisonous, and impervious to damp.

**THE CONTINENTAL DIAMOND ROCK BORING CO., LIMITED** (*Group XIV. No. 1444*).

Specimens illustrating a process for manufacturing white lead pigment.

**THE PATENT LIQUID FIREPROOF CYANITE PAINT CO., LIMITED** (*Group XIV. No. 1440*).

Exhibits specimens of coloured cyanite. The "Fireproof Cyanite" is a liquid which may be procured either colourless or coloured for staining wood, canvas, felt, etc. It is also used as a priming for paint, varnish, etc. Combustible substances, such as those named, coated with it, are certainly rendered completely unflammable. Some wood chips sent to the writer, as having been coated with the preparation, were found slightly covered with a whitish powder almost like an efflorescence, and on wetting were found to taste, as well as to react, strongly alkaline.

This being the case, the fire-proofing liquid is not unlikely to be a mixed solution of silicate of alumina and silicate of soda (or soluble glass). In any case the chips of wood refuse to burn in a flame, and only slowly char. The wood that has been impregnated was found to have preserved its integrity perfectly. Besides communicating nothing of a poisonous nature to the wood, it is claimed that the treatment with this liquid prevents dry-rot, and that only one coating is needed. According to the testimony of the *Builder*:—"Two wooden structures, one only coated with the above-named preparation, the other not coated at all, were fired; the one coated withstood the action of the flames, whilst the non-coated building was destroyed." *Engineering*, referring to the coated building in the experiment, states that "the prepared building was merely scorched." Captain Shaw, C.B., Chief of the London Fire Brigade, considers that "wooden stairs cyanited are, in case of fire, much safer than stone." The small experiment with the cyanited chips certainly bears out this statement, for a similar fragment of stone exposed in a flame to a temperature at which the wood is only commencing to char, would have cracked and flown to pieces.

**MESSES. BOLTON & PARTNERS, LIMITED, BRISTOL** (*Group XIV. No. 1452*).

(1.) Specimens of strontia paints, colours and glazes; and (2.) Specimens illustrating certain improvements in the manufacture of caustic soda.

**TANNING, LEATHER, GLUE, AND SIZE.**

**THE EGLINTON CHEMICAL CO., GLASGOW** (*Group XIV. No. 1441*).

This firm exhibits specimens illustrating the chrome-tanning of leather, and articles made from the leather so tanned. (See this Journal, iii. pp. 615-620).

**T. NORDENFELT, LONDON** (*Group XIV. No. 1439*).

Exhibits specimens illustrative of his new methods of extracting albumen, fish-oil, glue, gum, etc., from fish, and of preparing guano from the residue.

**B. CANNON & CO., LINCOLN** (*Group XIV. No. 1438*).

Show samples of concentrated size and glue powders made by their firm.

**AGRICULTURE, MANURES, ETC.**

**THE AGRICULTURAL AND HORTICULTURAL ASSOCIATION, LIMITED, LONDON** (*Group XIV. No. 1455*).

Specimens are shown of various improved artificial manures, suitably classified according to the crops which they are intended to promote. An interesting and able account, not suited for reproduction here nor yet for useful abstraction, is presented by the Association, and it treats in detail of the different manures made, the crops for which they are suited, and the proportions of the constituents composing these manures, with prices.

Among certain directions given for the valuation of compound manures by analysis, is one which runs as follows:—

"Great care is required in sampling a compound manure for analysis. A small portion should be drawn from almost every bag, and these small lots carefully mixed together. *All dirt, stones, etc., which would vitiate the result, should be carefully excluded.*" (The italics are the writer's.) After the preceding direction appears the following:—

"As analysts differ in their results, we must claim the right to have a second analysis made by a second

chemist, if necessary, and to strike an average of their results." It would seem, however, that the "great care required in sampling" above referred to, would lead the readers of the sentence in italics to regard that sentence in very different lights, according as they are buyers or sellers of a manure! Moreover, not unlikely "analysts differ in their results" more or less in proportion as "great care is" exerted "in sampling" by buyers and sellers respectively!

The directions for the use of common salt in manuring are interesting. It is stated that salt should be used in conjunction with almost all manures, whether farm-made or artificial. "It is especially advantageous for mangels, cabbages, kohlrabi, kale, potatoes, etc. It sweetens pastures, and where used is said to be an antidote to several diseases of sheep and cattle. It is best mixed with manures just before they are used, as otherwise it has a tendency to cause them to get damp." The following various kinds of salt are supplied by the Association:—"Agricultural salt, ground rock salt, clean broad salt, fish salt (containing some ammonia), saltpetre salt (containing some potassium nitrate), hide salt (containing some ammonia)."

In the directions for use it is stated: "For potatoes, turnips, mangels, carrots, old-laid grazing lands and sour pastures, from 5 to 10cwt. are sown broadcast in the early spring." "Farmyard manure should be regularly salted, while compost heaps of earth and lime would be greatly improved and give better results by the addition of a little salt." "Nitrate of soda, and similar strong nitrogenous manures, should be mixed with three or four times their weight of salt before sowing." It would thus appear that sodium chloride, by virtue of its ready solubility and osmotic power, plays a part in assisting in the assimilation and digestion of manurial and earth-food by the plant, similar to that played in the animal economy when salt is partaken with food by man.

EDWARD WEBB & SONS, WIDNES AND STOUR-  
BRIDGE (*Group XIV. No. 1456*),

This firm exhibits (1) samples of Webb's manures for all crops; (2) raw materials from which the manures are manufactured.

CLAY & LEVESLEY, LONDON (*Group XIV. No. 1456*),

Show samples of Clay's fertiliser, a special horticultural manure.

EDWARD PACKARD & Co., IPSWICH (*Group XIV. No. 1454*),

Exhibit specimens of concentrated superphosphate, and also phosphates of soda, potash and ammonia, with other compounds, manufactured by processes protected by letters patent (Eng. Pat. 2182, May 31, 1878), in which also the use of a special form of mixing apparatus for assisting in dissolving phosphates, is comprised. The mode of separating the gypsum and solid mass from the superphosphate solution by means of filtering presses, particularly wooden ones: the mode of concentrating the superphosphate solution so obtained, and several other processes connected with the manufacture of superphosphate, etc., are also patented. (See Eng. Pat. No. 6176, April 9, 1884; also Nos. 6750, 6751, and 6752, April 24, 1884.)

The chief feature of novelty is the cheap method of manufacturing a concentrated form of phosphoric acid (superphosphate). If bones be reduced to a meal and added to a syrup of this concentrated superphosphate, and after thorough incorporation the mass

be thrown in a heap and allowed to remain for a few weeks, it will gradually dry and become friable, and in a fit state to be applied to the soil. Phosphatic guanos may be treated in a similar manner.

J. SIMON-LEGRAND, BERSÉE, FRANCE (*Group I. No. 2705*),

Apparatus for forcing or germinating grain.

SUGAR, STARCH, GUM, &c.

EDWARD PACKARD & Co., IPSWICH (*Group XVII. No. 1564*),

Exhibit specimens illustrating their improvements in the manufacture of sugar from cane-juice. These comprise samples of sugar made in the Mauritius under the new process invented by Messrs. Icery, Bernard & Ehrmann, and patented by them. By the use of this process, great economy is claimed as being effected in the manufacture of cane-sugar.

This firm exhibits, further, various reagents used—the processes referred to, including a particular form of phosphoric acid, really a crystalline superphosphate termed "Ehrmannite," which is entirely soluble in water, and the manufacture of which is patented by the exhibitors. There are two qualities of this superphosphate, the "A" quality containing about 55 per cent. of soluble phosphoric acid, and "B" about forty per cent. Before use, the substances are dissolved in cane-juice or water. In these they are easily soluble.

These superphosphates are used in the following way:—The usual process of defecating the cane-juice is carried out by adding lime until the point of neutralisation is reached. The juice is then "over-tempered," half as much lime again being added as had been required to neutralise the raw cane-juice. The solution of the superphosphate is then run in, until the excess of lime purposely used is precipitated, and the neutral point again attained. The resulting liquor, when drawn off, is found particularly clear and free from objectionable extraneous matters. The advantage of the use of the superphosphate arises from the floccular nature of the precipitate it forms with lime, for this mechanically collects along with it all the suspended matters in the juice, throwing them to the surface in the usual process of "cracking" the liquor, as it is termed in the West Indies. The mud from liquor so defecated is valuable for manure from the extra amount of precipitated phosphate of lime it contains.

BOLTON & PARTNERS, LIMITED, LONDON (*Group XVII. No. 1561*),

Show specimens illustrating their improvements in the treatment of saccharine juices, and the manufacture of oxide of strontium for the production of refined sugar direct from beets.

J. A. R. & J. DUNCAN, AND B. E. R. NEWLANDS, LONDON (*Group XIV. No. 1449*).

(1) Alum process for removing potash from saccharine solutions; (2) Improvements in the manufacture of sulphate of alumina.

On referring to Eng. Pat. 2090, 1871, by James Duncan, John A. R. Newlands and Benjamin E. R. Newlands, it will be found it treats of what is commonly known as the "alum process" for removing potash, ammonia, and other impurities from saccharine solutions.

Cold solution of sulphate of alumina is added to the cold syrup in quantity sufficient to form an alum with the whole of the potash present. The mixture

is well stirred for a few minutes, and then allowed to repose for a few hours, when the alum falls to the bottom of the vessel, and the clear acid liquor is then removed by decantation.

The acid liquor is next neutralised by milk of lime. The liquor is afterwards heated and filtered. It will then be found that a large part of the mineral matter has been removed, and also a good deal of organic impurities. The alum produced has a ready sale, being remarkably free from iron. During the past few years, five thousand tons of this potash-alum have been produced at Mr. James Duncan's sugar refinery, Clyde Wharf, Victoria Docks, London.

In connection with this process, the following samples are exhibited:—The solution of sulphate of alumina used and the alum produced, the latter in the form of alum-meal and of a large crystalline block. The syrup is shown before treatment, also after addition of sulphate of alumina (with the deposit of alum), and, lastly, after completion of the process.

Eng. Pat. 5287, 1880, by B. E. R. Newlands, covers a process for the manufacture of sulphate of alumina containing very little iron or free acid. Solution of sulphate of alumina, containing more or less impurities, is concentrated until it partially solidifies on cooling, to form a magma, or mass of crystals. This magma is pressed in a filter press, and cakes of sulphate of alumina are thus obtained containing scarcely any free acid, and only a very small amount of iron.

The residual mother-liquor is concentrated by heat till it is sufficiently strong to give a magma of crystals on cooling, and this second magma is submitted to pressure as before, and yields a tolerably pure sulphate of alumina. The same operation may be repeated, and the impure mother-liquor finally left yields a sulphate of alumina containing a considerable amount of iron. This sulphate may be used for the purification of sewage, or for any other purpose for which sulphate of alumina is required, and in which the presence of iron is not objectionable.

In connection with this process the following samples are exhibited:—The Eglinton alum-clay used in making the sulphate of alumina; the concentrated solution of sulphate of alumina with the magma in it; and the first quality, second quality, and residual products obtained.

GUSTAV FRITSCHÉ, MORAVIA (AGENT, P. BORN, LONDON) (*Group XVII. No. 2704*).

Show samples illustrating the improved method of the above-named, for refining beetroot sugar-juice.

ADOLPH LIST, LEIPZIG (*Group XVII. No. 2705a*), Exhibits specimens of saccharine made from coal-tar.

#### (A) FOODS, (B) SANITARY CHEMISTRY, (C) DISINFECTANTS.

##### (A) FOODS.

HOLLANDIA, FABRIQUE DE PRODUITS DE LAIT, NETHERLANDS (*Group XVII. No. 2715*).

Samples illustrating the process of this firm for preserving milk and cream without sugar.

This condensed milk is prepared at the manufactory, "Hollandia," near Rotterdam, the only addition to the milk being the required amount of sugar to act as a preservative after the tin is opened, and only the best cane-sugar is employed for this.

The milk is moreover condensed and conserved without the addition of any foreign matter. The condensed cream consists of the pure article.

JOHN FORDREY, LONDON (*Group XVII. No. 1569*).

Specimens of (1) Malted food preparations—viz.: (a) Allan & Hanbury's malted farinaceous food and malted jelly; (b) Hill & Sons' malted nursery biscuits. (2.) Samples of torrefied grain with model—viz.: (a) Barley, maize, rice, etc., for brewing, distilling, and vinegar making; (b) Maize prepared for horse and cattle food by the Torrefied Grain Company. (3.) C. Spencer & Sons' malted cake for cattle feeding.

##### (B) SANITARY CHEMISTRY.

THE PATENT POROUS CARBON CO., LIMITED, LONDON (*Group XIV. No. 1459*).

This company illustrates its methods for deodorising sewage, for filtering water, refining sugar, and for the decolourisation and purification of liquids by means of a patent carbon. Plans also of patent carbon closets, etc., are shown.

##### (C) DISINFECTANTS.

H. B. CONDY, BATTERSEA, S.W. (*Group XIV. No. 1445*).

Exhibits specimens of (1.) A new permanganate disinfectant, which contains also aluminium sulphate, which, it is said, increases the oxidising effect of the permanganic acid, plays a useful part in neutralising ammonia, and adds antiseptic value to the preparation. In this new disinfectant, all the available oxygen of permanganic acid is utilised, whereas only 60 per cent. of this amount is utilised with the alkaline permanganates. (2.) A new medicinal salt, sodium hyposulphate, and also other hyposulphates.

J. MARTIN SMITH, LONDON (*Group XIV. No. 1422*).

Shows specimens of disinfecting cleansing powder.

##### PAPER, PASTEBOARD, &C.

THE CHEMICAL PAPERS CO., LIMITED, LONDON (*Group XIV. No. 1460*).

Illustrative specimens of (1) improvements in the manufacture of papers and felts for protective, antiseptic and germicidal purposes; (2) moth-destroying papers; (3) anti-tarnish and building papers.

HENRY NEWALL & SONS, MANCHESTER (*Group XXVI. No. 1986*).

Specimens of (1) mechanical and chemical wood-pulps; (2) wood-flour, etc., used in the manufacture of paper, linoleums and other fabrics.

T. GRAHAM YOUNG, DURRIS, ABERDEEN (*Group XXVI. No. 1992*).

Illustrates his chemical process in the preparation of wood-pulp, with suitable samples.

W. M. RIDDELL, LONDON (*Group XXVI. No. 2004*), Illustrates the manufacture of paper, paper boards, waterproof paper, and other articles of a fibrous texture from waste bark.

G. F. GREEN & CO., LONDON (*Group XXVI. No. 2044*).

Specimens of wood-pulp boards and wood-papers made by their firm.

THOMPSON & NORRIS MANUFACTURING CO., LIMITED, LONDON (*Group XXVI. No. 2043*).

Exhibit samples illustrating their improvements in the manufacture of corrugated paper to be used as a packing material and parcels post wrapping.

THE DANZIGER CELLULOSE FABRIK (AGENTS, C. F. GREEN & Co., LONDON) (*Group XXIV. No. 2653*).

The following are the details of this exhibit:—

1. Specimens illustrating the stages of the manufacture of chemical wood-pulp (soda process).
2. Samples of pulp manufactured by the new sulphate process, and of paper produced from this material.
3. Samples of wood-pulp boards and fancy boxes made from them.
4. Samples of pure wood middles for card-making.
5. Samples of tinted wood cartridge-paper or boards for tickets, etc.
6. Samples of pure wood wrapping-paper.
7. Samples of mechanical wood-pulp.

(Nos. 4, 5 and 6 are made from this kind of pulp—i.e., mechanically-ground wood).

#### FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

BRIN FRÈRES, PARIS (*Group II. No. 138*).

#### THE INDUSTRIAL PRODUCTION OF OXYGEN AND NITROGEN, AND THEIR SEPARATION FROM ATMOSPHERIC AIR.

Anhydrous barium oxide is first prepared, then placed in a kind of tabular retorts arranged in series, and heated to between 500° and 600° C., atmospheric air, which has been previously deprived of carbonic acid and moisture, being passed over it. The oxygen is absorbed, barium peroxide is thus produced, and the partially-exhausted air is passed through other retorts of the series until at length all the oxygen is said to be absorbed, and nitrogen passes on to a gasholder. The temperature is regulated by means of a pyrometer specially constructed, so that at the end of the pyrometric bar a lever is fixed which holds a suspended disc, so adjusted as to proportion exactly the mixture of air and carbonic oxide employed as fuel. This bar, in expanding, closes the disc-valve or clapper which admits the air to the furnace, and there is at once a fall of temperature to 500°. When the pyrometric bar contracts, the valve is again open, and the temperature rises to 800°, and at 800° deoxidation of the barium peroxide produced is said to take place, pure oxygen being of course evolved. Thus great regularity in the heating of the retorts is said to be obtained, a considerable saving in plant through the danger of overheating being prevented, not to speak of the perfection in working, all independent of the attention given to the furnaces by the workmen. The apparatus works in a precise, because in an automatic way; for a disc or a single valve when shut virtually produces the peroxidation, and when open, the deoxidation, by the action of the pyrometric bars already mentioned. Messrs. Brin Frères calculate that 1 kilo. of anhydrous barium oxide produced by their process will give at the first operation 25 litres of oxygen. The production will increase from day to day, and they have observed that after eight days of continuous working this same kilo. will produce 68 litres of oxygen. They claim, therefore, that in a regular course of production, they can count upon an average return of 50 litres of pure oxygen for every kilo. of anhydrous barium oxide for each operation.

*Description of the Apparatus.*—The barium oxide is placed in iron retorts, set in horizontal layers or batteries. These retorts have at each of the ends metallic friction joints. For the complete demonstration of the process, Messrs. Brin Frères have at their shed in the Exhibition coupled two furnaces, each with 15 retorts of 2·80 metres in length, and 0·16 metres diameter inside measure. Two double-

acting pumps communicate with these batteries, one of the pumps drawing air into the retorts, and so into contact with the barium oxide, when peroxidation takes place. The other pump creates a vacuum in the retorts at the proper time, and when the temperature rises to 800°, and draws off the oxygen, which had combined with the baryta, to form peroxide of barium. The air before entering the retorts is deprived of carbonic acid and moisture by passing it through the chambers of an apparatus containing quicklime or caustic soda. The coupling of the two furnaces allows of the direction, by means of pipes and valves, of the peroxidation or deoxidation, or one or other of the two furnaces, as may be desired.

The experimenting establishment of Messrs. Brin Frères is large enough to enable them to produce 100 cubic metres of pure oxygen per diem, and this is of course more than mere laboratory work.

The oxygen produced is quite free from the small quantities of chlorine found in the gas generated from potassium chlorate, and which interfere with its use for medical purposes.

*The Nitrogen; its Collection and Employment.*—A simple change of valves at the outlet of the retorts makes it possible to send each gas into its respective gasholder. For every cubic metre of oxygen about four cubic metres of nitrogen are obtained. The latter element it is proposed to utilise, and the method to be adopted is experimentally illustrated by the exhibitors. The medium, or reagent, chosen for effecting the synthesis of the nitrogen and hydrogen is a very thorough mixture of finely-divided carbon and caustic baryta. This mixture is placed in retorts, and nitrogen, previously rendered moist by bubbling it through water, is passed through them, their temperature being maintained at 150° C. The steam at this temperature is, according to the inventor, decomposed, the affinity of baryta for carbonic acid being apparently powerful enough to determine the formation of the latter, whilst nascent hydrogen unites with the nitrogen, forming ammonia, which, passing on, is absorbed by sulphuric or hydrochloric acids, or otherwise treated.

*VARIOUS APPLICATIONS:—Oxygenised Water.*—Oxygen is forced into water under high pressure, and a beverage is produced, which, it is said, medical men have experimented with very successfully in the amelioration or cure of certain disorders. That the water is charged as stated, is easily proved by the simple experiment with a red-hot match on opening the tap of one of the syphon-bottles containing the oxygenised water.

*Metallurgical Applications.*—The usefulness of the pure oxygen in conjunction with hydrogen, for producing the intensely-hot oxy-hydrogen flame, is illustrated in a variety of interesting operations and specimens exhibited.

*Light.*—The Drummond light is shown, as produced with a flame yielded by pure oxygen and hydrogen, and it is suggested that this beautiful light would become more generally applicable and useful were pure oxygen so cheaply and easily obtained as the exhibitors believe their process would enable it to be.

*Ozone.*—It is pointed out by the exhibitors that the production of pure oxygen on the large scale would probably soon lead to the attention of scientific and practical men being drawn to the preparation of ozone by the action of the electric current on oxygen, or otherwise, and to its employment in the medical treatment of certain complaints.

GEORGE BARTH & Co., LONDON (*Group XIV. No. 1437*).

Exhibit (1) apparatus for the administration of nitrous oxide gas in combination with ether; (2)

portable apparatus for the inhalation of oxygen or other gases in combination with atmospheric air.

JOHN ORCHARD, LONDON (*Group XIV. No. 1432*), Shows specimens of compressed and liquefied gases, valves and bottles.

MACKEY, MACKEY & Co., LONDON (*Group XIV. No. 1446*),

Show a fine set of specimens of neutral soluble salts of cerium for medicinal purposes, comprising the following:—Ammonio-citrate of cerium, ammonio-tartrate of cerium, potassio- and sodio-citrates and tartrates of cerium, lactates of cerium.

The mineral used as the source of cerium is cerite, which is chiefly composed of silicates of cerium, lanthanum and didymium, the oxide of cerium on the average present being 39 per cent.

The first introduction of cerium as a therapeutic agent appears to be due to Sir James Simpson, who recommended cerium oxalate as a specific against obstinate cases of vomiting, and its good effects Simpson found not to be confined to the forms of vomiting which depend on the sympathetic derangement of the stomach caused by changes functional or pathological, in the uterus or other organs, but which are manifested also in those forms of the complaint which are due to different morbid conditions of the stomach itself. He expressed the opinion that other salts of cerium would answer as well as the oxalate; but this salt was the one then most easily procurable. "The action of cerium on the stomach seems to be that of a sedative tonic, resembling, in some degree, the action of salts of silver or bismuth, and I have" (writes Simpson) "seen it successful in curing the most obstinate cases of vomiting. The effect is sometimes instantaneous, sometimes the vomiting ceases after a few doses, sometimes not until the remedy has been persevered with for several days."

The "*Liquor Cericæ cum Bismutho*," a specimen of which is shown, is said to be a very powerful specific at present recommended for the prevention or reduction of vomiting.

HOWARDS & SONS, STRATFORD, E. (*Group XIV. No. 1467*).

**Alkaloids.**—This firm exhibits exceedingly fine specimens of cinchona barks and alkaloids; also an interesting variety of salts of certain organic acids and alkaloids useful in pharmacy. The samples of bark shown illustrate the great change which the introduction of cultivated bark has brought about in the quinine industry. In 1862 South America was looked to as the source of cinchona bark as a matter of course. At the present time, however, the East India barks are almost entirely worked. There still remains a great deal to be done in choosing the varieties, and in cultivating the bark to the best advantage. Ten and twelve per cent. of quinine sulphate are not unusual yields from picked trees, and there is no reason to think that the maximum is reached; while the renewing process, which was discovered by Mr. Melvor, has enabled the growers of *Cinchona Succirubra* to double the yield of quinine. The alkaloids exhibited by this firm are novel as to purity. The various alkaloids found in commerce are now completely separated, and ought to be obtained of a degree of purity far greater than was the case formerly. Amongst the salts of quinine shown, the following immediately strike the eye of the chemist:—*Chlorate of quinine*, *salicylate of quinine*, *iodide of quinine*, *acetate*, and *valerianate of quinine*.

Interesting specimens are shown of crude China and Japan camphors, the Japanese article, as regards

whiteness and apparent purity, decidedly bearing the palm.

Samples of camphor cakes are also exhibited. They consist of compressed camphor, and the effect of the compression is to produce a mass resembling in its structure and appearance glacier ice, the process furnishing an example of true regelation.

**Iodoform.**—Till within the last few years iodoform was merely a chemical curiosity, but now it is become of great value in surgery, and is used in enormous quantities, and with most remarkable results.

A beautifully-crystallised specimen of iodoform is exhibited by Messrs. Howard.

MAY & BAKER, BATTERSEA, S.W. (*Group XIV. No. 1467*),

Exhibit some of their finer chemicals. Gallic and tannic acids are shown, with a specimen of pyrogallol in beautiful white crystals. Benzoic acid prepared from "gum benzoin," with a series of benzoates, amongst which a finely-crystallised specimen of benzoate of ammonium ( $\text{NH}_4\text{C}_7\text{H}_5\text{O}_2$ ) is worthy of notice. The mercurial preparations form a complete and exceedingly well-crystallised set, and the bismuth compounds are crowned by a beautifully-crystallised specimen of the metal.

Messrs. May & Baker also show specimens of the recent pharmaceutical novelty—viz., true oleates obtained by precipitation, which, besides possessing the advantage of reliable composition, are probably in a form most convenient for the production of effective ointments. These metallic oleates are variously-coloured pasty masses. A specimen of pure oleic acid is also shown. The "Sublimed Transparent Tablet Camphor" exhibited by this firm appears in all shapes and sizes. Some of these tablets, indeed, bear considerable resemblance to Iceland spar, and by a modification of the process, indelible lines and marks are produced throughout the blocks, taking the form of monograms, designs, etc. A mould or "template" in sections is shown to illustrate the patented method of "working" up the metallic bomb-lows used in subliming into the ring form, the older form of sublimation being illustrated by a small ring or "bell" of camphor and "bomb-low."

HOPKIN & WILLIAMS, LONDON (*Group XIV. No. 1467*),

Exhibit specimens of their manufacture of fine chemicals.

A series of samples of metallic oleates is shown, almost all of them being in the dry form. The series has certainly the appearance of a remarkably fine set of preparations.

The copper sulphate is purified by a novel process, and is perfectly pure.

Its entire freedom from iron is easily proved by supersaturating a solution of some of the salt in water with ammonia, and allowing it to stand for some hours, when any iron present will be deposited.

The specimens of bichromate of ammonia and sulphocarbonate of zinc represent preparations largely made by this firm.

By many medical men the salicylic acid, which is the natural product obtained from the oil of wintergreen (*Gaultheria Procumbens*) is considered superior to that obtained synthetically and artificially from carbolic acid, which may possibly not always be quite pure. A specimen of this natural salicylic acid in very fine crystals is exhibited, and a series of salicylates all prepared from the natural acid. It is needless perhaps to remark that the salicylates usually found in commerce are now prepared from the synthesized salicylic acid. The following is a list

of the specimens shown by Messrs. Hopkins & Williams:—

Potassium chromate (pure).	Sodium chlorate (pure).
Calcium borotrihydrate.	Calcium benzoate.
Camphor monobromide.	Quinine hydrochloride (soluble).
Silver oleate.	Chronic anhydride.
Copper ..	Lead iodide (crystallised).
Iron ..	Chromium chloride (sublim'd).
Zinc ..	Cantharidine.
Cadmium ..	Cocaine (pure).
Aluminium ..	Acetonitine (pure, English).
Mercury ..	Mercuric iodide (biniodided, sublimed).
Nickel ..	Sodium nitroprusside.
Tin ..	Ammonium bichromate.
Arsenic bromide.	Urea, pure.
Anthraquinone (sublimed).	Thienc.
Alizarin, artific. (sublimed).	Salicylic acid (natural).
Zincina (pure).	Sodium salicylate (natural).
Barium nitrate (pure).	Quinine
Iron (ammonia) alum (pure).	Cinchonidine .. ( " ).
Zinc sulphocarbonate.	
Copper sulphate (pure)	

ROBERT H. DAVIS, CHEMIST TO THE SOCIETY OF APOTHECARIES, APOTHECARIES' HALL, LONDON (Group XIV. No. 1467).

Exhibits a collection of chemical and pharmaceutical preparations illustrative of the employment of this class of agents by the medical profession of this country. The specimens include some typical preparations of pharmacy which have long been in use, such as tinctures and extracts, as well as the most of those more recently introduced remedies such as iodoform, kairine, antipyrine, paraldehyde, etc., that must at present be considered to be upon their trial, since they have not yet received the seal of full official approval, granted by a place in the National Pharmacopœia.

THE WASHINGTON CHEMICAL CO., DURHAM (Group XIV. No. 1467).

Shows specimens illustrating its manufacture of fine chemicals.

W. LASCELLES-SCOTT, ESSEX (Group XIV. No. 1469).

Diagrams showing improvements in apparatus for the preparations of pharmaceutical and other extracts.

THOMAS CHRISTY & CO., LONDON (Group XIV. No. 1467).

Show specimens of their fine chemicals and pharmaceutical preparations. The following is an account of some of the more interesting of these. *Doundaké Barks*.—Under this name several barks obtained from the West Coast of Africa have been examined in France. One of these is identical with the bark of a root coming from Siberia, and known as peach root; it is obtained from *Sarcocephalus Esculentus*, a plant belonging to the cinchona family. Messrs. Heckel and Schlagdenhauffen consider it capable of replacing cinchona bark as an astringent and febrifuge, and also regard the beautiful yellow colouring matter contained in the bark as worthy the attention of dyers. According to these authorities the Doundaké plant is found from 16° N. latitude to 5° S. latitude, from Senegambia to the Gaboon. The bark from Sierra Leone has a greyish smooth surface, cracked here and there, and presenting small hard excrescences of a darker colour. When older the bark becomes blackish, the cracks multiply, and the epidermis falls off as a reddish dust. The interior of the bark is of an ochrey yellow, and is situated longitudinally. The bark has a bitter taste, and when chewed gives a yellow tinge to the saliva. The bark from Rio Nunez is similar, but has no blackish excrescences, and the internal surface is darker yellow. The bitter taste is due to two nitrogenous principles of a resinoid character, differing in their solubility in alcohol, and having the respective formulæ  $C_{25}H_{19}NO_{13}$  and  $C_{19}H_{16}NO_9$ . The bark

also contains a tasteless crystalline principle soluble in caustic potash, and also glucose and traces of tannin. It appears that another variety of Doundaké was examined by MM. Bochefontaine, Fériss, and Marcus, and found to contain a poisonous principle, and the bark of this poisonous species was of an orange red colour. To prevent confusion with the tonic and febrifuge bark, it would be best doubtless to retain for the latter the name "African Peach Root."

*Gouania Domingensis*.—This plant contains a principle which renders it most valuable for the manufacture of tooth preparations of a similar kind to floriline. A specially-useful gargle has been prepared from it. In the United States the stem of the plant is cut into pieces about six inches long, and each piece is bruised at one end and used as a tooth-brush. The effect is said to be very strengthening to the gums, as well as cleansing to the teeth.

*Gutta-Percha*.—A specimen is shown of a new species from a tree, the botanical name of which has not yet been ascertained. According to Sir Joseph Hooker (Kew Report, 1881, p. 38), the time cannot be far distant when the natural sources of gutta-percha will be definitely used up. It is therefore most important that the gutta-percha tree should be planted in colonies where it will grow, as it will doubtless in the future prove a source of considerable profit. Unfortunately the best gutta-percha tree is of very slow growth, and it has become so rare that it is difficult to obtain seeds. There are, however, other trees of more rapid growth which yield gutta, and which are worthy of attention. One of these which yields gutta-lundek has recently been identified by Dr. Trimen as *Paysona Leerii*. The tree grows in swampy places near the coast, even where the water is salt, and land of this character can therefore be turned to account by the planting of this valuable tree. As yet no means have been discovered of obtaining the whole of the gutta from the bark, indeed it is calculated that only one-thirtieth part of the juice contained in the bark is obtained by incision. It has been proposed, however, to strip off alternate layers of bark, pound them and boil with water. It is thought that in this way the whole gum might be obtained. Various kinds and qualities of gutta-percha are afforded by different sapotaceous trees, but the pure red gutta-percha of Borneo, which is considered to give the best quality, is yielded by *Dichopsis Gutta*. This species is characterised by trees of red and rough stems, generally found among old jungle on the hill sides, growing to a height of 100 to 150 feet, with a diameter varying up to 3 feet. The natives on finding a tree, say 12 inches in diameter, proceed as follows:—They fell it, cut off the top, and ring the bark at distances of about a foot. The sap gradually drains away for about two or three days, and is collected in any convenient vessels, such as leaves, cocoa-nut shells, etc., from which it is transferred to a pot and boiled with a little water for half-an-hour or so. The milk is boiled to prevent it from hardening on exposure to the air, as if allowed to do so it becomes comparatively valueless. It is very difficult to estimate the yield, as the quantity varies so much according to the size of the tree and the time of the year, the flow of sap being greatest when the tree is producing most leaves. A small tree will yield generally 33½ lb., while the largest may yield even as much as 100 lb. The red gutta is often mixed with the inferior product of other species. Another species, *Dichopsis Macrophylla*, yields an inferior gutta of white colour. It is of smaller growth than the *Dichopsis Gutta*, being 50 to 60 feet high, and differing slightly in the foliage. The gutta beds are being gradually exterminated, as they are of

slow growth, and the natives do not take the trouble to plant seeds or cuttings. *It becomes most important, therefore, that the tree should be planted in suitable localities in the British colonies, and it is moreover highly probable that by proper cultivation and care the variation in the yields of gum could be prevented by the attainment of a tolerably uniform minimum yield.*

*Hydrocotyle Asiatica*.—The leaves of this plant are usually administered in the form of a powder, which is obtained by removing the stalks from the fresh leaves and then drying the latter in the shade in the open air. Thirty pounds of fresh leaves yield about three or four pounds of the powder. *Hydrocotyle* contains a peculiar principle called "vellarin," which is an oily liquid, not volatile, and possessing the odour and taste of the herb. It is recommended as a poultice to stimulate ulcerated surfaces to healthy action, as snuff in cases of ozena, and as an ointment mixed with lard in cases of skin disease. It is also well spoken of when used in cases of secondary syphilis, leprosy, etc.

*Jatropha Curcas*.—This is a seed, the oil of which should certainly be experimented with by soap makers, as well as by the medical profession. The oil possesses properties resembling those of castor oil, but not the disagreeable smell of the latter. It has an agreeable almond-like taste, and 30 to 60 drops act as an efficient purgative. The plant forms an excellent hedge, as cattle will not eat the leaves, and cuttings rapidly take root. It is indigenous to tropical America, but is found almost everywhere in warm climates. The seeds are regularly exported to Portugal from the Cape de Verde Islands to the extent of about 350,000 bushels annually, for the expression of the oil. Before expression the seeds are slightly roasted and crushed, when the shells are easily removed. 1000lb. of seed give 640lb. of kernels yielding about 260lb. of oil. From Portugal the oil appears to find its way to France, *probably for the manufacture of transparent soap.* The oil could be obtained in any quantity for manufacturing purposes. The juice of the fresh plant is a valuable haemostatic, and is said to rapidly coagulate the blood even in an artery, so that it can be probably used for the cure of aneurism.

*Kava-Kava*.—This extract has just recently been suggested to the exhibitors as a rapid and certain cure for gout and gonorrhoea, and is now being experimented with in the London Hospitals. It is also claimed for it by a gentleman, who resided for some time in Fiji, that it has the power of adding the quality known as "age to the rawest whisky" very rapidly. This statement is one worthy of experimental investigation.

*Kola Nuts and Paste*.—Kola nuts are now coming largely into use for a variety of purposes, the most important form being that of the paste, a sample of which is shown. This paste, which could not easily be distinguished from ordinary cocoa-paste, contains a little over 2 per cent. of caffeine, and forms therefore a stimulating food of great value. It is important to remember that the paste shown is made from the kola nut without any mixture whatever. If this paste, which is five times as strong as cocoa, be added to the lowest quality of the article, it raises this quality so as to render it equal to that of the best Caraccas cocoa. Owing to the abundance of caffeine in this paste, it is said to be of the greatest service in counteracting the effects of drink, by restoring clearness to the head. It is said that after chewing the Kola nut on the West Coast of Africa for the purpose just named, a drunkard cannot return to stimulants for some days without feeling nausea. If this be so, a judiciously-prescribed diet of kola

nut would suggest itself from the preceding, as possibly offering a practical and valuable solution of a difficult problem for a considerable percentage of the inhabitants of the British Isles!

*Menthol Cones* are shown in a variety of patterns to suit all markets, and are made of pure menthol crystals without admixture. The best menthol is the Japanese from the plant *Mentha Arvensis var. Piperascens*, and it contains more of the oil of peppermint than any other varieties.

*Papaine* forms an important solvent, and is obtained both in the form of a white powder and of a dried juice, and is known commercially as Papaine-Christy. It is made specially from the fresh milk of the fruit of *Carica Papaya* for Mr. Christy by a chemist residing on the Papaw plantations. Papaine has been proved by Prof. Finkler, of Bonn, to be capable of dissolving in pure water 1000 times its weight of fresh fibrin. Finkler states that it dissolves very rapidly the membranes of diphtheria and croup, and that not a single patient he has treated in the University Hospital or in private practice has died, but that all have recovered. In every case the membrane was dissolved by painting it with papaine about five times a day. He further adds that since "papaine can be applied with salicylic acid, which increases its action, he maintains that there is no other drug in existence equally powerful for the purpose stated." Finkler found that when the membrane was dissolved the fever disappeared. According to the *Berliner Klinische Wochenschrift*, Dr. Schoffer, who has tried most of the remedies recommended for diphtheria, has obtained the best results with papaine. Last summer (1884) he treated 47 cases of this deadly complaint with a 5 per cent. solution of it. He begins the treatment as soon as possible, and orders the patches to be painted every five or ten minutes; in a few hours the membranes are said to be removed, and at the same time the fever disappears.

*Pine or Spruce Extract (Christy)*. This has been tried in a London hospital, and proved to be of the utmost service in kidney and bladder diseases.

*Pine Extract for Baths*, is an extract made from the fir or pine. It is dissolved in boiling water, and the solution is added to the bath-water. The medicinal and strengthening properties are, it is said, very beneficial, especially for children, and the aroma is extremely pleasant.

*Cinchonamine*.—This is likely, it is stated, to become a very important drug, both therapeutically and chemically.

Cuprea bark has been imported in large quantities into London for the last few years. It consists of several varieties, two of which have a marked difference in their chemical composition. The one, *Remijia Pedunculata* contains quinine and homoquinine, the other, *Remijia Parviflora*, contains little or no quinine, but an alkaloid named cinchonamine by its discoverer, M. Arnaud. (*Compt. Rend.* xvii. 174.) Cinchonamine combines readily with acids, forming salts which crystallise well, are only slightly soluble in water, especially in presence of excess of acid. They are more soluble in hot alcohol. The property possessed by the anhydrous hydrochloride of crystallising very readily, is used as a means of separating the alkaloid easily from the other alkaloids of the bark. The nitrate also crystallises with extreme facility, and is almost insoluble in acidulated water. The crystals are well-defined and easily recognisable. It is proposed to turn this property to account analytically, by using cinchonamine as a test for nitrates. Iodides must, however, be first removed by addition of silver acetate. For testing Arnaud prefers to use the hydrochloride.

He thinks the method may be very useful in solving certain problems connected with vegetable physiology, such as the formation of nitrates in plant tissue and their circulation and metamorphosis in different parts of the plant. (See *Pharm. Journ.* [3], xiv. 162.)

ARNOLD SPILLER (*Group XXIX. No. 2254*)

Exhibits photographs developed by means of hydroxylamine and various alkalis. A gelatino-bromide film is prepared, also gelatino-chloride of silver transparencies, developed with hydroxylamine and various alkalis.

A prize of considerable value has already been offered in Mülhausen, in Alsace, for a good commercial method for preparing hydroxylamine, and this application to photography by Mr. Spiller would add further value to such a discovery.

EUGENE RIMMEL, LONDON (*Group XIV. No. 1436*),

Exhibits (1) Working model of Rimmel's Myrogene, a new apparatus for extracting the perfume from fresh flowers; (2) Specimens of new sanitary perfumery; (3) Toilet articles.

The *Myrogene* consists of three bodies (Fig. 1) A, B and C, fitting into each other, and forming a column which rests upon three feet D. The upper body is a reservoir to contain the prepared alcohol, with a cover on the top, and a bottom pierced with small

FIG. 1.

holes, above which is a valve E, set in motion by a string F, worked on a pulley. The body B is a long case through which the alcoholic shower passes without being exposed to evaporation. At the lower extremity are two external catches G. Inside the body C slides a cylinder H, carrying on the top a movable sieve I to receive the flowers, and at the bottom a tap, through which the extract is drawn

off. The cylinder H fastens on to the catches G by means of hinged hooks J, which are turned down when the sieve requires removing or replacing. In order to make the apparatus more secure, it is

FIG. 2.

advisable to erect it in the corner of a room, and make it fast to the walls by means of a piece of wire tied round the body B. The model shown is a nickel-plated and elegant piece of apparatus (see Fig. 2).

*Mode of Operation.*—Unfasten the hooks J (Fig. 1), and let the cylinder H slide down; take out the sieve I, and fill it with freshly-gathered flowers, carefully picked, removing all the green and leaving only the petals, pistils and calyx. Replace the sieve in the cylinder, raise it up and refasten it to the catches G. Fill the upper reservoir A with prepared alcohol, pull the string F, and as soon as the liquid has passed through the flowers, draw it off through the tap K, and repass it twice in the same way over the same flowers. Let the sieve be again filled with fresh flowers, and repeat the operation until the alcohol is sufficiently impregnated. The usual proportion for one pound of flowers divided into three or four portions, is one pint of alcohol, but it is impossible to lay down a general rule, as the quantity of flowers necessary to produce a strong extract naturally depends upon the intensity of their aroma, which also varies according to the climate. Thus cassie and jonquil yield a powerful perfume with a single operation, whilst violets and mignonette must undergo at least four. Flowers that have been operated upon are drained in a covered filter to lessen the loss of absorption; they may afterwards be submitted to moderate pressure, but the extract then drawn off is of inferior quality. All flowers possessing odour can be successfully treated by this process, but alcohol alone does not suffice to fix their aroma in a permanent manner; it requires for that to be mixed with another ingredient, in the proportion of one ounce of the latter to the gallon of ordinary alcohol, in order to give the prepared alcohol. This ingredient, or "chemical basis," as it is termed by the exhibitor, is specially prepared and sold by him and his agents.

## EXPLOSIVES.

NOBEL'S EXPLOSIVES CO., LIMITED, GLASGOW  
(Group XXV. No. 1899).

Nitroglycerine has been successfully applied by Capt. Alfred Nobel to explosive purposes as effected by detonation, and to this end the method of manufacture involves important details. Specimens illustrating (1) dynamite and blasting glycerine, (2) detonators, and (3) electric fuses, are shown, the products of the above well-known firm.

THE SCHULTZE GUNPOWDER CO., LIMITED (Group XXV. No. 1900).

Specimens are shown of the Schultze's patent smokeless gunpowder, made from wood. It is a perfectly white substance, in a granulated form. Wood is rendered explosive by being nitrated, and the product is then granulated. Cartridges charged with it are shown.

## ANALYTICAL CHEMISTRY.

ARNOLD EILOART, LONDON (Group XXV. No. 1467).

Exhibit specimens of patent airtight stopcocks.

These stopcocks were devised principally to prevent the possibility of leakage occurring in the manipulation of gases in chemical experiments. They are simply ordinary stopcocks made airtight by means of a "liquid joint" arrangement, so contrived that the taps occupy no more space than the ordinary ones.

In the earliest form, the case of the tap was cupped at the top and closed at the bottom to receive liquid. But the cheapest and best way of making the chambers for liquid is to form annular grooves in the plug, one above and one below the bore. The case into which the plug fits is then of the common form. This tap can be used to close either a vertical or a horizontal tube. Leakage along the tube to be closed, round the plug, has still to be guarded against. For this, taps are shown the plugs of which have straight grooves at right angles to the two ring-grooves and joining them. (The plug may then be turned in only one direction to close the tube, and back to open it.) It might be thought that in trying to fill these grooves, entirely closed in by glass as they appear to be, when the plug is in position, a practical difficulty must occur; but this is not so.

The most interesting exhibit is a little arrangement which may in many cases be used instead of a stopcock, and is about one-fifth the cost of one. This is a T-piece arrangement, of which one branch

is a tube of half-inch bore into which a smaller tube *a* is fused at right angles; half-an-inch below the joint the wide tube is open; half-an-inch above the joint it begins to taper off (at *b*). An indiarubber

plug *c*, not tapering, and covered with a layer of mercury, is pushed upwards past the joint, and so completely shuts off the passage of gas from the side tube, into which also some mercury flows. The passage is opened by slightly lowering the plug. Thus the gas is never in contact with the rubber, but only with glass and mercury.

ADDENDUM TO REPORT OF THE EXHIBIT OF MESSRS. CHAPMAN & MESSEL. (SEE P. 520.)

## MANUFACTURE OF ANHYDROUS SULPHURIC ACID.

Dr. Messel made his specific gravity determinations at the temperature of 80° F., where all the anhydrides are liquid, though afterwards calculating the results of these to specific gravities at 60° F., when some of the anhydrides become crystallised. It was thought that the readers of this report would be interested in comparing the actual table of results obtained at 80° F., and Dr. Messel has kindly furnished these numbers. The complete table should therefore appear as follows:—

SPECIMENS.	Percentages of SO <sub>3</sub>	SPECIFIC GRAVITIES.	
		At 80° F. (26.6° C.)	Calculated to 60° F. (15.5° C.)
—	8.3	1.842	1.852
Liquid .....	30.0	1.930	1.940
Crystalline mass resembling nitre	40.0	1.956	1.970
	41.5	1.961	1.975
	46.2	1.963	1.977
—	53.4	1.980	1.991
Liquid .....	60.8	1.992	2.006
	65.0	1.992	2.006
	69.1	2.002	2.016
Crystallised .....	72.8	1.985	1.983

## Communications.

## ON THE ESTIMATION OF SULPHUR IN PYRITES.

BY JOHN CLARK, PH.D.

In the July number of the *Journal of the Society of Chemical Industry* (page 449), Prof. G. Lunge makes some remarks on my process for the estimation of sulphur in pyrites, and states, as his objections, that it estimates the sulphur in galena, and the sulphates of lime and baryta, whilst in the wet process nearly the whole of the useless sulphur is left behind in the insoluble; and I presume that in his opinion this is the cause of the difference between the wet and the dry process. Now, the samples of pyrites upon which I operated contained no weighable quantity of sulphate of barium, less than one per cent. of lead, and from 1 to 2 per cent. of lime. In fact, they were typical samples of shipments of Spanish pyrites. I admit that the sulphur in the galena and sulphate of lime is estimated by my process, but it is also estimated by the modification of the wet process employed by the chemists of the Tharsis Company and by Mr. Tatlock, with which alone my process has

been compared. The modification to which I have referred consists in treating the pyrites (twenty grains) with aqua regia, and after evaporating to dryness, dissolving in one ounce of hydrochloric acid, filtering, and making up with the washings to a bulk of thirty ounces. After adding the proper quantity of chloride of barium and allowing the precipitate to stand, the clear liquid is decanted and the precipitate washed, first with thirty ounces of hot water containing 300 measured grains of hydrochloric acid, and finally with thirty ounces of pure water. I think it will readily be admitted that with such quantities of acid and water, the whole of the lead and lime usually present in Spanish pyrites will be found in the solution; so that the question at issue between my process and the modification of the wet process is, in my opinion at least, really limited to the solubility of the sulphate of barium in hydrochloric acid, and, whether rightly or wrongly, it is to this cause alone that I attribute the difference in the results. Prof. Lunge may, perhaps, consider that this modification of the wet process is inferior to his own, and quite as objectionable as the dry process, but I would point out, what he has already remarked, that this modification gives very concordant results; whereas, even in the hands of such skilled analysts as the assistants of Fresenius, the wet process, as described by Prof. Lunge, cannot be relied upon to within half a per cent. of sulphur.

# THE MANUFACTURE OF PHOSPHORIC ACID FROM PHOSPHORUS.—A BRIEF REVIEW OF THE METHODS IN USE AND A DESCRIPTION OF A NEW PLAN FOR THE PRODUCTION BY THE SLOW OXIDATION OF PHOSPHORUS IN MOIST AIR.

BY ADOLPH SÖMMER,

University of California, Berkeley, Cal., U.S.A.

THE author commences by a critical description with details of the various methods of manufacturing phosphoric acid from phosphorus itself, as distinguished from its manufacture from bone earth or glacial phosphoric acid. Eight processes are discussed, viz:

- (a) oxidation by burning in air;
- (b) " by strong  $\text{HNO}_3$  at a low temperature;
- (c) " by dilute  $\text{HNO}_3$  at a high temperature;
- (d) " by Br and water;
- (e) " by I and water;
- (f) " by dilute  $\text{HNO}_3$  and a little Br;
- (g) " " " " " " I;
- (h) " " " " " " I and Br.

The conclusions of the author as to these processes are as follows:—

(a) When phosphorus is burnt in air on a manufacturing scale the operation is attended with danger, and the products of combustion are variable. At the same time this is the only possible process if one desire to obtain phosphoric anhydride.

(b) When strong  $\text{HNO}_3$  is used, as recommended by Von Schroetter, the operation is attended with danger, unless the phosphorus be in the amorphous form, which materially adds to the cost.

(c) When excess of dilute  $\text{HNO}_3$  at a high temperature is employed, subsequent extraction of the arsenic (a body invariably present) is rendered complex. This method is recommended by the Pharmacopœias.

(f) When excess of Br and water is used as recommended by Wagner (*Deut. Ind.* 1875, p. 403), more HBr is formed than  $\text{H}_3\text{PO}_4$ . It is also costly and dangerous. (See this Journal, 1884, p. 20.)

(e) The same objections apply to the use of I and water unless iodides are made a collateral object. (See Pettenkofer, in *Dingl. J.* 181, p. 218; and *Ann. der Chem. u. Phys.* 138, p. 51.)

(f) When dilute  $\text{HNO}_3$ , with a little Br as a carrier of oxygen, is employed, action ceases when the  $\text{HNO}_3$  becomes very dilute, and heating tends to dissipate Br.

(g) The use of I in the place of Br as in (f) has the advantage that I is less volatile, but in this case heating tends to convert the P into the amorphous variety.

(h) The use of a mixture of Br and I in the place of the single element as in (e) and (g) with dilute  $\text{HNO}_3$  has been attended with fairly good results. (See Markoe in *Am. Jnl. Pharm.* 1875.)

All these methods, except (a), have one great objection in common:—viz., that the inevitable excess of oxidising agent, whether  $\text{HNO}_3$ , Br, or I, has to be removed before the arsenic which is invariably present can be removed by  $\text{SH}_2$ , or reduced into the metallic state.

The author therefore gives his preference to slow oxidation at a low temperature by moist air, in which process there is no excess of oxidising bodies to retard the removal of the arsenic.

Wenzell (*Proc. Am. Pharm. Assoc.* 1882, p. 556) was the first to practically apply this property of phosphorus. As early as 1796, Pelletier (*Cres. Dict. Chem.* 1828, p. 67) had devised a process for the manufacture of "phosphatic acid" by the slow oxidation of cylinders of phosphorus disposed each in a glass tube drawn out at one end to a fine orifice. These glass tubes, to the number of 30 or 40, were placed in a funnel the beak of which was passed into a bottle standing in a plate of water, and the whole was covered with a bell-glass with inlet and outlet for a small current of air. The phosphorus slowly oxidised, and the product deliquesced and dripped into the bottle. This "phosphatic acid" was proved to be a mixture of phosphorous and phosphoric acids by Thénard, Dulong and Leverrier (*Ann. Chem. u. Phys.* 67, 278), but the simultaneous formation of ozone, peroxide of hydrogen, and ammonium nitrate was only recently observed, prominently by Schönbein and Leeds (*Journ. Am. Chem. Soc.* iii. 6). Buchholz (*Beitr. zur Kenntn. der Chem.* i. 63) first recommended the production of  $\text{H}_3\text{PO}_4$  from this body by heating with  $\text{HNO}_3$ . A. Vogel (*Gmelin*, vol. ii. Lond. 1849, p. 121) and Liebig (*ib.* p. 128) proposed methods for the elimination of the arsenic, invariably present.

The author first adopted a modified form of the process of Wenzell (*o.s.*). In a shallow trough fitted with a porous cover were placed horizontally cylinders of phosphorus supported on strips of plate glass, and as much distilled water as would suffice to leave about one-eighth of an inch of the phosphorus above water. In three or four days the phosphorus was found to be eaten away down the surface of the water. Portions of the liquid were then successively withdrawn until the whole of the phosphorus was dissolved. In order to reduce the arsenious acid to metallic arsenic, the acid liquid thus formed was heated in a dish to  $190^\circ \text{C}$ , at which temperature bubbles of hydrogen phosphide were evolved, marking the completion of the operation. The reaction is expressed by the following equations:—

After cooling the liquid was filtered and any further traces of phosphorous acid were oxidised by  $\text{HNO}_3$  or Br.

The tediousness of the above induced the author to devise a new process. A glass jar, in which rested

a funnel, was placed in a tin can fitted with a cover through which passed a thermometer, the bulb of which descended into the funnel. By an arrangement of holes in the cover a regulated supply of air was admitted, and the inside of the can was lined with cloth, the capillary action of which served to convey sufficient moisture to the air of the can from a measured quantity of water, proportionate to the quantity of phosphorus to be oxidised, placed in the bottom. The cylinders of phosphorus were disposed in the funnel and the bulb of the thermometer buried among them, an atmosphere of  $\text{CO}_2$  being used to ensure safety during this part of the operation. According as the temperature ranged above or below  $35^\circ \text{C}$ , less or more air was admitted until the temperature remained constant, in which state the oxidation was left to complete itself. When finished, if properly performed, the phosphorus was found to have completely disappeared, and the jar contained a mixture of phosphorous and phosphoric acids which were treated as above described.

For the construction of a continuous and transparent oxidising chamber, preferably one of white and very clear glass is selected, and the bottom very carefully cut off. This is best done by means of

the flower-pot, is then inserted in such a way that the funnel-tube passes through the bottom of the flower-pot and the neck of the bottle. Into the neck of the bottle the funnel-tube is securely fastened by means of a perforated paraffined cork, which must be water-tight.

This portion of the apparatus is then placed, neck downward, over a large glass jar in which stands a narrow cylinder filled with water. The cylinder is to be in such a position that the end of the funnel-tube will dip into the liquid contained in the cylinder.

Through the centre of the bottom, which was cut off the bottle, a hole of at least  $\frac{1}{2}$  of an inch in diameter is drilled. The bottom is then put into its original position on the bottle and fastened by gluing strips of paper over the joint. The hole in the bottom is loosely closed by a cork through which passes a thermometer. When the oxidising chamber is thus completed the cork is removed, and by means of a funnel, having a long bent tube, water poured into the space between the walls of the bottle and the flower-pot, until its level is within a short distance from the upper edge of the funnel within the flower-pot. Then a tube connected with a carbonic acid generator is inserted into the hole and carbonic

- (f) Funnel filled with P.
- (t) Thermometer.
- (p) Flower pot.
- (j) Glass jar.
- (w) Water.

- (s) Perforated stopper.
- (c) Tin pan.

specialty-prepared carbon pencils made of powdered charcoal, saltpetre and tragacanth. A common unglazed flower-pot, the largest that will go into the bottle, is inserted into the open bottle so that the bottom of the flower-pot is directly over and in contact with the neck of the bottle. A funnel, the conical part of which is at least an inch shorter than

acid gas passed into the oxidising chamber. When the air within has been entirely displaced by the gas, sticks of phosphorus are dropped through the hole into the funnel until the latter is nearly filled. The thermometer and cork, in the sides of which a few notches have been cut, are then placed into position and the apparatus allowed to stand for about twenty-four hours. If at the end of this time the temperature of the P is below  $35^\circ \text{C}$ , a little more ventilation may be given by enlarging the notches in the cork.

The flower-pot in this apparatus performs the same function as is fulfilled in the former by the cloth lining—namely, that of absorbing the water and moistening the air. The acid which is formed runs first into the small cylinder and thence into the glass jar which serves as receiver. Whenever it is seen that that the phosphorus is nearly consumed or the water evaporated, a fresh supply is added through the hole without taking the apparatus apart.

A still simpler form of a continuous oxidising chamber I have constructed in the following manner: Through the bottom of a tin pan a hole of about 1 in. in diameter is cut and a tube of tinned iron about 4 in. long soldered into it. By means of a perforated cork a funnel is fastened into this hole so that the funnel-tube passes through the bottom, while the body of the funnel is inside of the tin pan. Into the end of the funnel-tube is inserted and fastened by a bit of rubber-tubing, a glass tube bent in a half-circle. A common unglazed flower-pot is inverted over the body of the funnel and a cork with a thermometer inserted into the hole, which is in the bottom of the flower-pot. The whole apparatus is then placed over a glass jar and some water poured into the tin pan. After the pouring of a few drops of water into the funnel, whereby the bend of the glass tube is closed against a downward escape of gas, the filling of the apparatus with carbonic acid and phosphorus is proceeded with in the same manner as has been mentioned under the description of the previous apparatus. When a very large quantity of phosphoric acid has to be made, a number of funnels may be fastened into the bottom of a wooden water tank, and each of them provided, as above described, with a bent glass tube, glass receiver and flower-pot.

The rate at which the phosphorus is oxidised by my method is a comparatively slow one. In an apparatus of style 1, in which the temperature was kept on an average 11° higher than that of the surrounding air, and the phosphorus, which was in the form of a solid cake of nearly 5 in. in diameter, exposed a surface of about 18 square inches, the phosphorus was oxidised at the rate of about 10 gm. a-day.

The difference between the inner and outer temperature does not seem to be affected to any extent by an increase or decrease of the prevailing temperature, for nearly 200 observations, which were taken at temperatures of the atmosphere ranging from 10° to 22° C., gave, while all other conditions remained equal, an almost constant difference.

The acid which collects in the receivers has a specific gravity of about 1.48, and is composed mainly of phosphorous and phosphoric acids in the proportion of 1 to 4, besides water. The exact composition differs with circumstances, and the determination of these circumstances may be the subject of some future paper.

The further treatment of this acid is in every respect the same as has already been described under Prof. Wenzell's process; but an acid prepared by my method has this great advantage over the one prepared by the former process, that it is already highly concentrated and requires very little evaporation before the arsenious acid is reduced.

\*\*\*\*\*

#### THE OXIDATION OF PHOSPHOROUS ACID TO PHOSPHORIC ACID BY MEANS OF BROMINE.—BROMHYDRIC ACID A BY-PRODUCT.

BY ADOLPH SOMMER,

University of California, Berkeley, Cal., U.S.A.

The product of the slow aerial oxidation of phosphorus contains about one molecule of phosphorous

acid to four molecules of phosphoric acid, and besides these some impurities, such as arsenious acid and others, mostly derived from the phosphorus. Of these impurities, the arsenious acid is particularly objectionable, and must be removed before the process of oxidising is entered upon. The removal of the arsenic, as has been described in my article on "The Manufacture of Phosphoric Acid from Phosphorus," is best effected by heating the acid to 190° C., subsequently diluting and filtering, after which the acid is ready to be oxidised.

Heretofore nitric acid has been the only substance employed for this purpose; but since the price of bromine has become so low (about thirty-five shillings per lb., in five-lb. bottles), that its cost is no longer prohibitory to its employment in the industries; and, furthermore, since the value of hydrobromic acid has been recognised both in analytical chemistry as well as in therapeutics, it may prove advantageous to substitute bromine for nitric acid in the oxidation of phosphorous to phosphoric acid.

From the equation—

it will be seen that it requires nearly two parts of bromine to every one part of phosphorous acid. But the total acidity of the mixture of phosphorous and phosphoric acids, when of a sp. gr. of 1.48, is about sixty-six per cent., the composition of which approximates the proportion of one molecule (or twelve per cent.)  $\text{H}_2\text{PO}_3$  to four molecules (or fifty-four per cent.)  $\text{H}_2\text{PO}_4$ . To convert the twelve per cent. of phosphorous acid into phosphoric acid would require theoretically  $2 \times 12 = 24$  per cent. of Br. This result agrees very closely with that obtained in practice, when it was found that with an acid of a sp. gr. of about 1.48 there was needed a little over one-fourth of its weight of Br to complete its oxidation. This operation may be performed after the arsenic has been removed, either in a bottle containing the acid and Br by shaking this mixture from time to time (it must, however, not be shaken too often nor too much at one time, since a considerable amount of heat is liberated by the reaction, which may easily reach the boiling point of Bromine 63° C.), or it may be accomplished more rapidly by pouring the two substances into a retort, and keeping the mixture agitated by slowly passing air through it. In order to prevent any Bromine vapour, which is carried off by the air, from contaminating the atmosphere of the laboratory, I cause the air which escapes from the retort to pass through two bottles containing a solution of caustic potash. When the mixture is no longer decolourised on standing for about twelve hours, but retains a permanent orange colour, which is due to an excess of Br, the oxidation may be considered completed. The excess of Br is best removed by the addition of a small portion of the unoxidised mixture of acids, which has been reserved for this purpose.

There remains then only the separation of the bromhydric acid from the phosphoric acid, which is accomplished by a distillation in a retort from an oil bath. The precautions which have been pointed out in a previous article on the manufacture of bromhydric acid, in regard to its liability to decomposition by organic substances, have to be observed here. The mere insertion of the neck of the retort into a well-cooled receiver is sufficient. Neither luting nor rubber connections are necessary. The first portion which comes over consists principally of water (and Br, if this has not been removed in the manner stated above), and should be withdrawn before the bromhydric acid, which does not evaporate
